During atrial pacing (S) at the beginning of the study (to determine AV Wenckebach cycle length), the WCT occurs (Fig. 22-2). Note the His potential *(red arrow)* with a normal HV interval (45 ms) during atrial pacing on the left half, and the much shorter HV interval during WCT on the right half (in fact, a negative HV interval—the His *[blue arrow]* is after the QRS onset *[dashed line]*). Three situations exist during which the His potential consistently occurs after the QRS onset: 1) ventricular preexcitation, 2) ventricular pacing, and 3) ventricular ectopy/tachycardia. Because this would be an unusual pattern of preexcitation and is definitely not ventricular pacing, VT is favored as the diagnosis. Although many electrophysiologists do not routinely use His recording catheters during EP studies, the simple recording of a consistent His potential can have great diagnostic benefits.

Baseline Arrhythmia

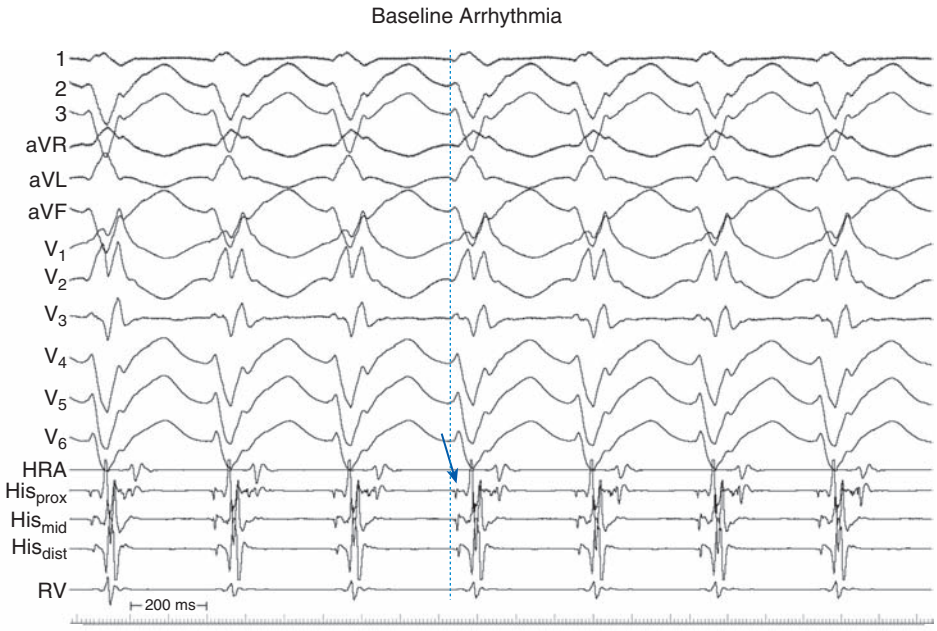

Figure 22-3

After cessation of atrial pacing, VT continues as shown in Fig. 22-3. The *blue arrow* is clearly seen after the QRS onset *(dashed line)*. Note that there is a 1:1 V:A relationship (explaining why dissociation was not evident on the regular ECG). The direction of propagation of the His recordings appears to be proximal to distal; this would be unusual with a retrogradely activated His during VT, but in this case, only the proximal electrodes are actually at the His bundle (with a modest atrial recording in sinus and VT), whereas the middle and distal electrode pairs are probably recording a right bundle potential. The VT spreads from the left ventricle (with RBBB pattern), ascends the left bundle branch, conducts retrogradely through the His bundle, and turns around to activate the right bundle branch anterogradely (whereas the right ventricle may be directly activated across the ventricular septum).

Table of Differential Diagnosis

RBBB WCT in the Absence of Structural Heart Disease:

- Verapamil-sensitive left posterior fascicular (LPF) reentry
- SVT with aberration
- Focal fascicular VT
- Papillary muscle focal VT
- Other myocardial VT

The differential diagnosis of an RBBB WCT includes several possibilities as noted above. Table 22-1 offers some useful distinguishing features. In our case, already determined to be VT, there is a Q wave in lead 1 but not V1, and the rhythm did not terminate with adenosine.

TABLE 22-1 Differential Diagnosis of RBBB WCT

	Verap. Sens. LPF VT	SVT + Aberration	Focal Fascicular VT	Papillary Muscle VT
QRS duration	Rel. narrow	Rel. narrow	Rel. narrow	Wider
Q in lead 1	Yes	Yes	No	No
Q in lead V1	No	No	No	Yes
AV relationship	Variable	1:1	Variable	Variable
Adenosine effect	None	Termination	Termination	None
HV interval	−20 ms	45 ms	−15 ms	−10 ms
Earliest Purkinje	(throughout)	After His	Before His	Before His
Overdrive pacing	Constant return cycle	Variable effects	Overdrive suppress	Overdrive suppress
Pacemapping	Not helpful	Not helpful	Excellent	Excellent

Right Ventricular Pacing in VT

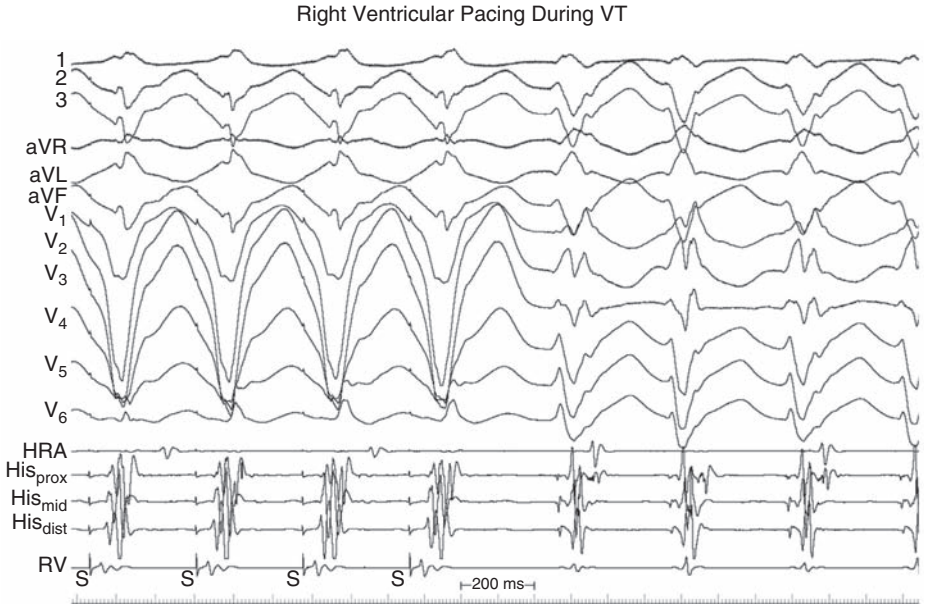

Figure 22-4

As seen in Fig. 22-4, VT had a stable cycle length of 315 ms; the timing of the first beat of VT after the end of right ventricular overdrive pacing during VT did not vary over a range of cycle lengths (310 ms, shown here, to 280 ms); pacing at 270 ms terminated VT. This would not be expected with a focal process, in which overdrive suppression of an automatic focus occurs (faster overdrive pacing results in longer delay until VT resumes); termination of a focal arrhythmia with overdrive pacing is also unusual. A constant return cycle over a range of overdrive paced cycle lengths and eventual termination of VT with more rapid pacing is entirely consistent with reentry, however.

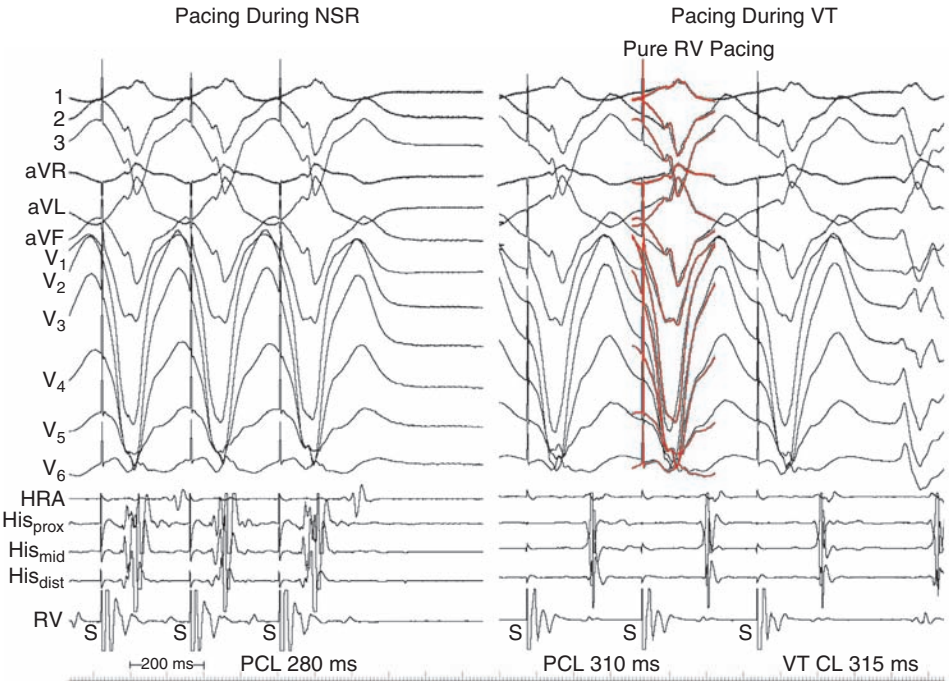

Figure 22-5

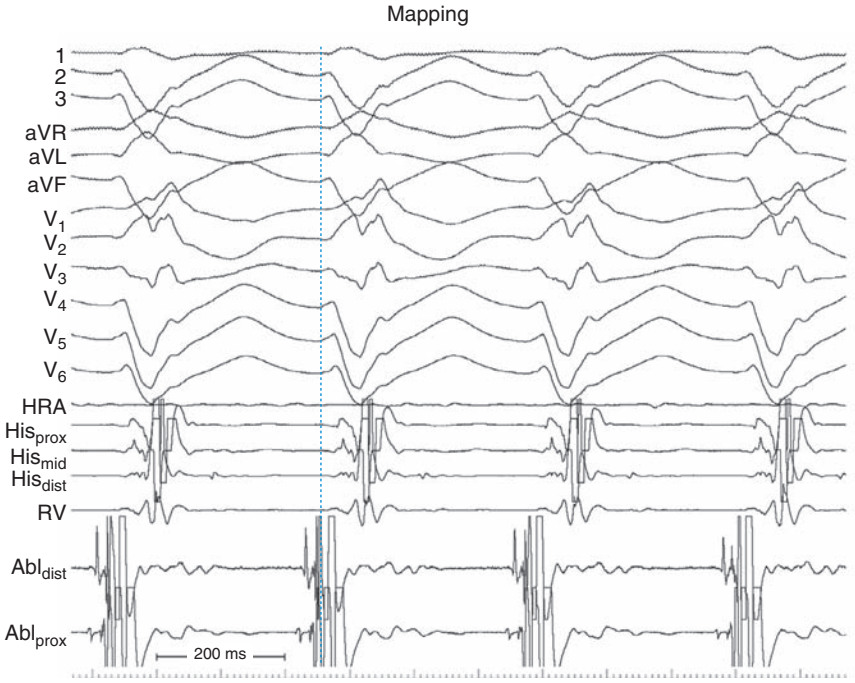
Pacing during VT may show fixed fusion (every QRS complex a consistent blend), and if so, is diagnostic of macroreentry. In Fig. 22-5, RV pacing during VT at a rate just slightly faster than VT is shown at *right*, and pure RV pacing (during sinus rhythm) at *left*. A single complex of pure RV pacing superimposed on RV pacing during VT shows little difference; it can be argued that V4 to V6 show some slight differences but these are minimal. Based on this one example, one may be tempted to conclude that because fusion is not evident, the rhythm is not macroreentry. This is an unwise conclusion, because although a single episode of pacing that shows fusion can diagnose macroreentry, it often takes pacing at many cycle lengths and different sites to show fusion. Based on all the information now available, the diagnosis of left posterior fascicular–related reentry ("verapamil-sensitive VT") seems secure at this point. Even though many VTs in the absence of structural heart disease terminate with adenosine injection, this one characteristically does not (although it does respond to verapamil). Before availability of adenosine, many cases of this VT were erroneously diagnosed as SVT because of their occurrence in otherwise healthy people, relatively narrow QRS in tachycardia, and termination with verapamil injection.

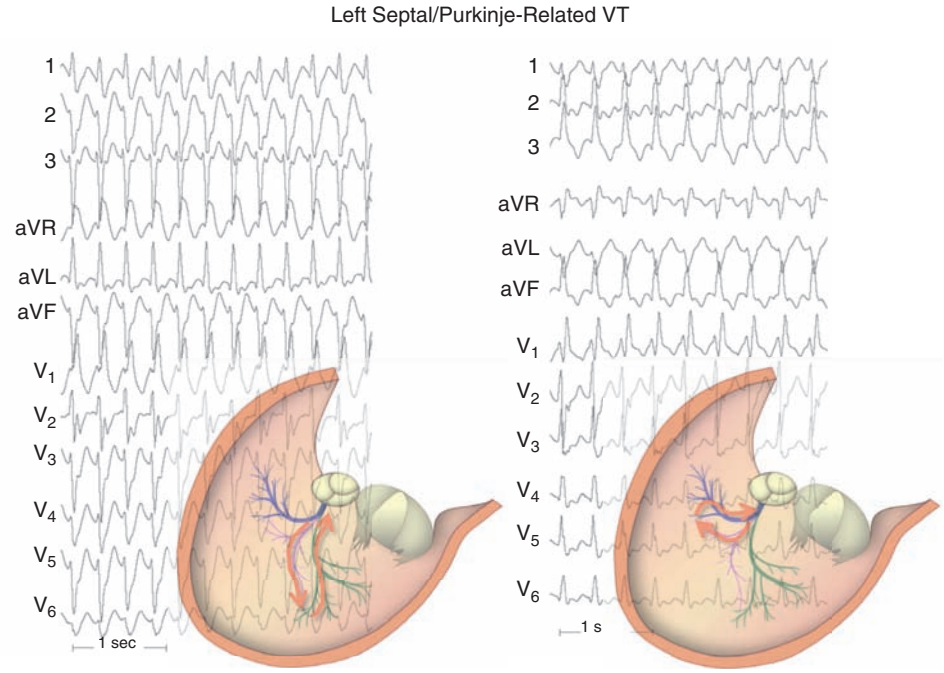
Mapping and Cartoons of Circuits

Figure 22-6



Having established a diagnosis of verapamil-sensitive left posterior fascicular VT, mapping can begin to find an appropriate ablation target. In previous years, finding the most presystolic Purkinje potential (10 to 40 ms, as in Abl_{dist} in the figure) was the goal; more recently, with the understanding that the posterior fascicle is the retrograde limb of tachycardia whereas a diastolic pathway composed of possibly partially depolarized Purkinje cells with calcium channel–dependent activation, or Purkinje cells in a false tendon, the target of ablation has become the lower turnaround site where the anterograde diastolic pathway joins the retrograde posterior fascicle. Recordings from the site in Fig. 22-6 may be >50 ms presystolic and have multiple deflections (as in Abl_{prox}), perhaps signifying activation of the two pathways.

Figure 22-7



The verapamil-sensitive Purkinje-related VTs displayed in Fig. 22-7 usually involve the posterior fascicle, at left, but can also involve the anterior fascicle, as shown at right.

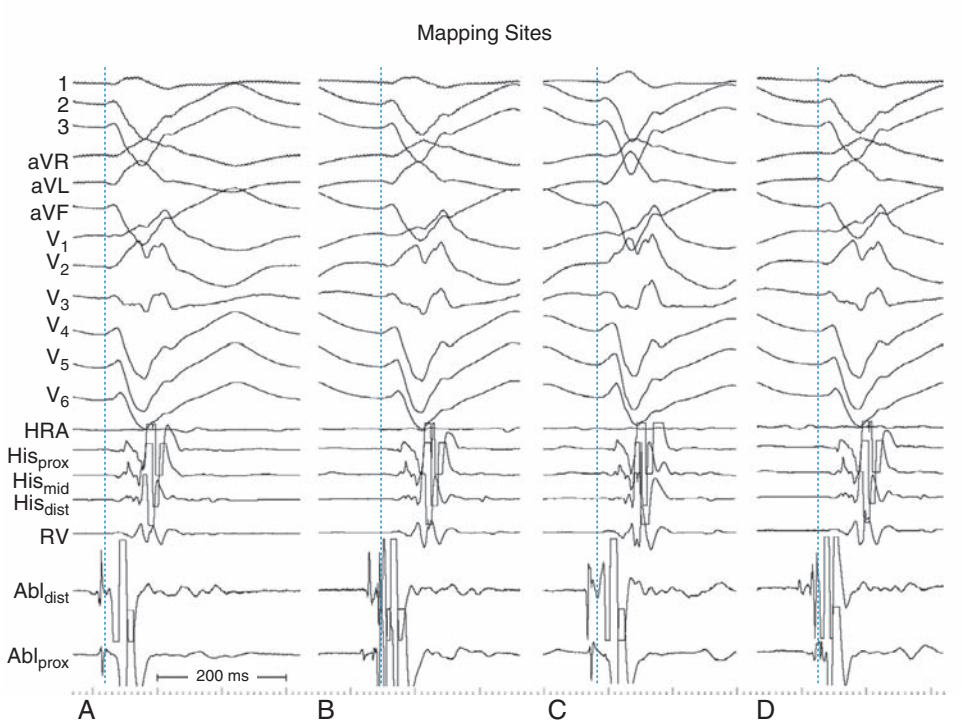


Figure 22-8

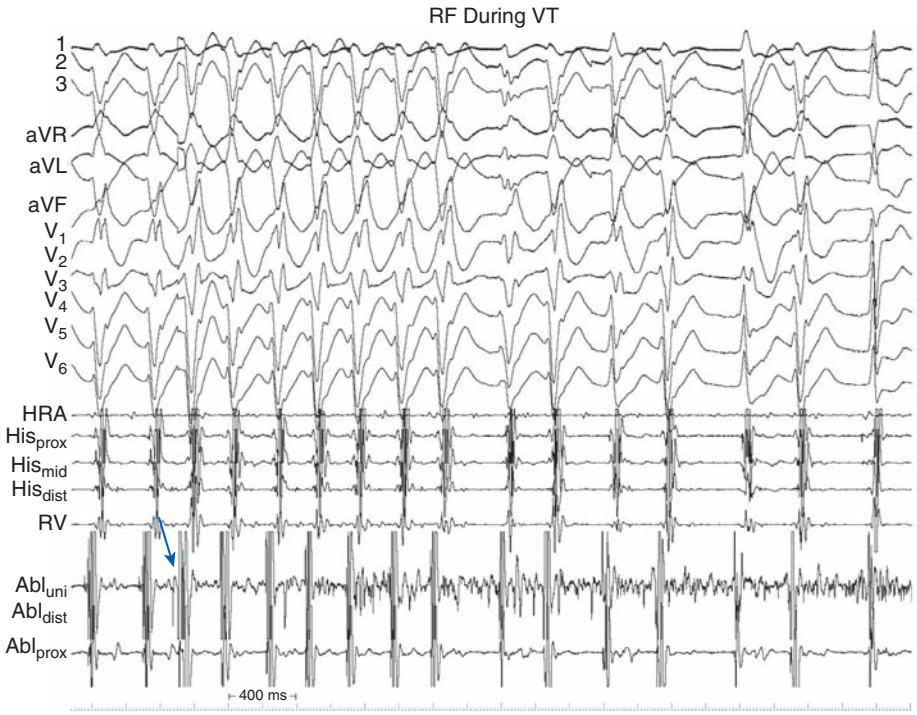
Several other mapping sites are shown in Fig. 22-8 (*dashed line* denotes onset of the VT QRS). Though all have presystolic potentials, which is the ideal target site? At site A, the distal electrogram precedes the proximal, but neither is very presystolic. At site B, the distal electrogram is earlier than that in A, but is later than the proximal recording and because ablation can only be done from the distal electrode, this site is not suitable either. At site C, the distal electrogram precedes the proximal, and both are reasonably presystolic, but the deflection is single rather than multiple and suggests posterior fascicle recording only. At site D, the distal electrogram precedes the proximal, is very presystolic, and is very complex (with multiple deflections). This is a very reasonable target site for ablation. Pacemapping during sinus rhythm at this site may or may not replicate the VT (because capture of surrounding myocardium may occur). Thus pacemapping is not a reliable tool for choosing ablation targets in this arrhythmia. Of note, these sites may be very sensitive to even mild catheter trauma, so great care must be taken to move the catheter tip slowly and cautiously; "bump termination" of VT may be followed by noninducibility for the rest of the procedure. Electroanatomic mapping systems that can record a three-dimensional location at which catheter trauma terminates VT can be used to guide ablation even when VT cannot be reinitiated (as long as location of the site was recorded at the actual time of catheter trauma and not seconds later, after the catheter may have moved).

Ablation

Figure 22-9



Radiofrequency energy is delivered at the target site during VT *(blue arrow)*. This causes a nearly immediate acceleration of the arrhythmia (more typical for focal automatic or triggered arrhythmias) and then "stuttering" of cycle length before termination (last complex), as seen in Fig. 22-9. VT could not be reinitiated thereafter, with or without isoproterenol infusion; the sinus rhythm ECG at the end of the procedure was unchanged (ie, no axis shift related to ablation near the His-Purkinje system). Ablation may lead to either acceleration or deceleration in this arrhythmia, whereas most reentrant tachycardias slow before termination during ablation.

Other Mapping Strategies

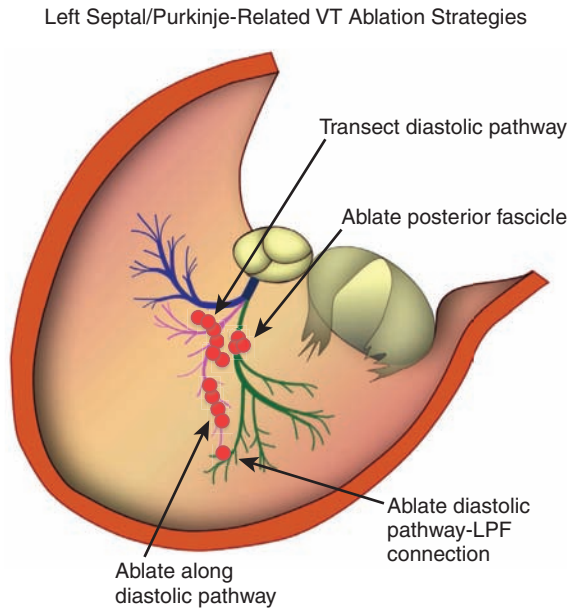


Figure 22-10

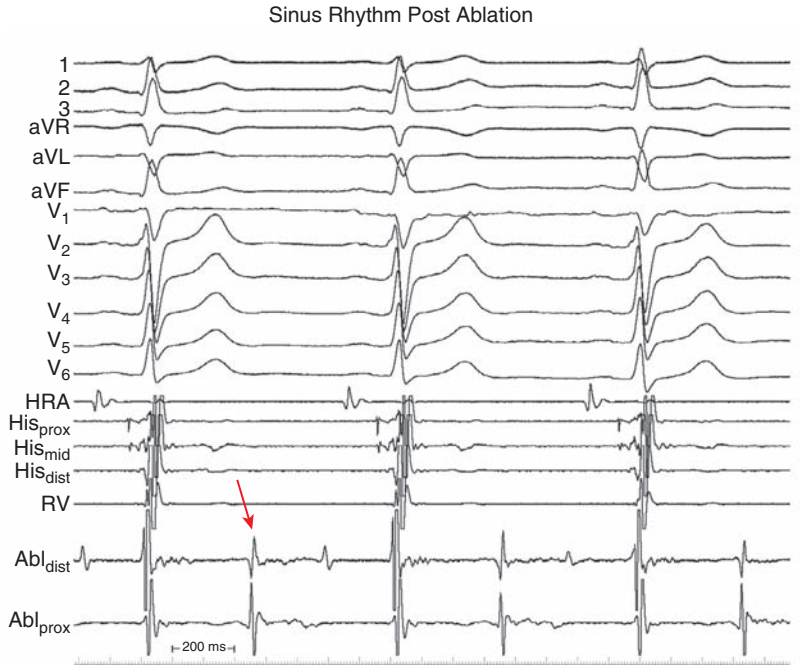
In Fig. 22-10, the left ventricle is shown opened along the lateral wall; the anterior fascicle is *blue*, the posterior fascicle is *green*, and the diastolic pathway during VT is shown in *purple*. Ablation strategies in this disorder include ablation at the site of connection of the left posterior fascicle and diastolic pathway (usually on the inferior left ventricular septum, as in our case); ablation along the diastolic pathway indicated by very delayed (and usually very small) potentials during sinus rhythm until these are eliminated; or linear ablation in the basal septum to try to transect the diastolic pathway. The latter may be the only option in cases in which VT cannot be initiated despite a reasonably clear diagnosis from the ECG during a prior spontaneous episode, or when catheter trauma during mapping precludes subsequent VT induction and thus mapping. Ablation of the posterior fascicle is not advised because this is a rather widely distributed structure and its elimination may require very extensive ablation (unwise in a normal heart).

Final Recordings

Figure 22-11



The large deflection indicated by the *red arrow* in Fig. 22-11 may be because of repolarization or recording artifact, or it may be a recording from the diastolic pathway used anterogradely during VT in these cases. Ablation at sites where these potentials are recording, eliminating them, is an effective ablation strategy when VT cannot be induced. Most often, if they can be recorded at all, they are much smaller than those shown here and may show multiple deflections.

Summary

- VT in the absence of structural heart disease often resembles, and is mistaken for, SVT on the ECG
- RBBB VT in the absence of SHD may be
  - Focal fascicular
  - Focal myocardial (including papillary muscle)
  - Verapamil-sensitive left posterior fascicular reentry
- In verapamil-sensitive left posterior fascicular VT, the diastolic pathway is very susceptible to catheter trauma
- Available mapping and ablation strategies include the following:
  - Targeting complex late diastolic potentials in VT
  - Targeting diastolic potentials in sinus rhythm
  - Transecting the presumed location of the diastolic pathway

Focal Cause of Ventricular Fibrillation

23

Case Presentation

The patient was a 45-year-old woman presented with cardiac arrest from polymorphic ventricular tachycardia (VT). Her history included ascending aortic disease with repair of aortic root and mechanical aortic valve replacement two months previously. She recovered well, but suffered unheralded cardiac arrest while shopping. She was hospitalized on cooling protocol, and she recovered well. The ejection fraction was 45%. Unfortunately she suffered recurrent polymorphic ventricular tachycardia/fibrillation. She was treated with amiodarone, beta blockade, and beta agonists, but there was no effect (i.e., she continued to have recurrent episodes of polymorphic VT). She was referred for electrophysiology (EP) study and possible ablation. What is the strategy?

Clinical Rhythm Strips

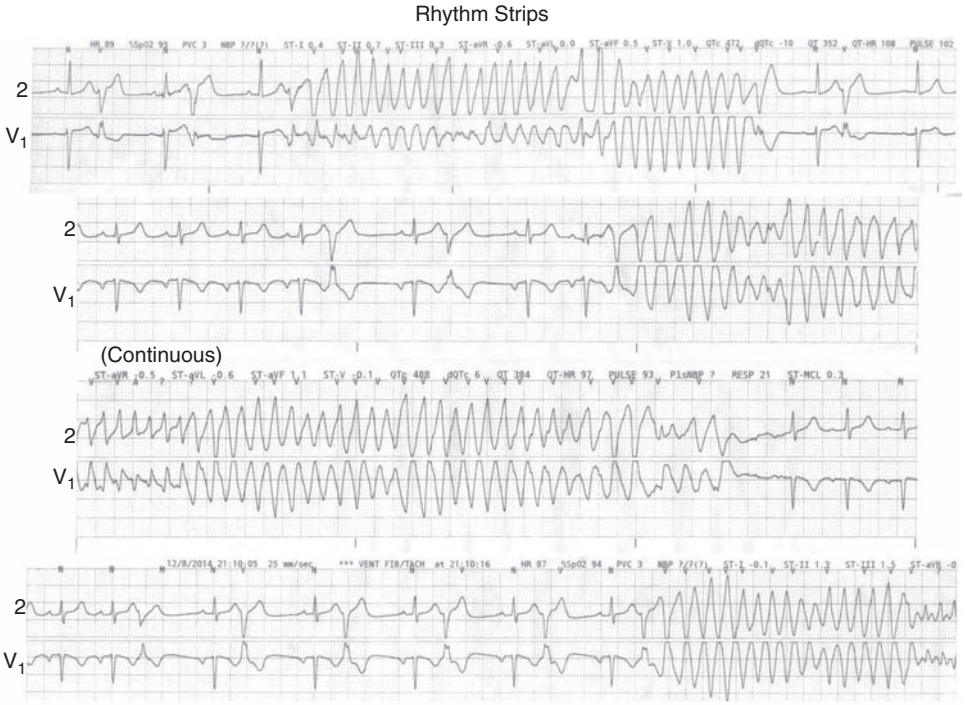


Figure 23-1

Repeated episodes of polymorphic VT (PMVT) are initiated by relatively narrow QRS premature ventricular complexes (PVCs) (Fig. 23-1).

Baseline ECG and Intracardiac Recordings

Figure 23-2

ECG (Fig. 23-2) is otherwise normal (apparent ST elevation in right precordial leads is an artifact of the recording system). The PVC morphology is clearer, having RBBB, leftward superior morphology, and the QRS complex is relatively narrow. Although not clearly fascicular, it is consistent with an origin in or near the Purkinje network.

Figure 23-3

Fig. 23-3 is the typical PVC morphology that led to repeated episodes of PMVT.

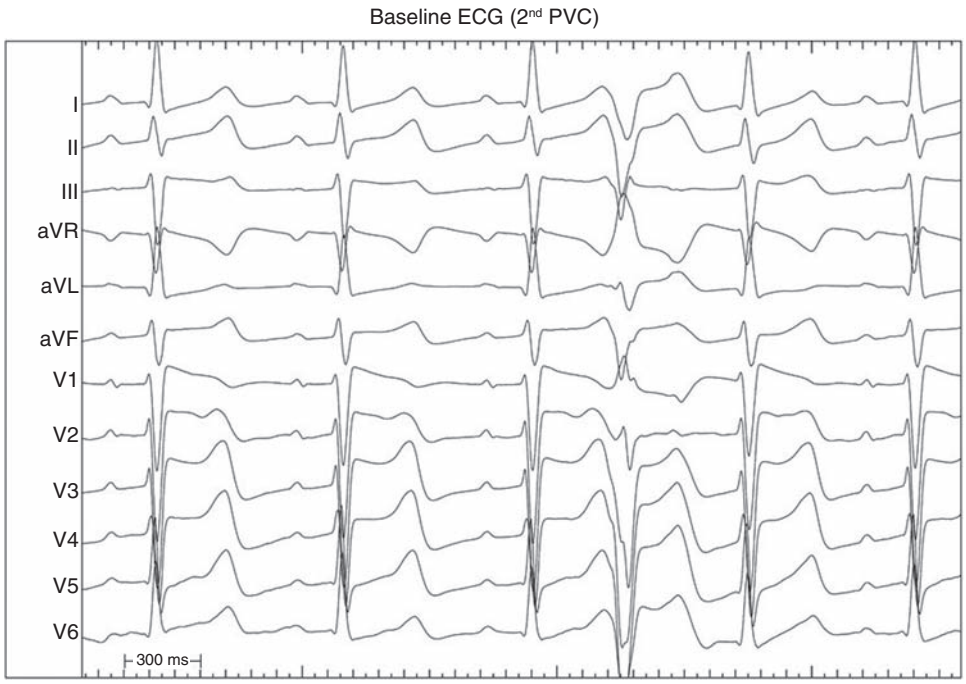

Figure 23-4

Fig. 23-4 is a second PVC morphology that occasionally preceded PMVT episodes (distinct from the main PVC, this has a rightward axis).

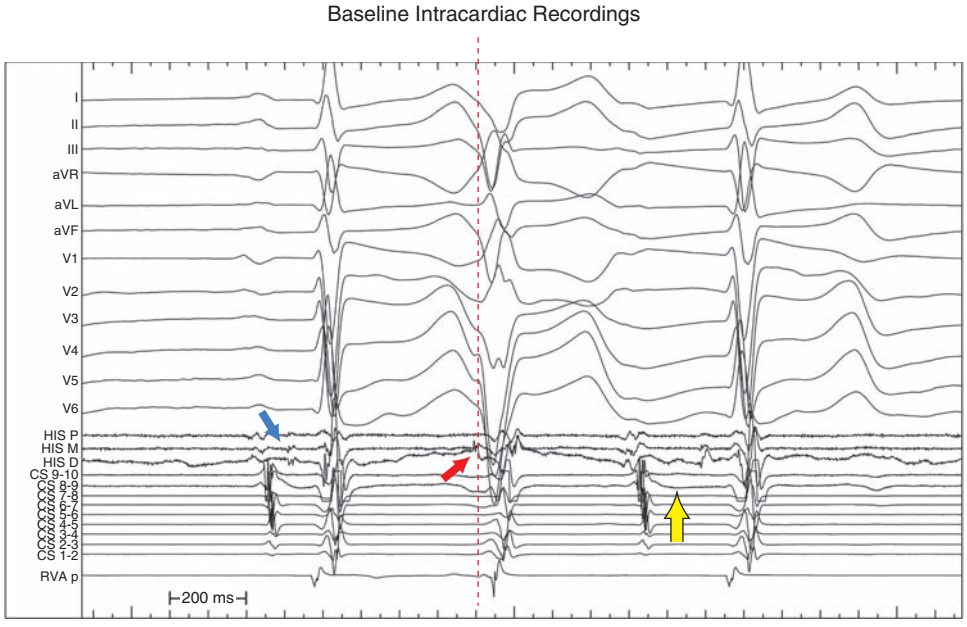

Figure 23-5

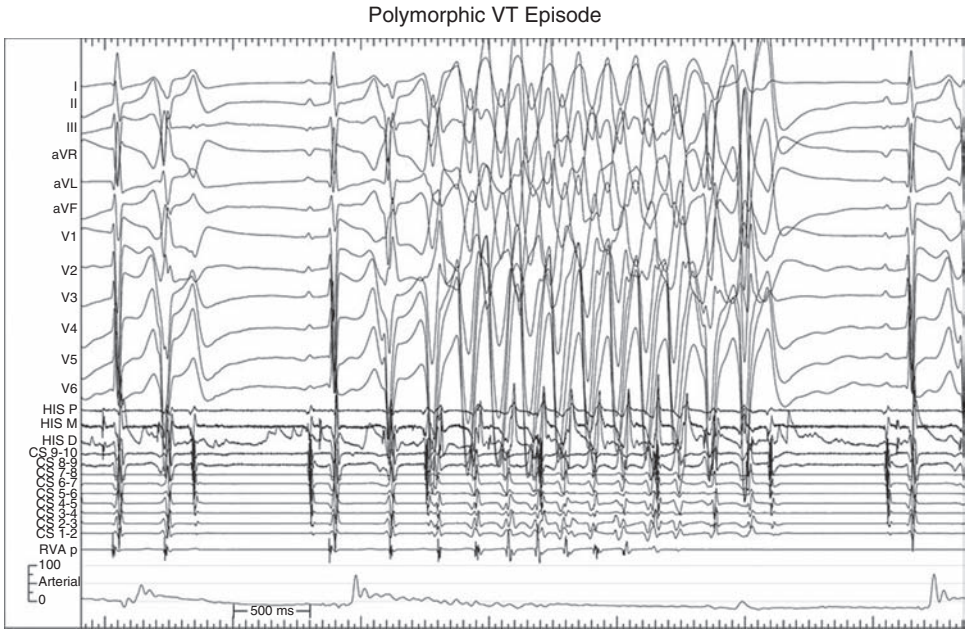
Once catheters are in place, an early indicator that the target PVC *(center)* is part of the Purkinje network is the finding that a His potential (Fig. 23-5, *red arrow*) precedes the PVC QRS onset *(dashed line)*. The *blue arrow* shows the same potential in sinus rhythm. The *yellow arrow* shows a longer AH interval on the following sinus complex, indicating retrograde penetration into, but not through, the AV node (concealed conduction).

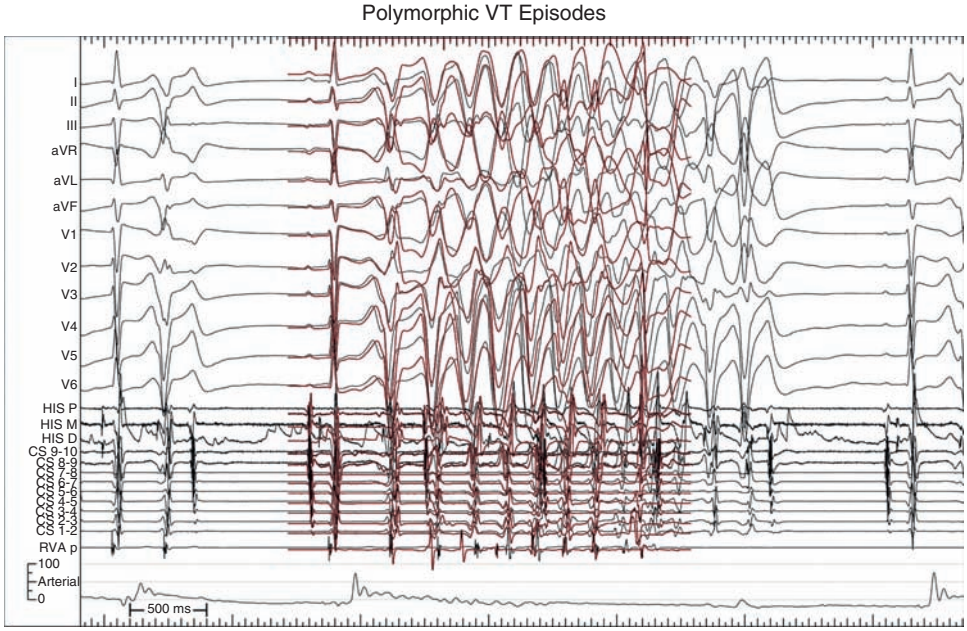
Polymorphic VT Episodes

Figure 23-6



While setting up for transseptal catheterization to access the left ventricle, PVCs initiated several episodes of PMVT (Fig. 23-6). Note that this particular episode was initiated by a relatively narrow QRS PVC with a rightward axis (not the same as the original PVC). Note also that blood pressure *(bottom tracing)* practically disappears for the entirety of the PMVT episode (about 3 seconds).

Figure 23-7



Two episodes of PMVT are shown in Fig. 23-7 with one superimposed on another; this illustrates that the first several cycles of episodes, although polymorphic, may be nearly identical. This suggests a consistent pattern of activation for these cycles until it becomes more disorganized.

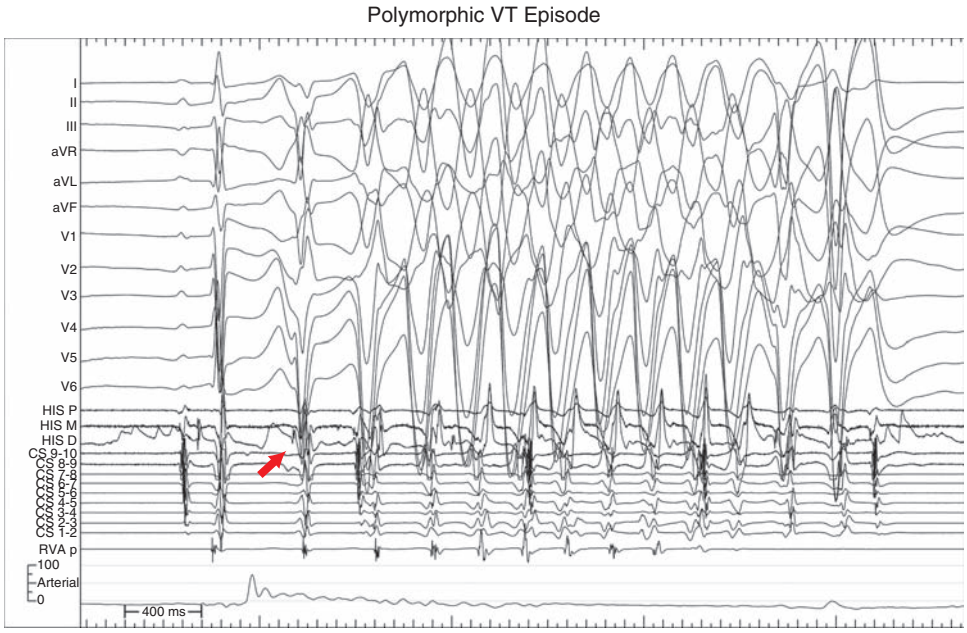


Figure 23-8

Fig. 23-8 is the same episode enlarged, to show the initiating PVC (right axis deviation) and the His potential at its QRS onset *(red arrow)*. This His timing can occur only when the origin is within the His-Purkinje system.

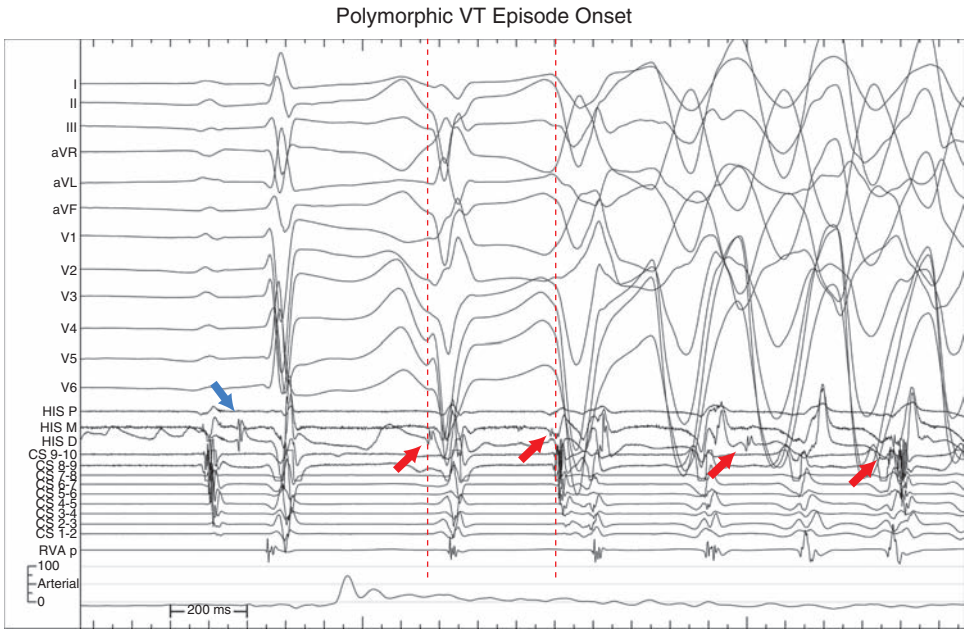

Figure 23-9

Fig. 23-9 shows the same episode enlarged further, to show the initiating PVC (right axis deviation) and the His potential (first *red arrow*) at its QRS onset *(dashed line)*. This sequence repeats, with a nearly identical QRS configuration, on the second complex. His potentials are seen with some, but not all, subsequent complexes. His potential in sinus rhythm is shown with a *blue arrow*.

Mapping Ventricular Ectopy

Is This a Good Ablation Site?

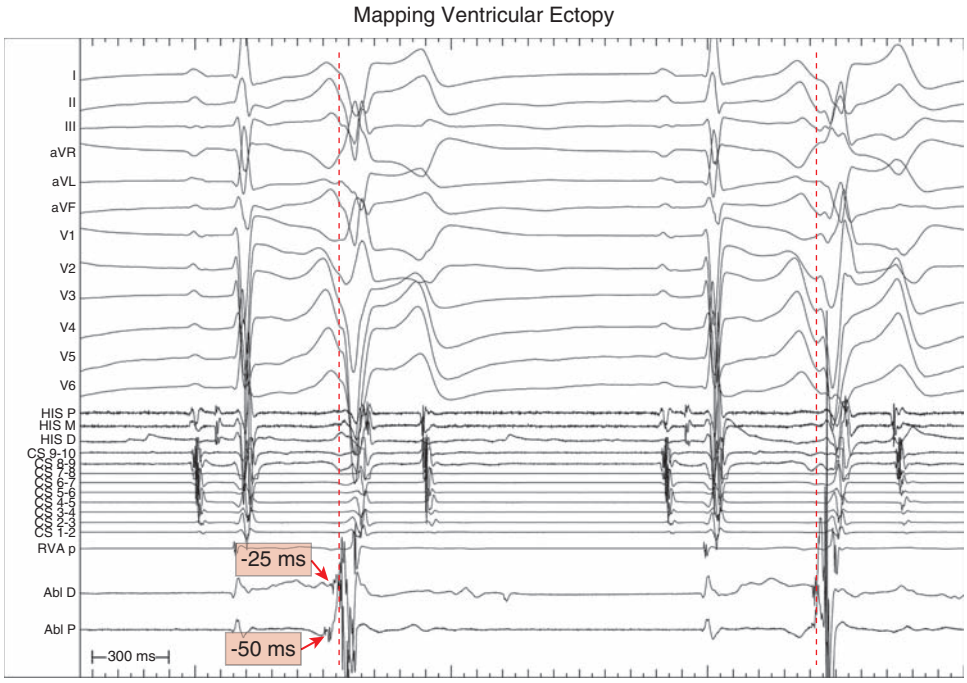

Figure 23-10

In Fig. 23-10, the ablation catheter has been introduced into the left ventricle via transseptal access (mechanical aortic valve). The PVC is of the rightward axis variety (which has caused PMVT episodes); the His potential is not well-seen with the PVC complex in this instance but an origin in or near the Purkinje network is suspected based on the sharp potentials on the ablation recordings. Whereas the distal mapping electrode has a potential 25 ms before QRS onset, which should be adequate for an ablation target, the proximal electrode has an even earlier potential. A Purkinje origin would be more strongly supported if such a potential were present in sinus rhythm (but it is not evident).

Where's the His? [Fig. 23-11] Is This a Good Ablation Site?

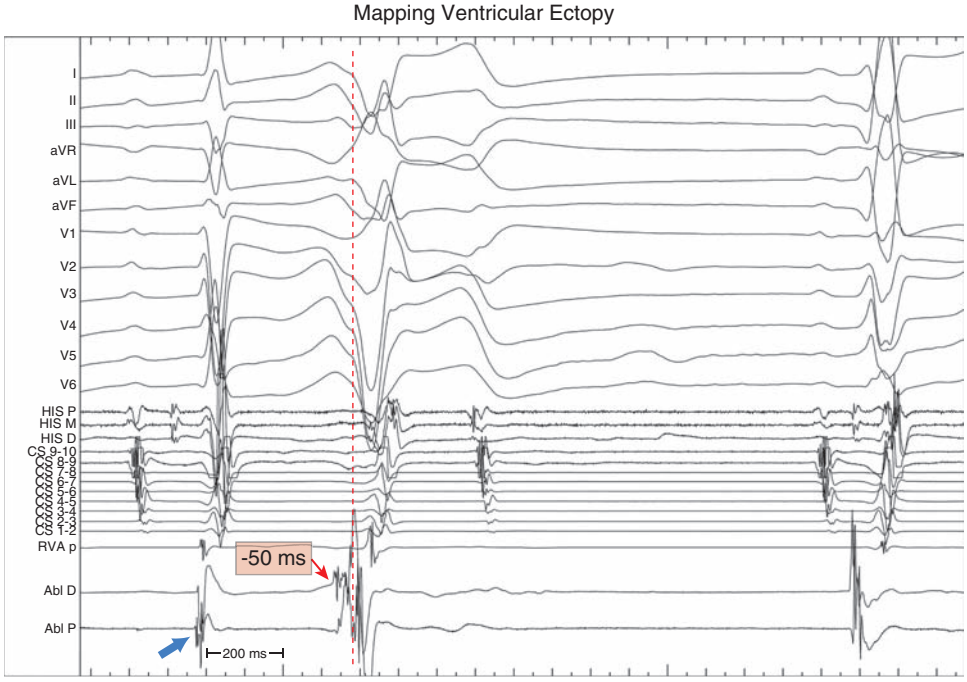

Figure 23-11

Fig. 23-11 shows another mapping site, this time with the distal electrode having a potential 50 ms before PVC onset. The His is again not clearly present during this PVC; the proximal electrode shows a potential consistent with Purkinje origin in sinus rhythm *(blue arrow)*. Attempts at pacemapping at these sites to confirm the same morphology as the PVCs produced inconsistent capture (not shown).

Site of RF and RF Delivery

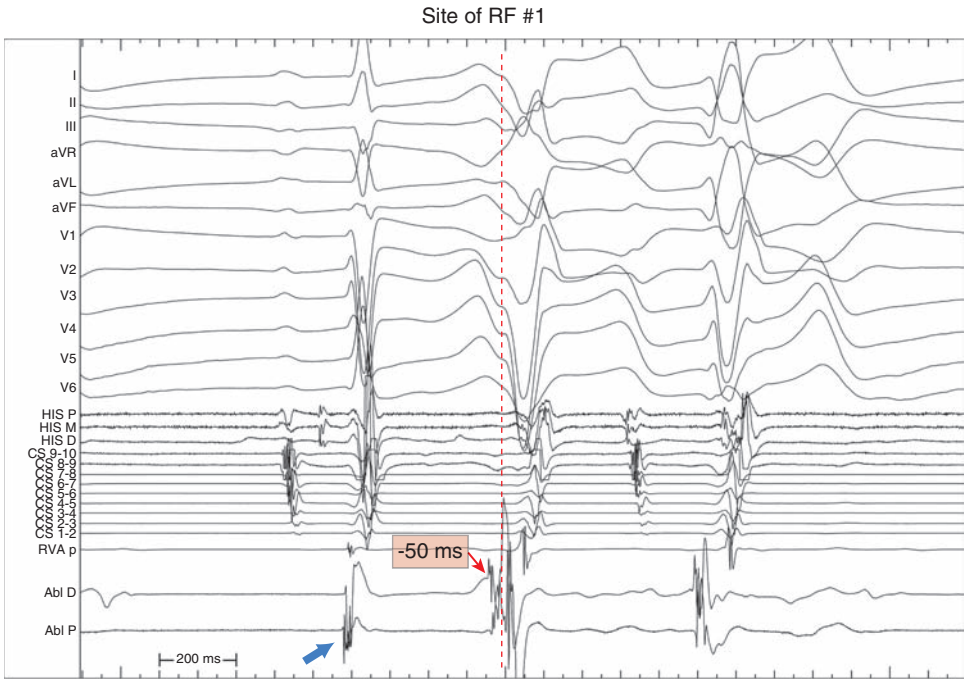

Figure 23-12

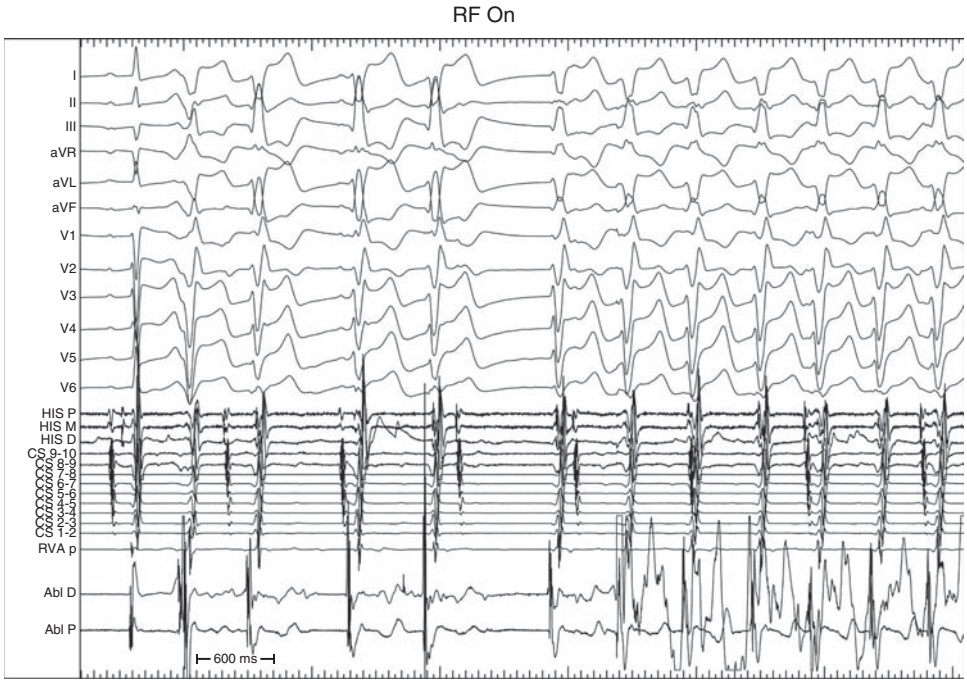
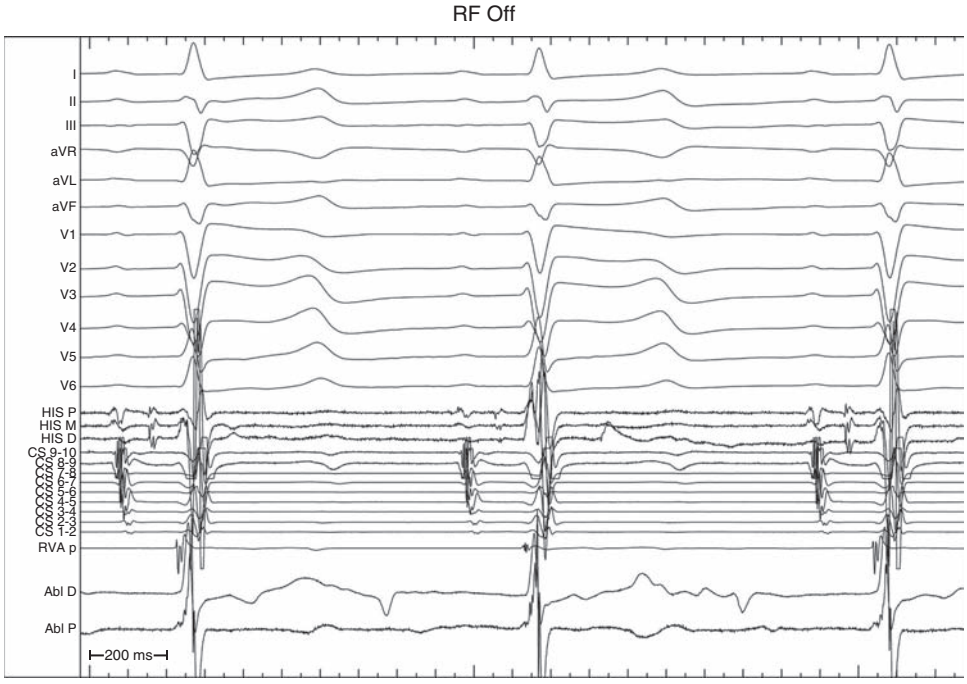
Fig. 23-12 displays the same mapping site, this time with the distal electrode having a potential 50 ms before PVC onset. The His is again not clearly present during this PVC; the proximal electrode shows a potential consistent with Purkinje origin in sinus rhythm *(blue arrow)*.

Figure 23-13



With onset of RF energy delivery *(right of center)*, a run of ventricular tachycardia occurs in Fig. 23-13, suggesting heating of tissue with the property of automaticity. This continued for another 25 seconds, then became nonsustained for 3 to 5 complexes, and then ceased.

Figure 23-14



Purkinje potentials are no longer evident at the ablation site (Fig. 23-14). Note also the presence of left anterior fascicular block (not present until ablation). This was transient.

Additional Findings

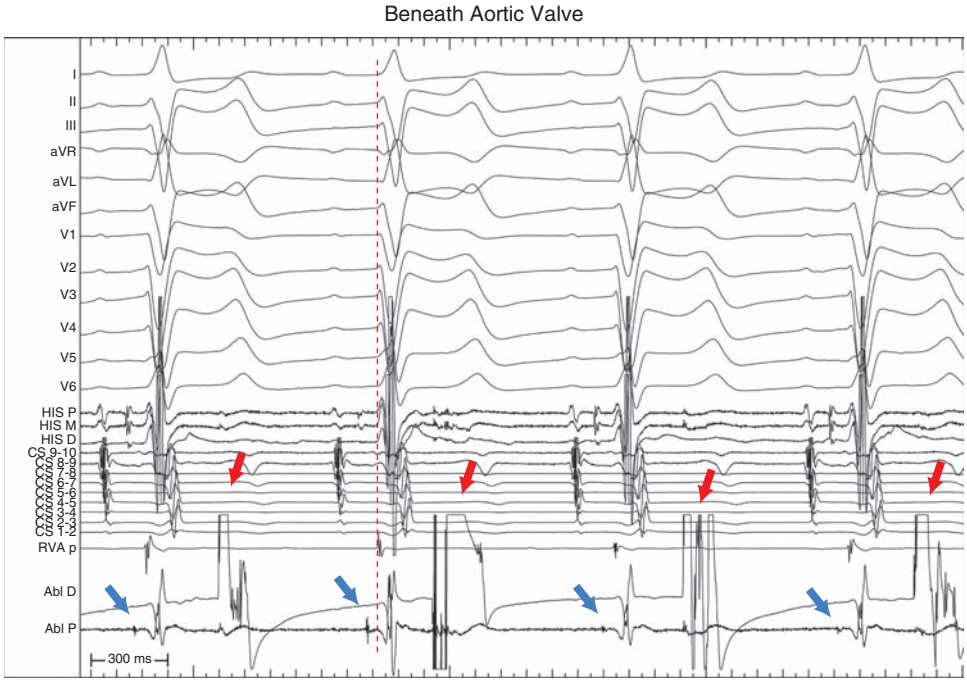


Figure 23-15

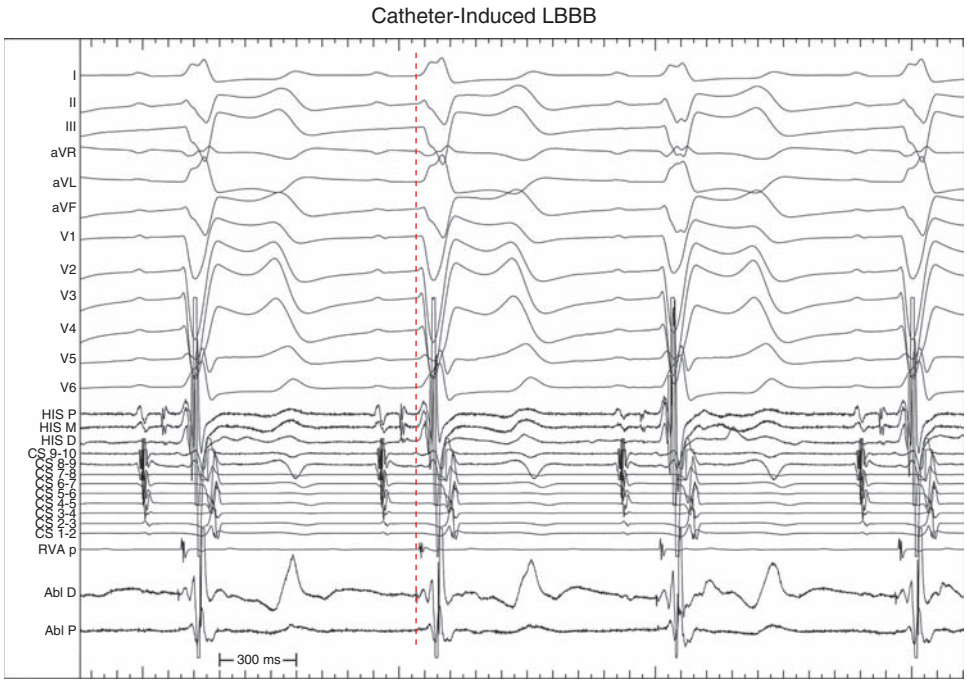
In Fig. 23-15, *blue arrows* are Purkinje potentials well before the QRS and without any discernible atrial activity—and recorded beneath the aortic valve. The location and timing are such that these are left bundle branch potentials. Mechanical injury to these can result in transient (or rarely, permanent) LBBB.

Red arrows denote electrical artifact generated by contact of the ablation electrode with the prosthetic valve struts. The signal is unphysiologically large, sharp, multicomponent, and not completely repetitive. It does not occur randomly, but periodically with cardiac motion.

Figure 23-16



In Fig. 23-16, with development of catheter-induced LBBB, the LB potential is no longer before the QRS onset *(dashed line)* but coincident with or even slightly after it. This may not be actual *block,* but possibly significant *delay.*

The patient had no further arrhythmias over a 5-day in-hospital follow-up; LBBB resolved; an ICD was implanted before discharge.

Electroanatomic Mapping

Figure 23-17

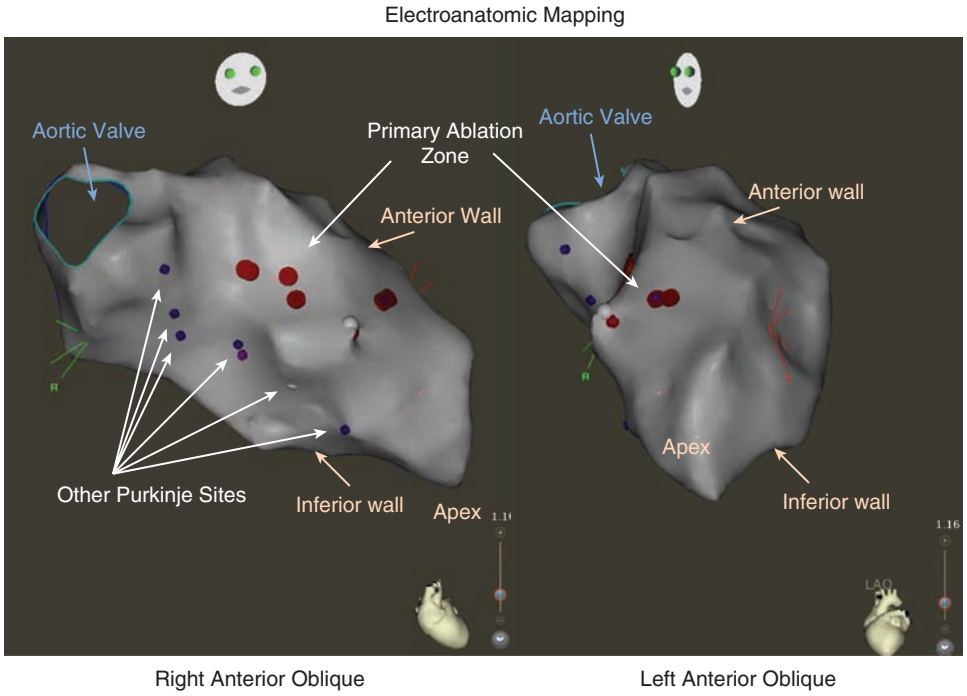


Fig. 23-17 displays an electroanatomic map during sinus rhythm showing sites with purple tags denoting Purkinje potentials as well as red tags denoting ablation sites where PVCs with the morphologies implicated in PMVT initiation were mapped, having Purkinje potentials preceding QRS complexes.

Summary

- Patients with recurrent polymorphic VT/VF should be investigated for severe ischemia, drug/electrolyte derangements, and progressive heart failure as well as the possibility that a focal source of fibrillation is responsible
- Focal-origin PMVT/VF has several features:
  - Episodes start with relatively closely coupled PVCs
  - Initiating PVCs generally have a consistent morphology
  - The first few cycles of PMVT are often identical
  - QRS complexes of initiating PVCs are relatively narrow
- Patients with suspected focal-origin PMVT/VF should have continuous telemetry with multiple leads (ideally full 12 leads) to determine whether initiations are stereotypic as well as defining morphology for potential ablation targets
- Ablation can be life-saving in such patients

24 Ventricular Tachycardia After Remote Infarction

Case Presentation

The patient was a 58-year-old man referred for catheter ablation of incessant ventricular tachycardia (VT). He had a history of inferior wall myocardial infarction (MI) and bypass surgery 5 years earlier. A ventricular fibrillation arrest occurred ~3 months after bypass surgery; he received a secondary prevention implantable cardioverter-defibrillator (ICD). At a routine office visit, his heart rate was 120/min, without symptoms; he was sent to the emergency room, where a tentative diagnosis of supraventricular tachycardia (SVT) was made (no response to adenosine). He was sent home, still in the arrhythmia, knowing that he had a scheduled visit with his electrophysiologist (EP) in several days. During the EP outpatient visit, VT was diagnosed and pace-terminated, and he was scheduled for elective ablation. Episodes recurred, and he was admitted to hospital for ablation more urgently.

Baseline ECG

Figure 24-1

In Fig. 24-1, this appears to be ventricular tachycardia with 1:1 retrograde conduction (*arrows* show P waves). Consistent with his history of inferior infarction, this appears to have a source (focus or exit from circuit) on the inferobasal septal wall, according to published algorithms.

Atrial Pacing Initiates VT

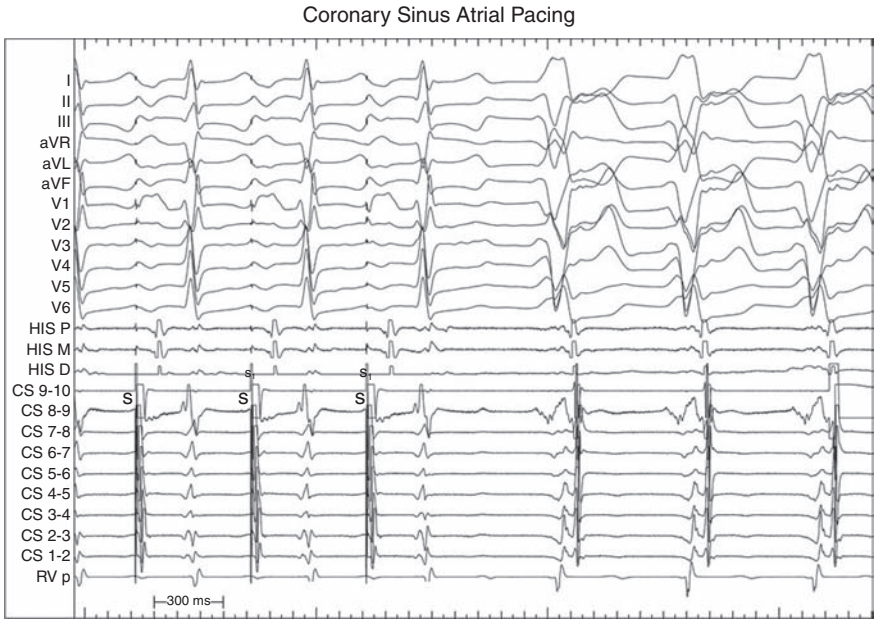

Figure 24-2

VT was accidentally terminated during catheter insertion and manipulation; in Fig. 24-2, during baseline atrial pacing, it is reinitiated. This unanticipated finding is quite unusual with VT at all, but when it occurs, most often a triggered (focal) mechanism is responsible for the VT.

Right Ventricular Overdrive Pacing

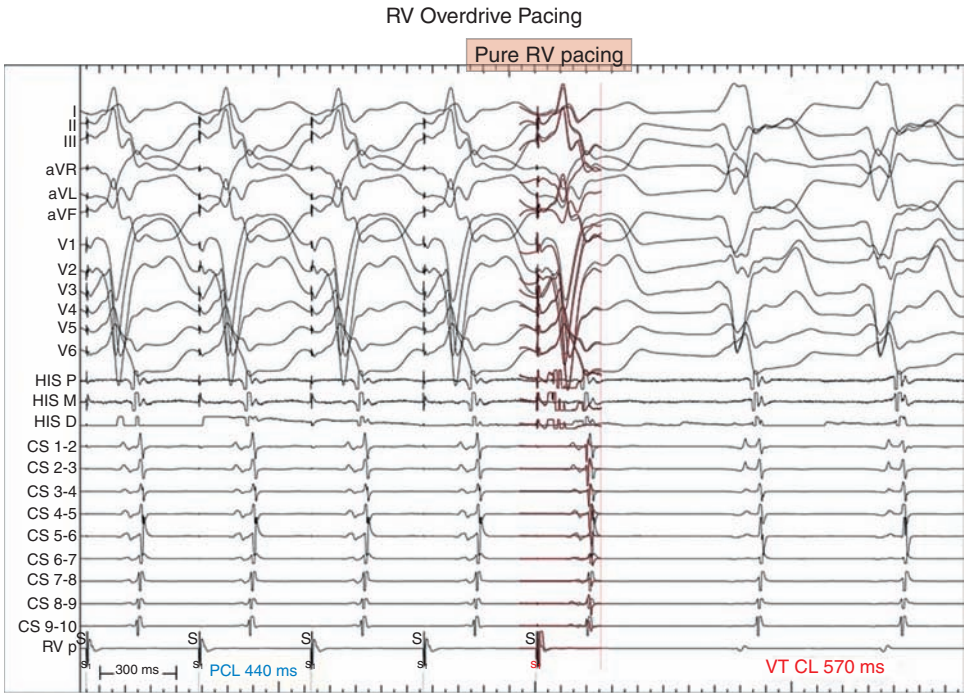

Figure 24-3

Incessant VT may be either focal or reentrant in origin. Because there was a question as to the VT mechanism (focal vs macroreentry) based on how it was initiated with atrial pacing, overdrive ventricular pacing was performed to investigate further. In Fig. 24-3, overdrive pacing at 440 ms is performed from the right ventricular (RV) outflow region, to maximize differences between VT and paced wavefronts. A single complex of pure RV pacing from later in the procedure is superimposed in *red*. This looks very similar to the paced complex during VT with only some minor differences. Because there is no clear fusion, macroreentry cannot be diagnosed; however, the absence of clear fusion on one example of pacing does not allow us to conclude that the VT has a focal origin. As such, this provides no definitive diagnostic information. (PCL, paced cycle length; VT CL, VT cycle length.)

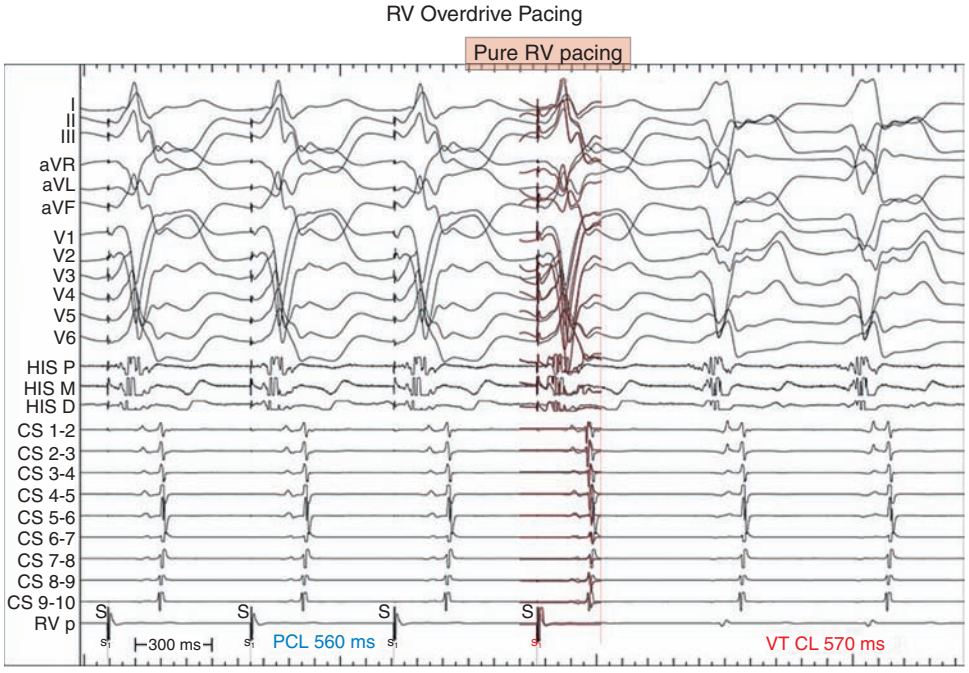

Figure 24-4

In Fig. 24-4, overdrive pacing is performed at a slower rate (560 ms) than before to further amplify differences between VT and paced wavefronts. Again, a single complex of pure RV pacing from later in the procedure is superimposed in *red*. This shows more differences between pure pacing and pacing during VT than were seen in Fig. 24-3: just as the more rapidly one paces during VT, the more all complexes will resemble pure pacing, it is also true that the *slower* one paces during VT (closer to VT cycle length), the contribution of the paced wavefront to the QRS will be less and fusion will be easier to discern. In this example, only minor differences are seen between pure pacing and pacing during VT (lead 1, V1-V2).

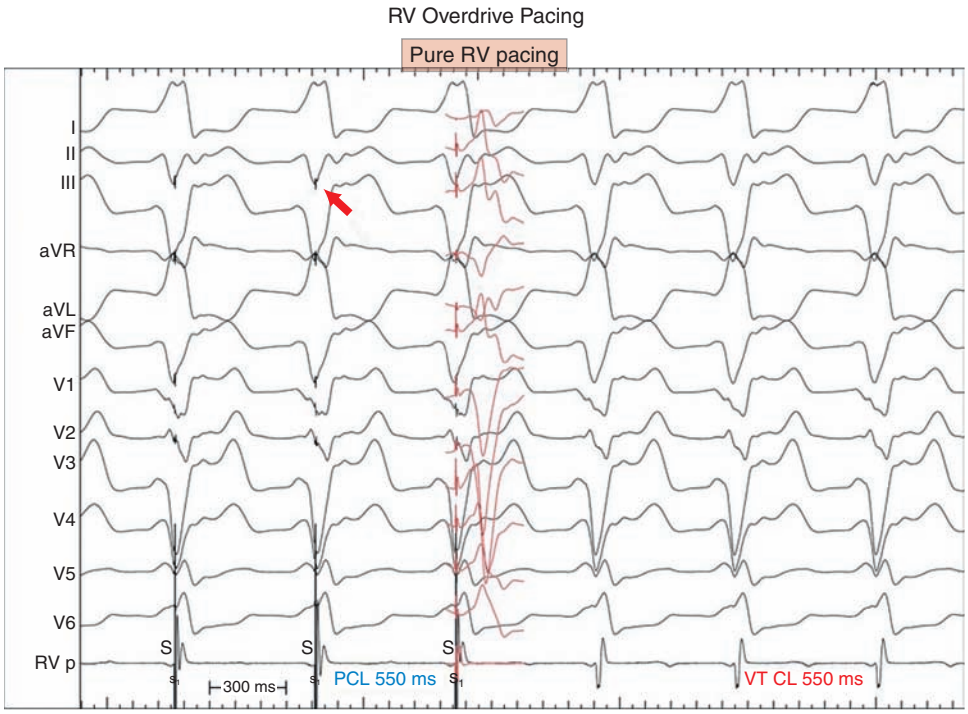

Figure 24-5

Fig. 24-5 shows RV overdrive pacing during VT a few minutes later; again, a single complex of pure RV pacing is superimposed for comparison. Now, it appears that there is a clear difference between pure pacing and pacing during tachycardia—indicating fusion—and thus implicating macroreentry. Note also that the stimulus artifact *(arrow)* occurs after the onset of a paced complex, another hallmark of macroreentry. Why is this so clear now when it was not before, pacing at the same site and rate? Careful inspection of the figure shows that one of the primary requirements for making an assessment has not been met: the VT has accelerated slightly such that its CL and the paced CL are the same. In fact, the RV electrogram starts before the stimulus—so none of it is actually captured (thus explaining why the "paced" QRS complexes are so similar to those of VT). This shows the importance of ensuring that capture is occurring when pacing during VT.

Figure 24-6

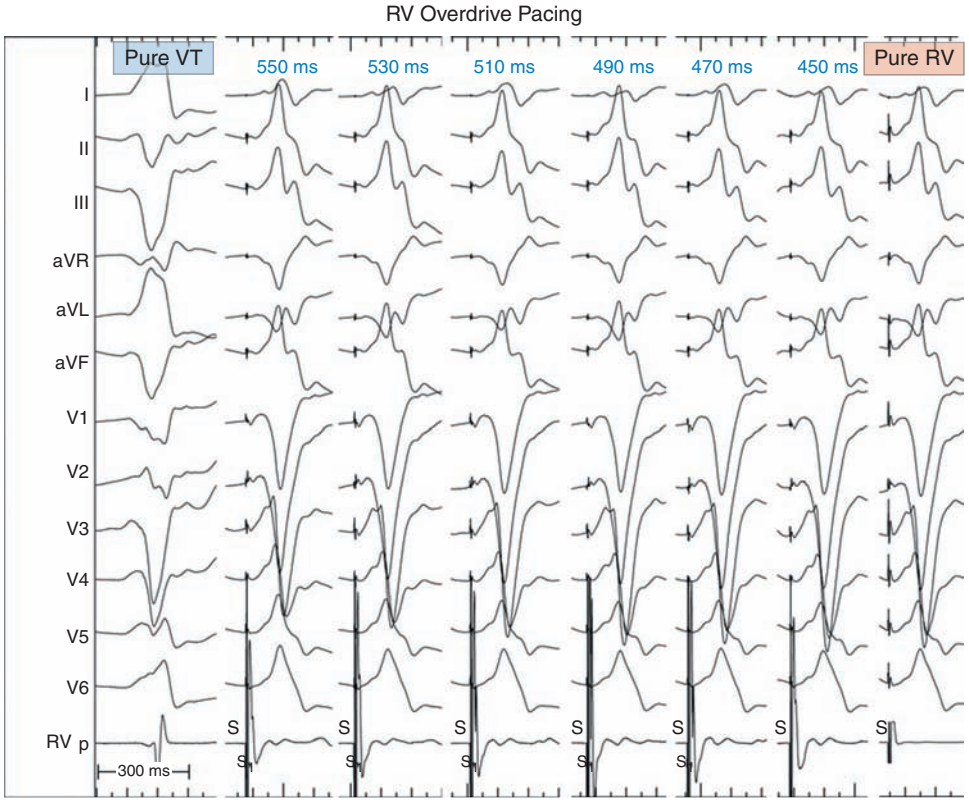

Fig. 24-6 shows a single complex of RV overdrive pacing at several different cycle lengths as indicated. Only minimal changes ("progressive fusion") are evident between pure tachycardia and pure pacing as the paced CL changes, mainly in lead 1. This is suggestive of macroreentry but not nearly as strong evidence as it could be.

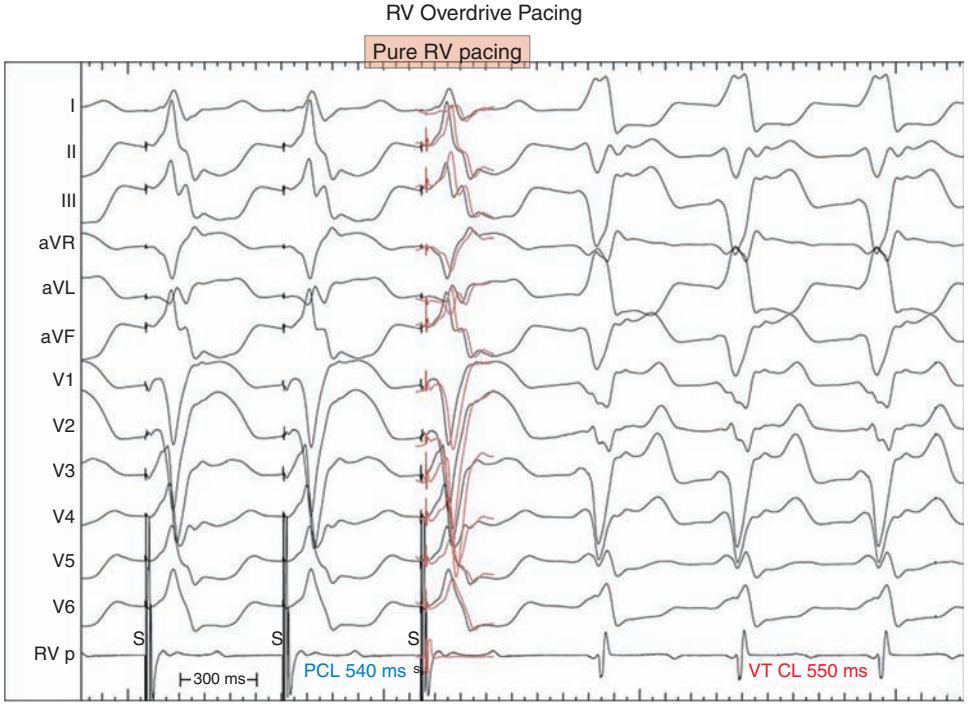
Figure 24-7



In Fig. 24-7, we have another attempt at overdrive pacing at 540 ms (when the VT CL is still 550 ms) that now shows clear differences between pacing during VT and pure RV pacing (again, a single complex of pure RV pacing is superimposed). This is clearly evident in lead 1 (also present in leads 3, aVR, aVL) and now makes a strong case for macroreentry.

Left Ventricular Mapping and Pacing

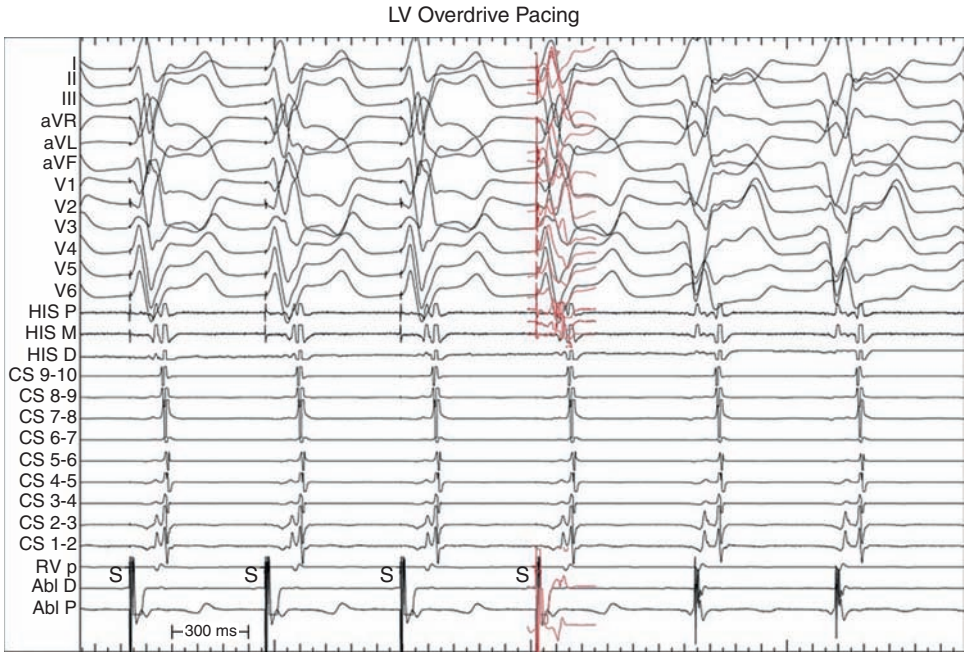


Figure 24-8

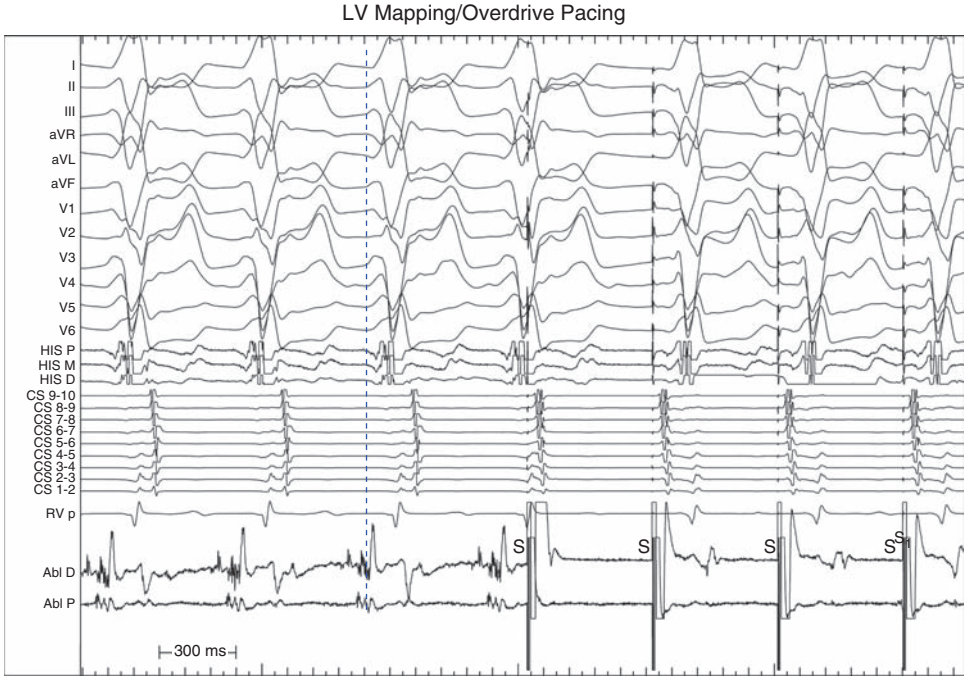
Another means of demonstrating fusion, and thus proving macroreentry, is to pace from different sites to accentuate differences between pure pacing and pacing during tachycardia. In Fig. 24-8, a site in the high lateral left ventricle is paced during VT, with a single complex of pacing from this site during sinus rhythm (superimposed in *red*) a few minutes later. Differences between the pure paced complex and those during VT are more marked than were evident with right ventricular pacing. Based on demonstration of fusion with different pacing strategies, macroreentry seems to be a secure diagnosis.

Figure 24-9



Having established a diagnosis of macroreentry, we can now search for a middiastolic electrogram as a reasonable ablation target site. In Fig. 24-9, a site in midlate diastole (*dashed line* denotes QRS onset) with marked fragmentation is shown. When attempting overdrive pacing at this site to determine whether it is a participant in tachycardia, the first stimulus results in termination of tachycardia without propagating to the rest of the heart *(arrow)*. If this is a reproducible phenomenon (ie, not spontaneous termination), it signifies that the site of stimulation is integral to the tachycardia circuit. After this stimulus terminates VT, further stimulation results in capture with a QRS configuration similar to VT, though not identical. Note also that the atrial recordings in the CS are accelerated to the paced CL and occur almost immediately after the stimulus artifact, indicating that there is direct atrial capture with stimulation (thus the catheter is very close to the mitral annulus).

Figure 24-10

In Fig. 24-10, pacing from the same site readily reinitiated the same VT. Of note, the paced QRS complex is similar, but not identical, to that during VT. Part of the difference may be because of atrial capture during stimulation resulting in P-wave distortion of the QRS onset; capture of ventricular tissue outside the diastolic corridor could also contribute to differences between paced and VT QRS complexes.

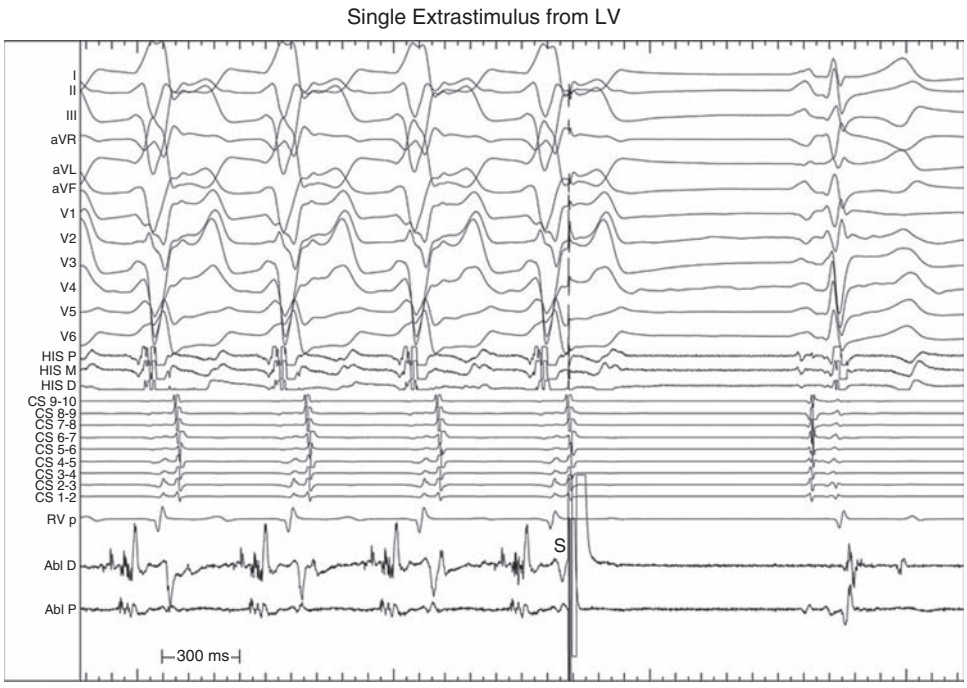


Figure 24-11

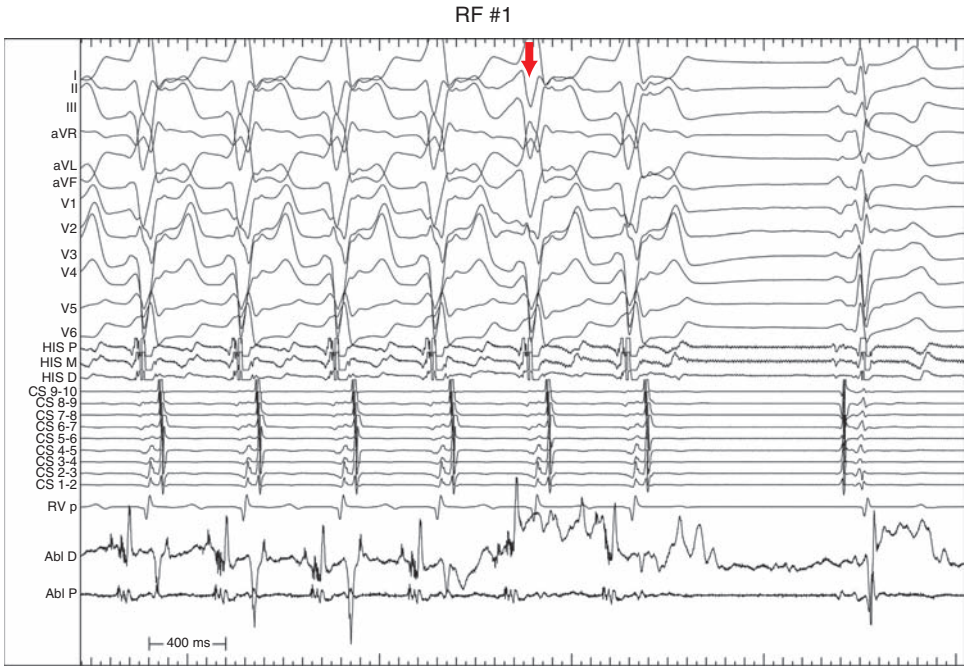
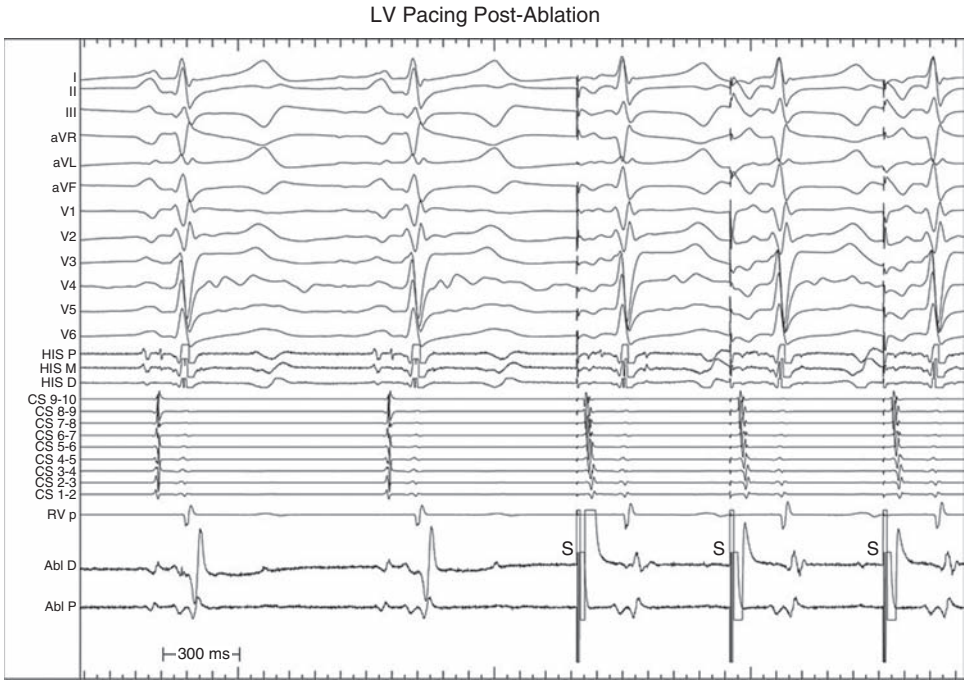
After VT was reinitiated, a single extrastimulus was delivered from the same location as in the prior figure; VT again abruptly terminates without propagation (Fig. 24-11). This sequence was repeated twice more, with the same results. This denotes that the site of stimulation is definitely within a critical isthmus of the VT circuit.

Figure 24-12



Based on the prior information that identified this site as being a critical part of the VT circuit, radiofrequency (RF) energy was delivered (*arrow*; Fig. 24-12). This resulted in termination of VT after <1 second.

Figure 24-13



As had been seen earlier, pacing from this site in the left ventricle can also capture the atrium—but here (Fig. 24-13), after ablation, only atrium is captured. This is despite there being a larger ventricular electrogram at the site in sinus rhythm. Before ablation, it was possible to capture ventricular muscle in this area, but ablation has damaged enough remaining muscle that local ventricular capture is not possible. Subsequently, a full stimulation protocol from the right ventricular site as well as a different left ventricular site (at which capture was feasible) resulted in no inducible VT. The patient has had no VT on follow-up.

Electroanatomic Mapping

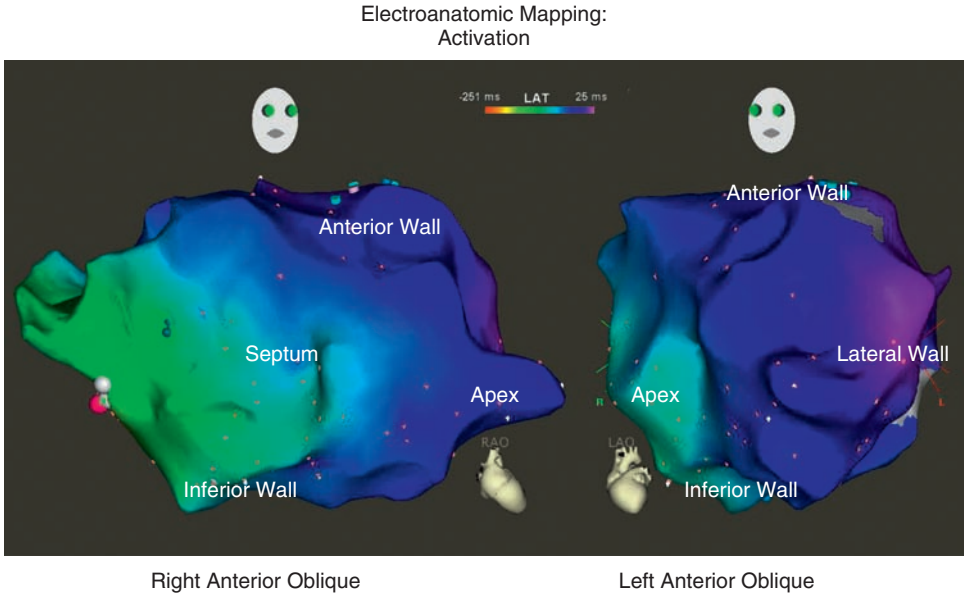


Figure 24-14

Fig. 24-14 (electroanatomic activation mapping) shows relatively late activation from standard right and left anterior oblique views because the pathology is on the inferobasal free wall.

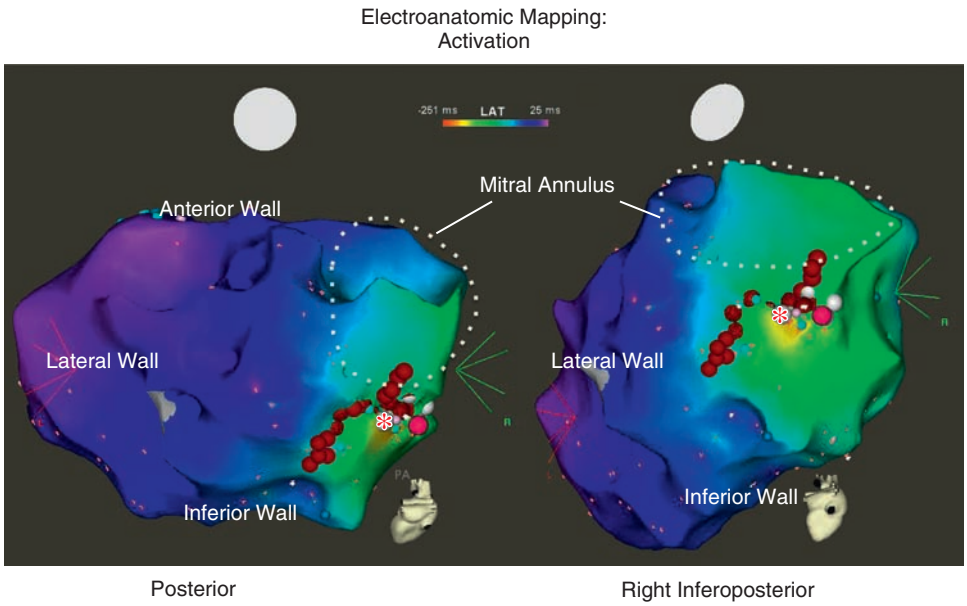

Figure 24-15

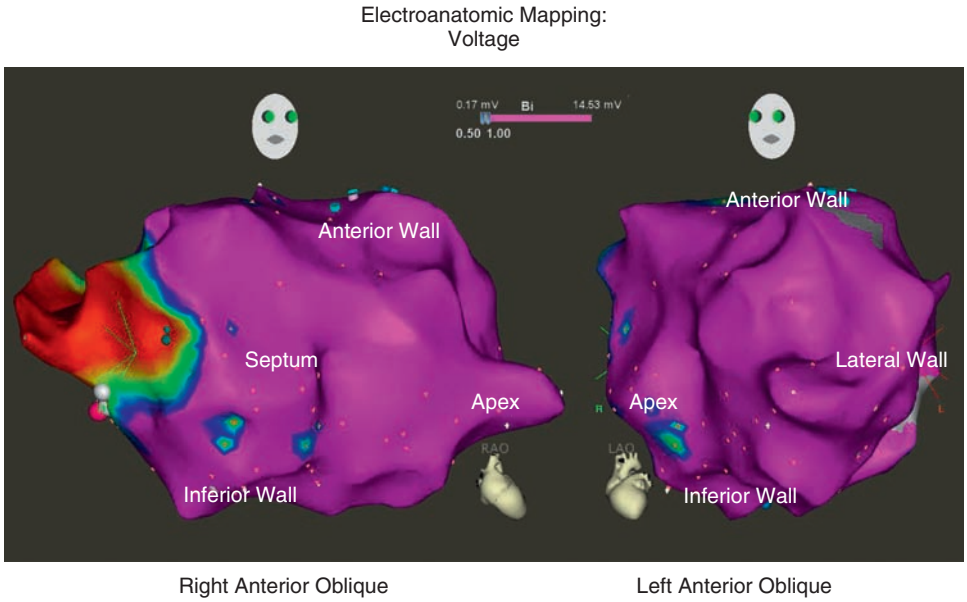
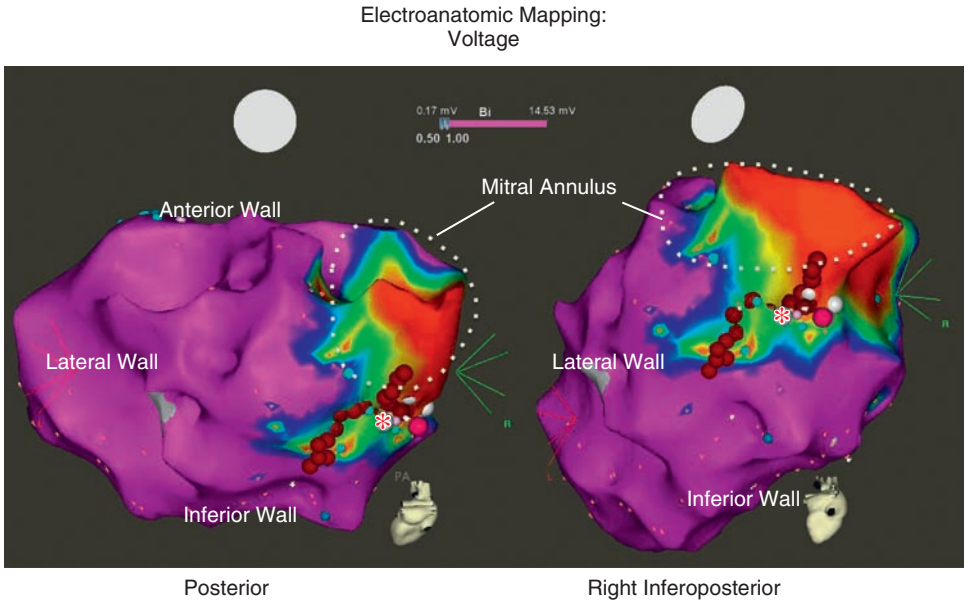
In Fig. 24-15, activation mapping viewed posteriorly shows the site of stimulation at which VT was terminated with a nonpropagated stimulus and where RF energy terminated it, rendering it noninducible thereafter *(asterisk)*. The *pink dot* denotes a site of pacemapping that yielded an excellent match with VT. *Red dots* denote sites at which RF energy was applied to connect the mitral annulus *(dashed line)* to more normal myocardium on the inferior wall (better seen on voltage map in Fig. 24-17).

Figure 24-16



In Fig. 24-16, electroanatomic voltage mapping shows some abnormalities at the basal left ventricle *(red)* in standard right and left anterior oblique.

Figure 24-17



In Fig. 24-17, voltage mapping viewed posteriorly again shows the site of stimulation at which VT was terminated with a nonpropagated stimulus and RF energy delivery *(asterisk)*. *Red dots* again denote sites at which RF energy was applied to connect the mitral annulus *(dashed line)* to more normal myocardium *(purple)* on the inferior wall.

Finally ECG

Interestingly, the final ECG during sinus rhythm (Fig. 24-18) shows no evidence of prior infarction—unusual in cases in which enough damage has occurred to result in relatively slow VT.

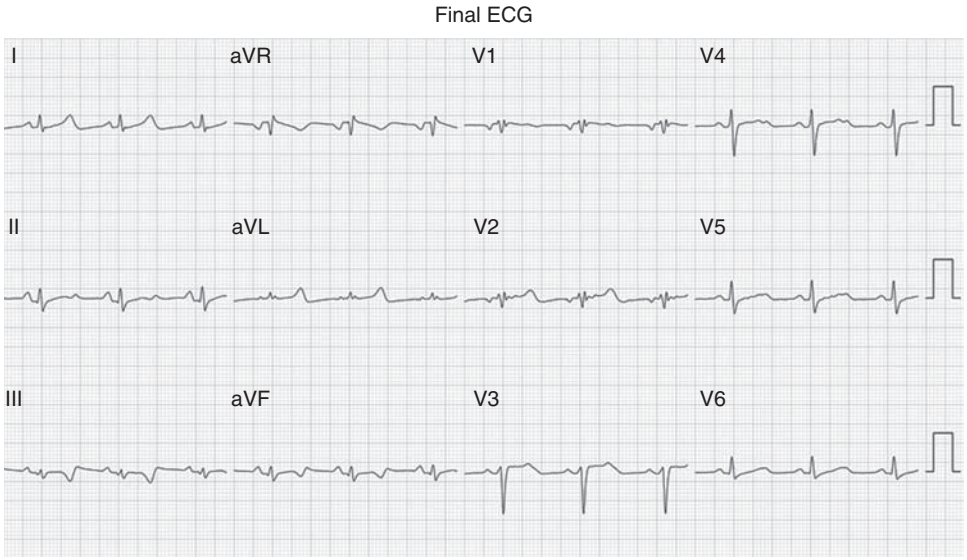


Figure 24-18

Summary

- It is important to determine the mechanism of VT before mapping and ablation in all cases, but especially:
  - In cases of incessant VT (which can be either focal or reentrant)
  - When there are unexpected findings (initiation of VT with atrial pacing or catecholamines)
- Overdrive pacing to determine presence or absence of fusion (and thus macroreentry) may yield data that are equivocal or require careful inspection to make correct conclusions
- Unanticipated diagnostic findings (nonpropagated stimulus terminating arrhythmia) may occur and should not be overlooked, because they have important implications regarding mapping and ablation

25 Focal Ventricular Tachycardia in the Postinfarction Patient

Case Presentation

A 56-year-old man with a history of myocardial infarction (MI) coronary artery bypass surgery had an implantable cardioverter-defibrillator (ICD) placed because of cardiac arrest several months after surgery. He began having episodes of palpitations and was found to have recurrent episodes of slow ventricular tachycardia. Medical therapy (beta blocker, a short course of amiodarone) failed to control episodes. Exercise stress testing 2 months earlier showed no evidence of residual ischemia. Left ventricular function was mildly depressed (ejection fraction 40%) with inferior wall motion abnormality; there was no ventricular thrombus. He was referred for electrophysiologic (EP) study catheter ablation.

Baseline Recordings

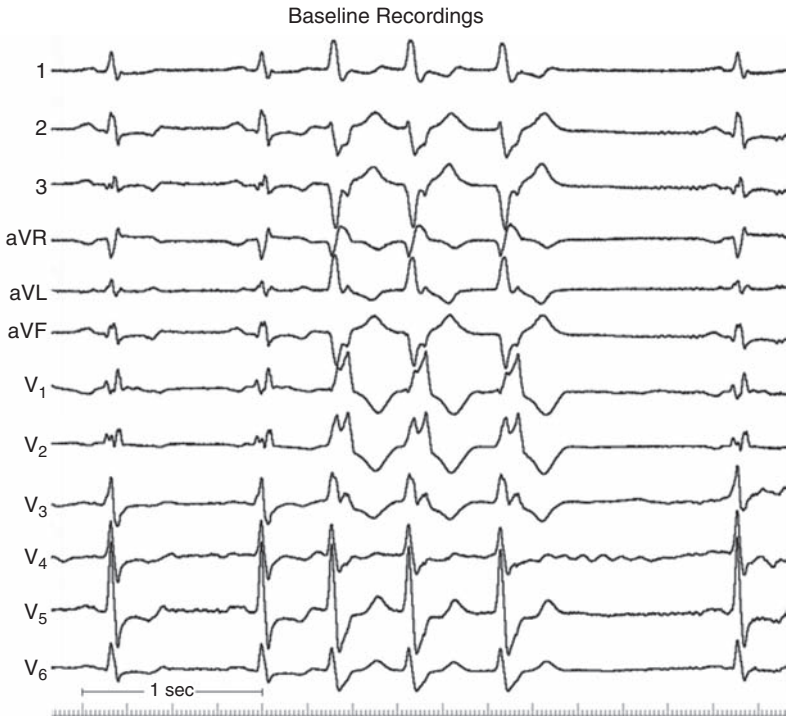

Figure 25-1

A recording of an episode of his typical VT morphology (right bundle branch block [RBBB], left superior axis, Fig. 25-1) was made before the EP procedure. VT starts spontaneously, with the initiating complex identical to all others, and the rhythm is slightly irregular before terminating. Although most VT in patients with prior MI is caused by reentry in the region of scar, the behavior of this VT is unusual for reentry, in which the initiating complex is often different from the rest of the VT complexes, and episodes tend

to be sustained and quite regular. The features of this patient's VT raise the question whether this could be a focal (automatic or triggered) process; this occurs in up to 9% of patients with prior MI. Foci are usually at the periphery of the scarred region. Further investigation is needed to sort out the mechanism of this arrhythmia because ablation-site characteristics (late diastolic signal) are very different from those of the usual macroreentry (middiastolic potential). The VT morphology suggests a left ventricular (LV) source; LV thrombus has already been excluded by echocardiogram (important information before placing a catheter in the LV).

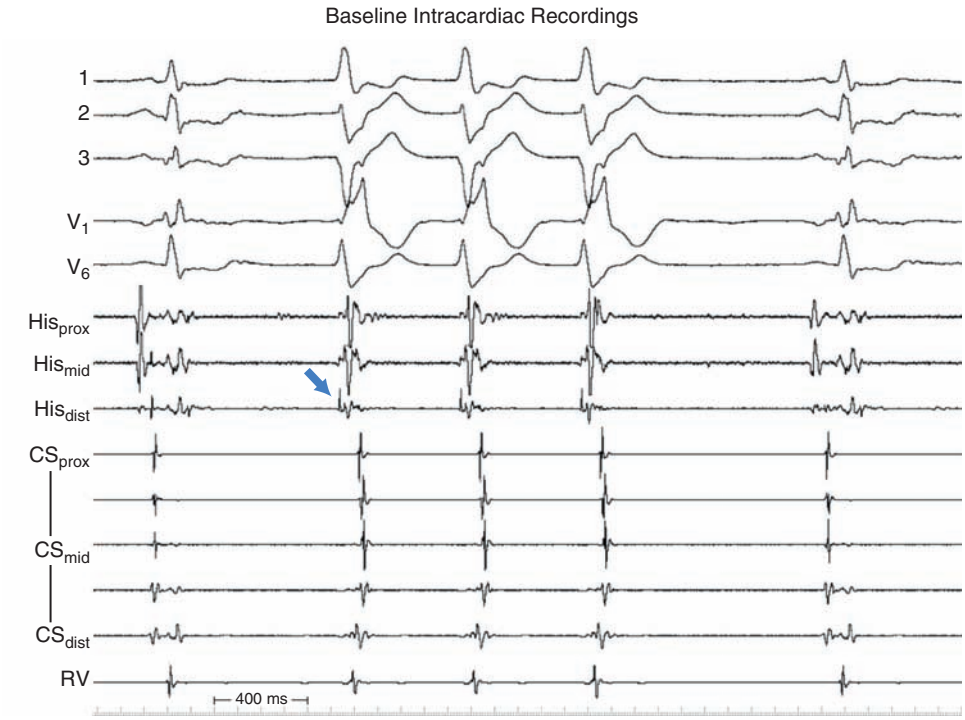

Figure 25-2

At the time of EP study, catheters were placed to be able to record and pace from atrium, His bundle region, and ventricle (Fig. 25-2). An episode of nonsustained VT is seen with corresponding intracardiac recordings. Retrograde conduction is present during VT, which (as seen before) starts spontaneously with the first complex identical to other VT complexes. The *arrow* points to a signal consistent with a His potential (also seen during the sinus rhythm complex at left). This raises the possibility that a focal fascicular tachycardia or reentry within the His-Purkinje system (HPS) could be operative, and the QRS morphology is reasonable for either of these.

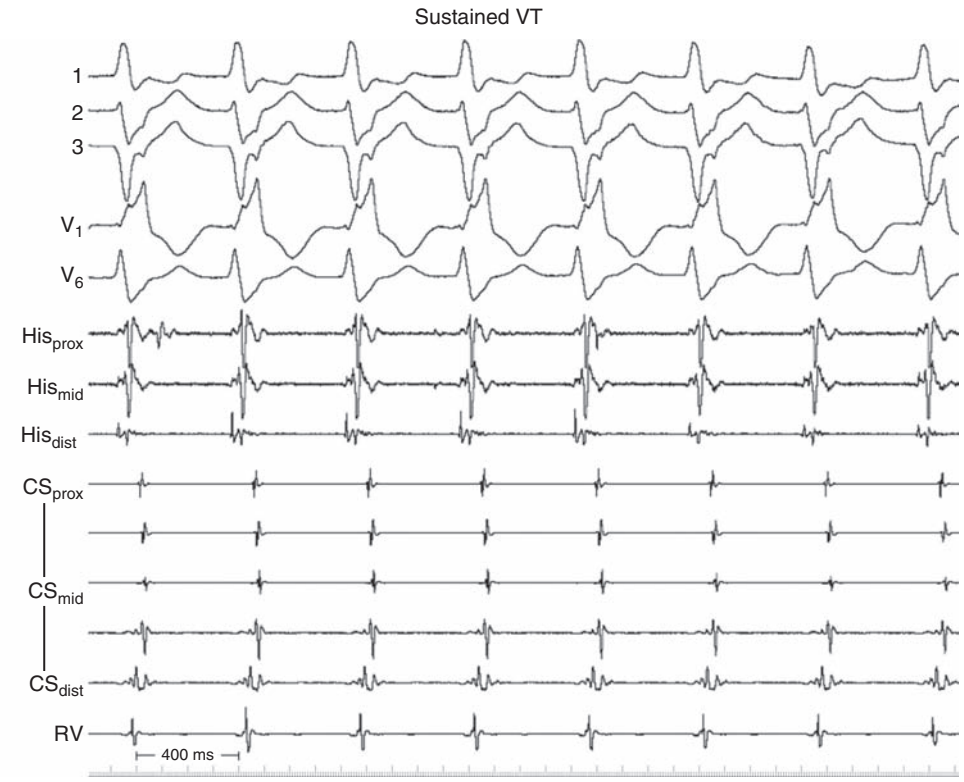

Figure 25-3

With isoproterenol infusion, VT became more sustained and slightly more regular (Fig. 25-3). This is again more consistent with a focal mechanism, but can occur with reentry.

Determining VT Mechanism

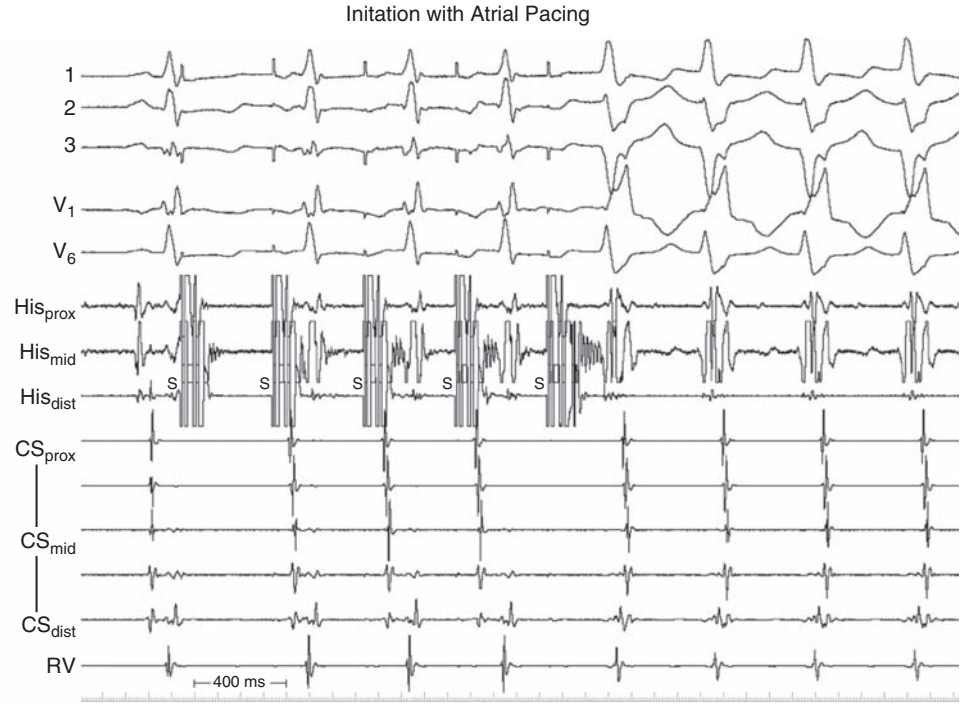

Figure 25-4

VT terminated spontaneously (not shown); in Fig. 25-4, atrial pacing initiates VT again. This was actually an attempt to pace the His bundle region to see if the resulting QRS complex was like that of VT, but instead of His or ventricular capture, only atrial capture

occurred and this initiated VT again (of five stimuli [S], only the middle three capture). This finding again favors a focal source of VT, but nothing is certain yet.

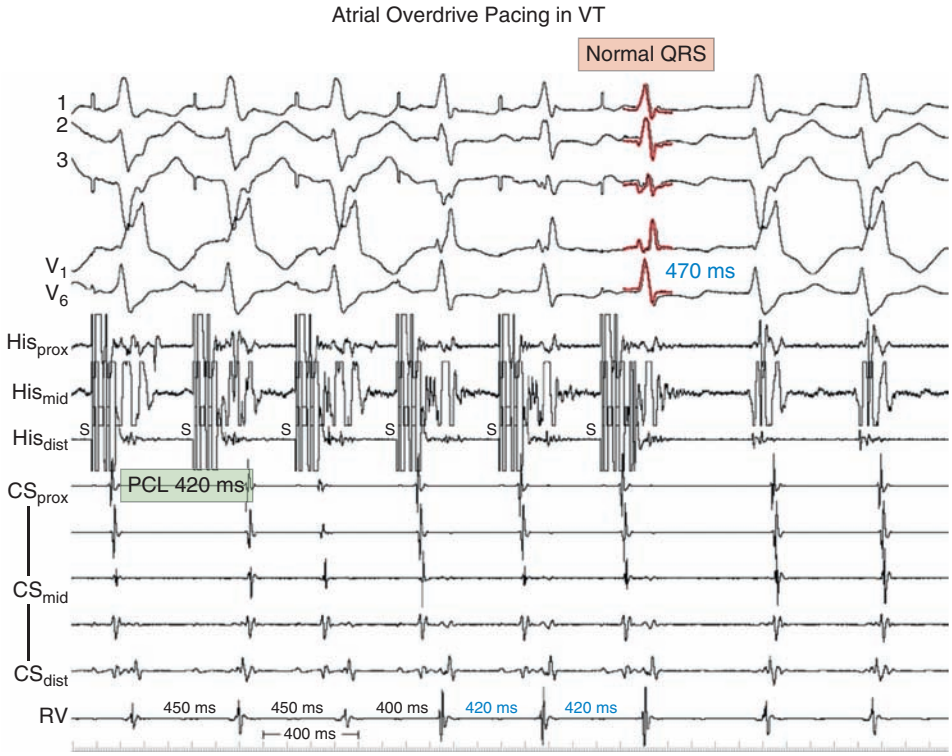

Figure 25-5

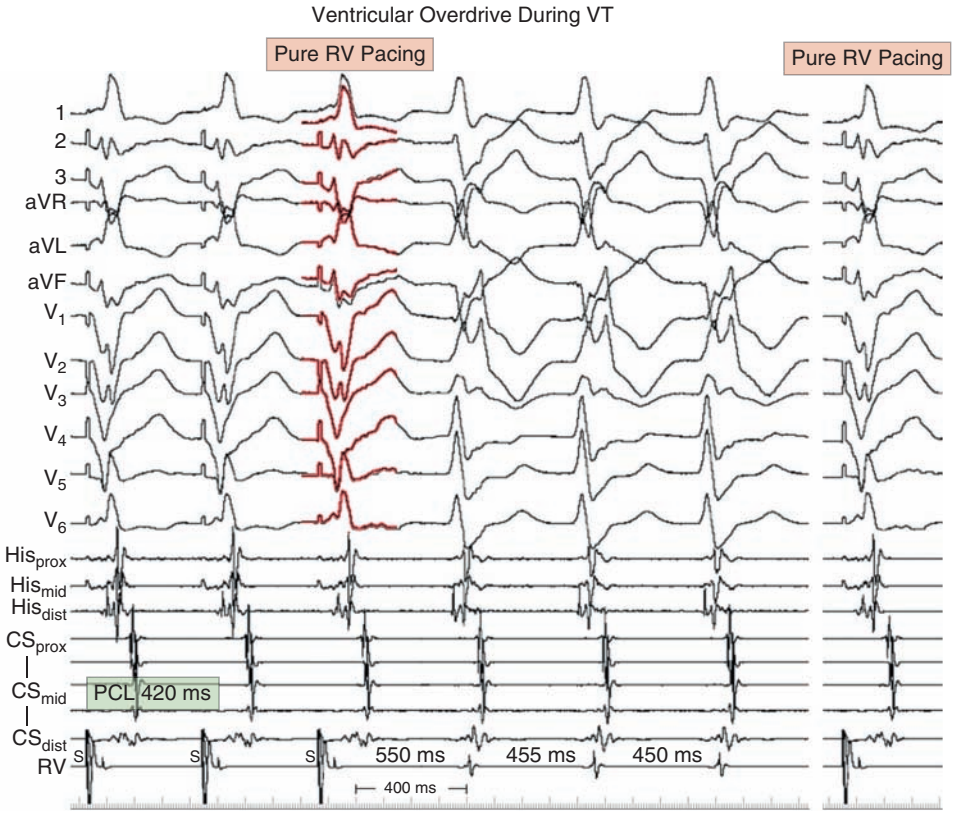
Another attempt at pacing from the distal His electrode during VT also results in atrial (not ventricular) capture (Fig. 25-5). Although the last four stimuli capture atrium, the last three affect the QRS complex by having some atrioventricular conduction, and after the last two stimuli, QRS complexes are identical to the sinus complex (superimposed in *red*). This indicates full control of the ventricles (also shown by RR intervals above the RV recording), and should terminate reentry within the HPS; however, the rhythm resumes after the last paced complex. The QRS-QRS interval at the first VT complex is 470 ms, just longer than the tachycardia cycle length (CL). Although HPS reentry is unlikely, a focal mechanism (fascicular or ventricular) is still quite plausible.

Figure 25-6



To try to determine VT mechanism more clearly, overdrive ventricular pacing is performed during VT. In Fig. 25-6, pacing from the RV electrode accelerates all complexes to the paced CL and the same VT returns on cessation of pacing. Although many would call this entrainment of VT, it is not possible to say just yet; fusion is necessary to declare that entrainment is present and thus diagnose macroreentry. Here, a single complex of pure ventricular pacing is shown at right, and is superimposed on a complex of pacing during VT; these appear to be identical. However, the absence of fusion on one attempt at overdrive pacing does not thereby diagnose a focal mechanism; one may have to pace at different CLs and different sites without showing fusion to more certainly diagnose a focal process. One additional feature to evaluate is the interval from last paced complex to first subsequent VT complex (the return cycle, here 550 ms); with reentry, this should stay constant no matter what CL or how many complexes of overdrive pacing are performed at the same site, but may show overdrive suppression with a focal mechanism when pacing faster or longer. Finally, the VT CL after resumption is usually the same as baseline with reentry but may be slower for a few cycles if overdrive suppression of a focus has occurred. Here, the VT CL is a little slower than baseline (450 ms). These again suggest a focal process.

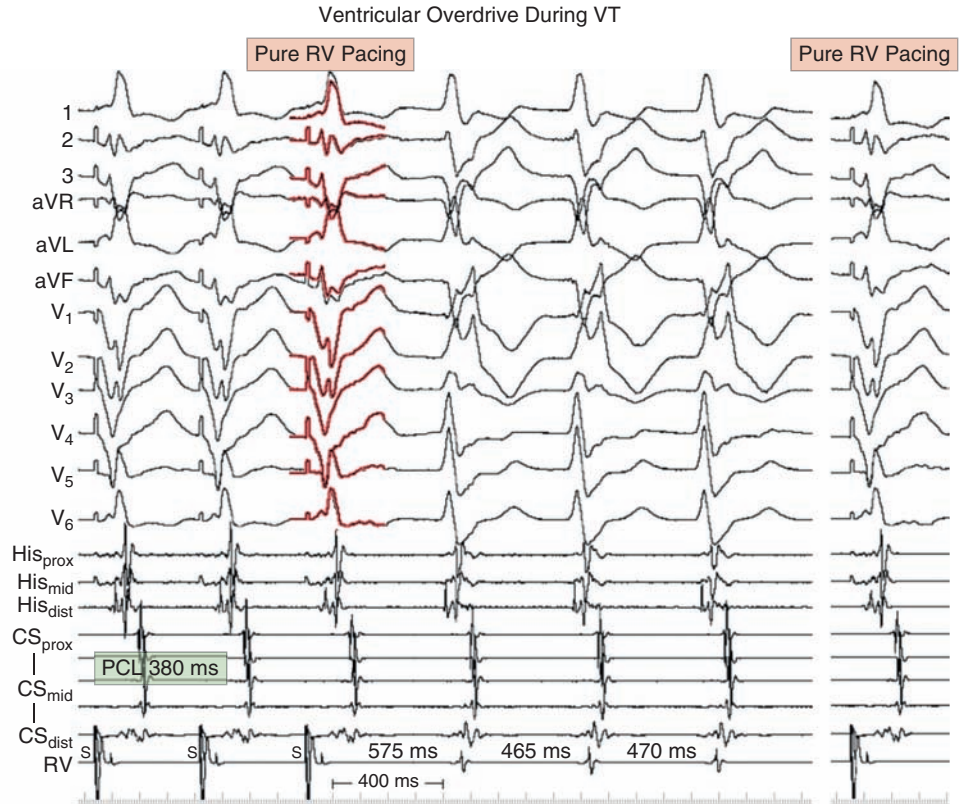


Figure 25-7

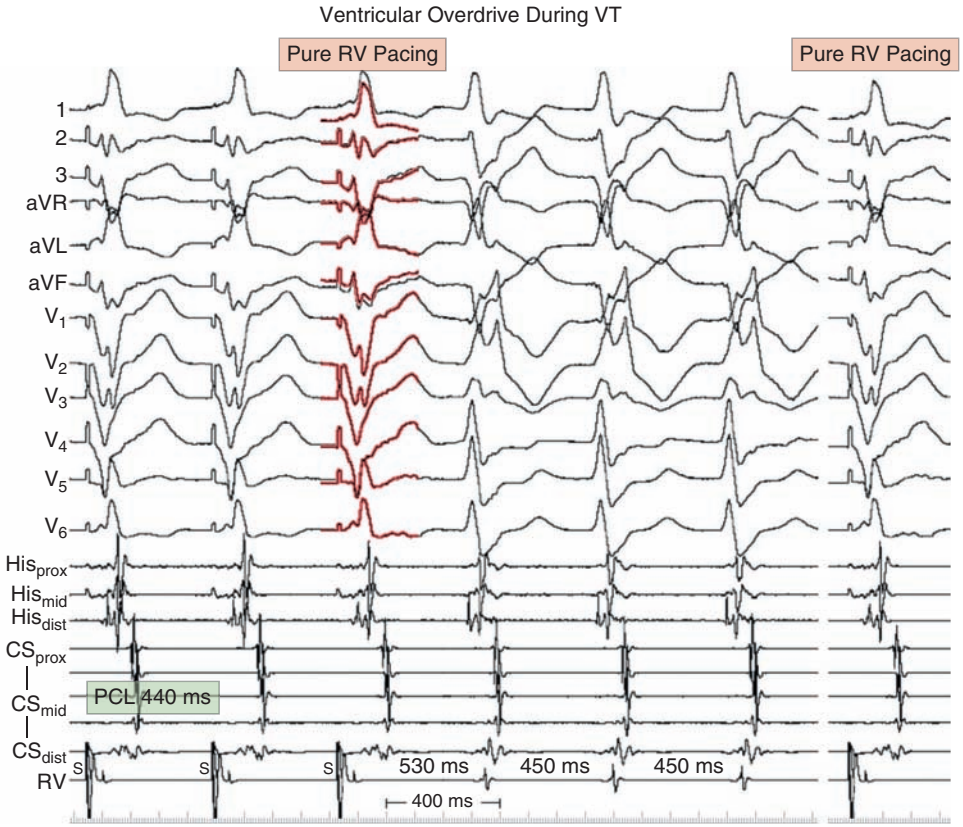
In Fig. 25-7, pacing during VT from the same site is performed at a faster CL (380 ms). The return cycle is longer than before (575 ms) and as shown the VT is slower as it resumes. These again suggest a focal process; there is again no fusion on the ECG during pacing, but one would not expect it even if macroreentry were present because if it were not seen at a slower paced CL it will not appear at a faster one. The best chance of showing fusion is to pace well away from where the anticipated exit site (or focus) is, and as close to the VT CL as possible to allow exit from the VT circuit to blend with the paced wavefront.

Figure 25-8



In Fig. 25-8, pacing is performed during VT as slowly as possible and still has capture (440 ms). This again shows no hint of fusion (all complexes look fully paced); the return cycle is shorter and the VT resumes at about the baseline CL. Two other pacing sites were used with the same outcome (not shown). All these data taken together (lack of fusion at multiple CLs and sites of pacing; appearance of overdrive suppression; transient slowing of resumed VT; initiation with atrial pacing) combined with the clinical behavior (irregular bursts of nonsustained VT with the first complex like all others) are very consistent with a focal, automatic process and nothing points to reentry. At this point, we can begin mapping, searching for a site with a late diastolic potential. Scarring around the site may produce some decrease in electrogram amplitude and a longer presystolic interval (50 to 80 ms) than is usually seen in VT in patients without structural heart disease (20 to 40 ms).

Mapping and Ablation

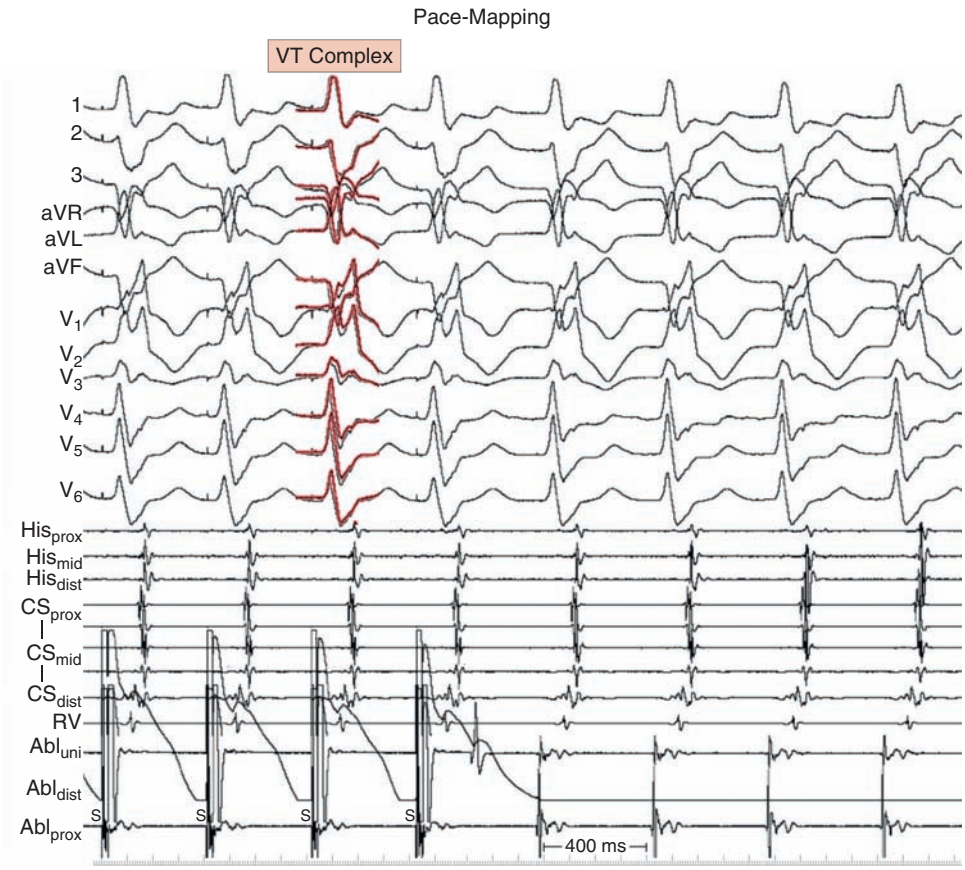


Figure 25-9

In Fig. 25-9, ventricular pacing is performed at a site with a late diastolic electrogram (not shown); a VT complex is shown in *red*, superimposed on a paced complex. Although the overall "match" is quite good, there are some slight differences (leads 2, V2 to V4). If one is pacing from the exact point of emanation from a focal arrhythmia, the resulting paced complex should ideally be identical. Mapping was continued without ablation at this site.

Figure 25-10

In Fig. 25-10, recordings from a site in the inferior LV are shown; the *dashed line* denotes the onset of the surface QRS complex. The distal ablation recording is complex and has a very small component *(blue arrow)* at its onset that is about 60 ms before QRS onset. It is possible that this small component represents a Purkinje potential (and thus the VT would be a focal fascicular tachycardia); VT was incessant at this point; thus it was impossible to know what the site looked like during sinus rhythm (ie, whether a Purkinje potential was present then). Of note, no such potential was evident after restoration of sinus rhythm with ablation, and the lack of an isoelectric interval between the small potential and the main portion of the local electrogram suggests that this is ordinary myocardium rather than fascicular tissue at the source.

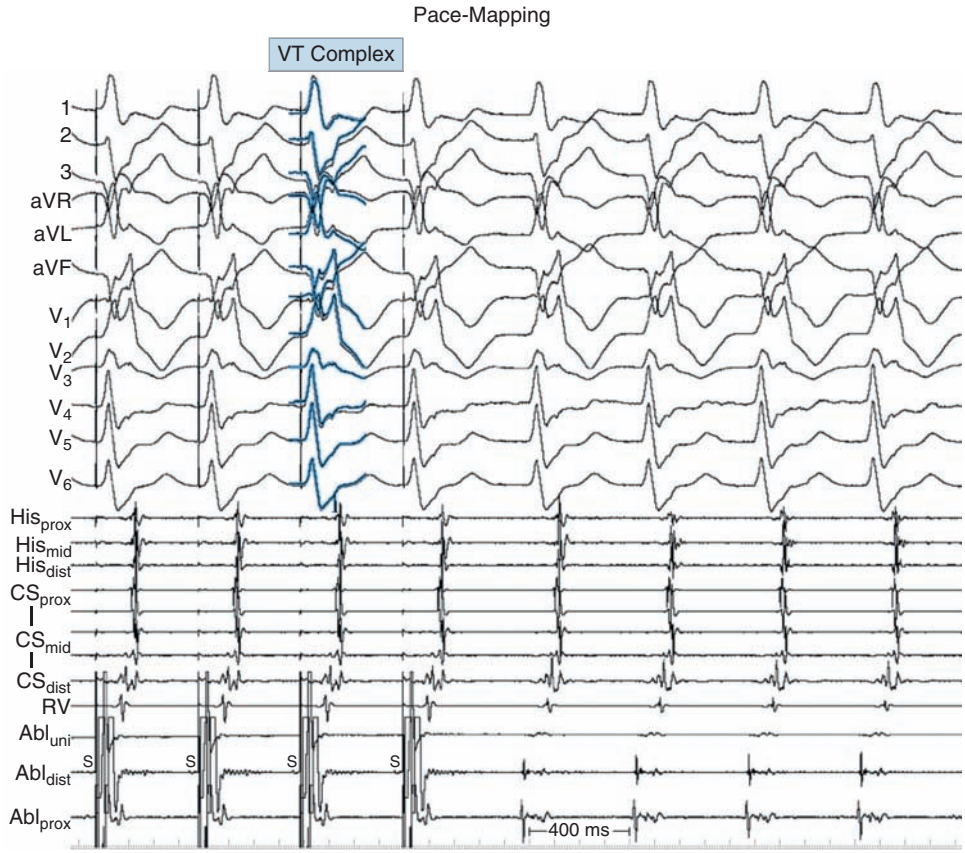

Figure 25-11

In Fig. 25-11, pacemapping is performed from the site shown in Fig. 25-10 to corroborate it as a reasonable site for ablation. As before, a VT complex is superimposed (in *blue*) over a paced complex, showing a perfect "match" with the VT. The stimulus-QRS interval is slightly less than the electrogram-QRS interval during VT, probably signifying the pacing was performed at a slightly excessive output (capturing some tissue beyond the actual focus). Similar to what was observed when pacing at a different site, although VT resumes after stopping pacing, this cannot be considered to be concealed entrainment because to do so, fusion (manifest entrainment) has to be demonstrated at some other time (but could not be in this case because macroreentry is not present).

Figure 25-12

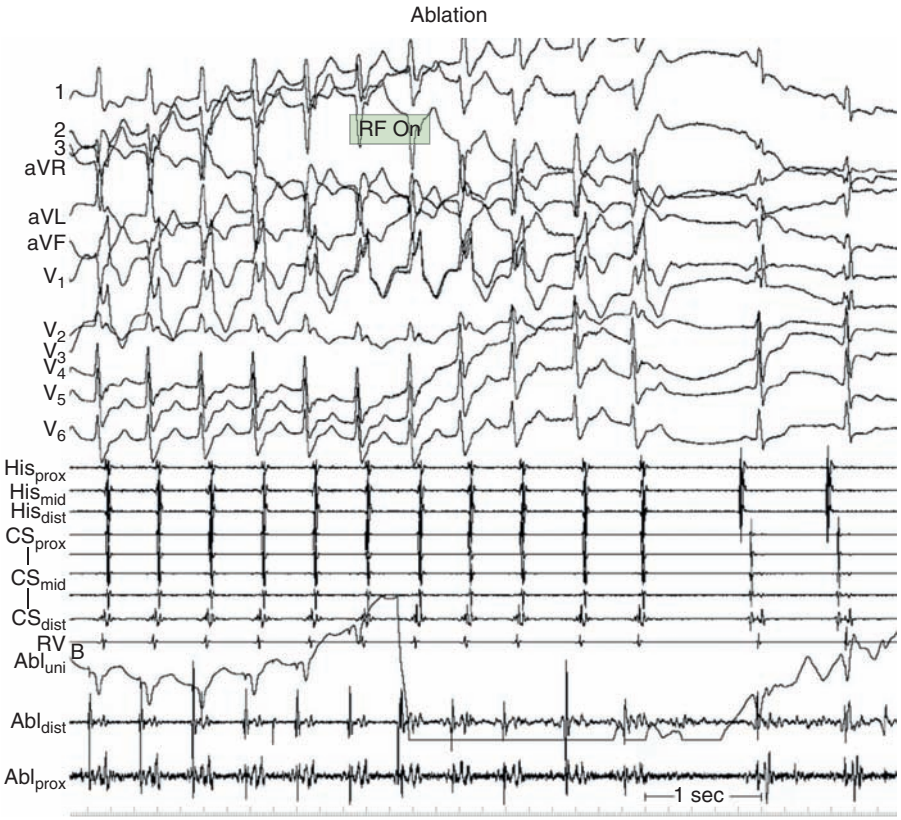

Fig. 25-12 shows the onset of ablation delivered during VT. Less than 3 seconds after the beginning of RF application, VT abruptly ceases after slight acceleration and then slowing. VT could not be initiated thereafter with atrial or ventricular pacing, nor increased isoproterenol infusion.

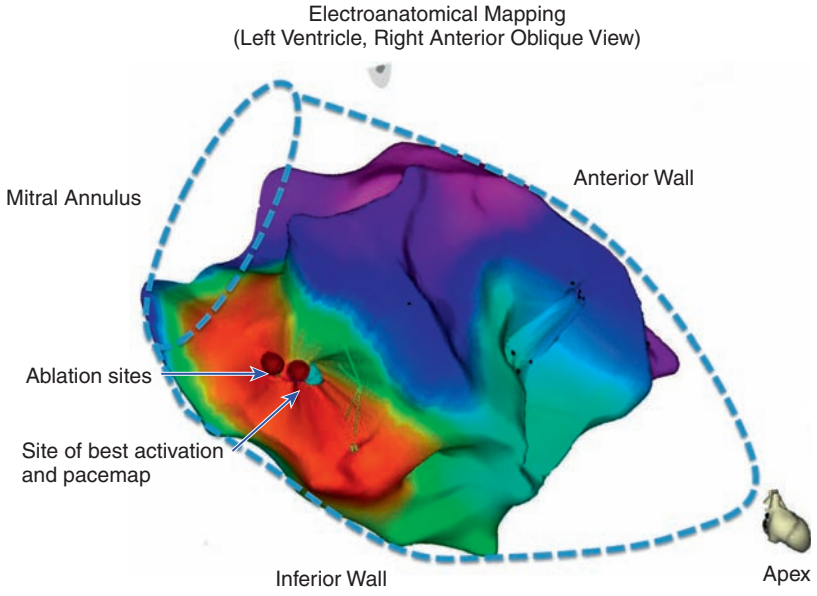
Figure 25-13



A partial endocardial electroanatomic activation map of the LV made during VT is shown, with an idealized outline of the LV in the left anterior oblique projection (Fig. 25-13). As can be seen, the focus was on the inferior basal portion of the left ventricle.

Summary

- In patients with prior myocardial infarction, a focal mechanism is present in up to 9% of VTs that are induced during electrophysiology study
- Focal VTs often occur in irregular bursts spontaneously or are initiated with atrial pacing, facilitated by catecholamines
- Careful investigation must be performed to ascertain whether a focal process is involved in VT when its behavior is atypical for reentry
- Mechanistic distinction from more typical macroreentrant VT in this population is important because ablation-site characteristics are very different

26 Focal Epicardial Ventricular Tachycardia

Case Presentation

A 38-year-old man was resuscitated from cardiac arrest at home. Ventricular tachycardia (VT) or ventricular fibrillation (VF) was initial rhythm, shocked to sinus, and then "sinus tachycardia with right bundle branch block (RBBB)." His history revealed significant alcohol intake, though none recently. He had been nauseated and bloated for 4 to 6 weeks before the event and had palpitations. Treatment included intravenous (IV) Amiodarone and repeated cardioversions for VT (not "sinus tachycardia with RBBB"); lidocaine was added (with no effect). He was maintained during VT on dopamine and then placed on a cooling protocol. ECG revealed severely dilated left (LV) and right ventricle (RV) with LV ejection fraction 15% to 20%. Catheterization showed a normal left coronary, but could not engage right coronary. VT persisted despite continued amiodarone infusion. Progressive hypotension was refractory to vasopressin, epinephrine and intra-aortic balloon pump.

Baseline VT ECG

The Most Likely Mechanism Is

A. HPS reentry
B. Myocardial reentry
C. Myocardial focus

Figure 26-1

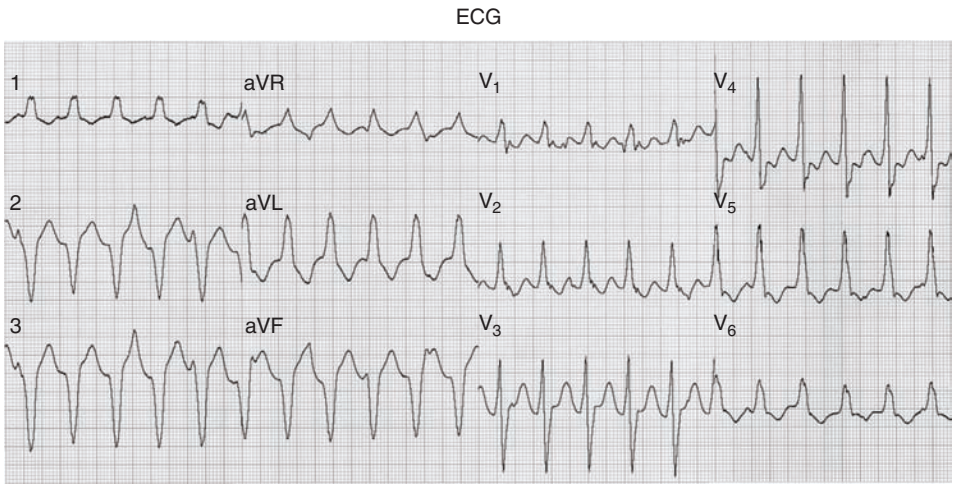


Fig. 26-1 shows a 12-lead ECG of the presenting arrhythmia, diagnosed as VT with AV dissociation (inferior leads) and standard morphologic criteria. The pattern is most consistent with a myocardial source rather than His-Purkinje reentry (which should generally resemble aberrant conduction patterns), but whether this is a focus in the myocardium or exit from a circuit cannot be determined from the ECG.

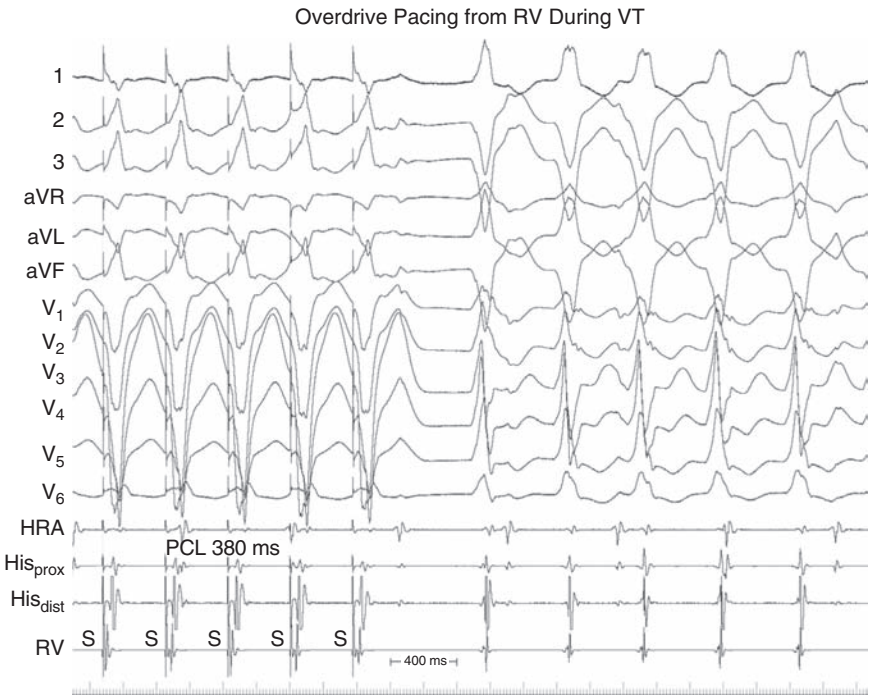
Overdrive Pacing from RV During VT



The Most Likely Mechanism Is

A. HPS reentry
B. Myocardial reentry
C. Myocardial focus

Figure 26-2

Once electrode catheters had been positioned, overdrive pacing was performed from the right ventricular catheter. Pacing was initiated during tachycardia, all electrograms were accelerated to the paced cycle length, and upon cessation of pacing, the same tachycardia resumed (Fig. 26-2). Although many would call this an example of entrainment, one essential piece is missing: fusion. It is difficult to demonstrate fusion with a single example of overdrive pacing during a tachycardia, and without demonstrating fusion, it is difficult to make a diagnosis of macroreentry. Making this distinction (macroreentry vs a focal process) is critical, because the characteristics of the ablation site are dictated by which mechanism is involved (late diastolic potential for a focal process, mid-diastolic potential for macroreentry).

What Do You Want to Do Now?

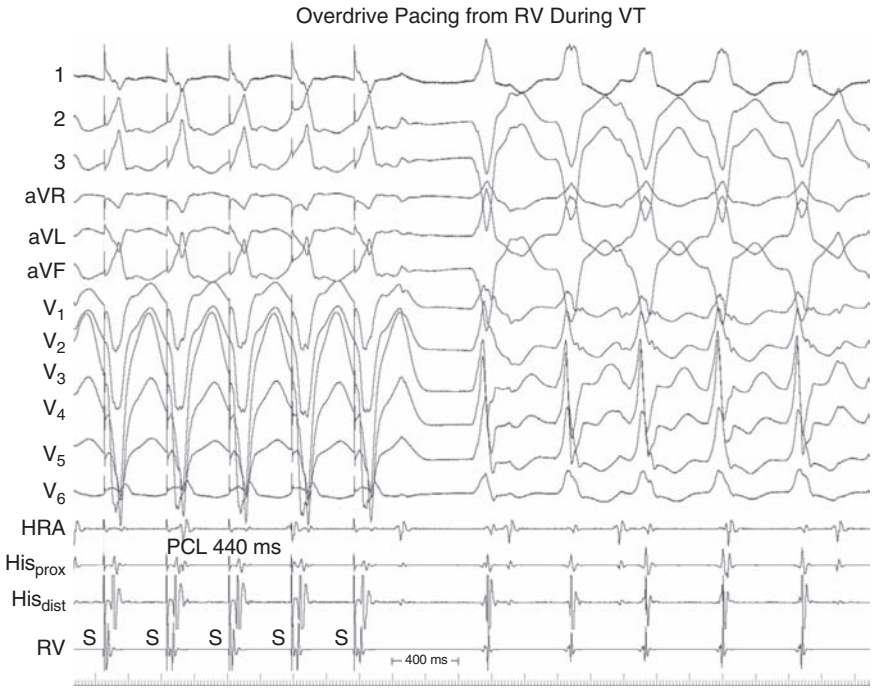


Figure 26-3

One way to ascertain whether fusion is present or not is to pace from the same site at different cycle lengths; the slower the pacing rate (closer to that of tachycardia), the more opportunity there will be to demonstrate fusion, and as the cycle length of pacing changes, the resultant QRS complex (particular blend of pacing vs VT) will change in the presence of macroreentry. In addition, selection of a pacing site can be very helpful: if the pacing site is close to the anticipated exit site of the tachycardia, it will be difficult to demonstrate fusion, whereas if a site is chosen far away from the anticipated exit zone, fusion will be more readily demonstrated. When presented with a RBBB, left superior axis VT, a pacing site was chosen that would produce a LBBB, right inferior axis complex—such that, if fusion were possible, it would certainly be evident when pacing during VT from such a site at a slow cycle length. However, if the VT is because of a focus, there will never be any evidence of fusion, and overdrive pacing from a remote site will always look like pure pacing from that site, no matter what stimulation rate is chosen. In the example shown in Fig. 26-3, pacing is performed at a cycle length (440 ms) just 30 ms shorter than the VT cycle length, yet the complexes during pacing appear to be identical to those when pacing at a more rapid cycle length (380 ms). In addition, the interval from the last paced complex to the first beat of VT that resumes is relatively long compared with the VT cycle length. This would be unusual for macroreentry, but not for an automatic focus that exhibits some degree of overdrive suppression of excitability.

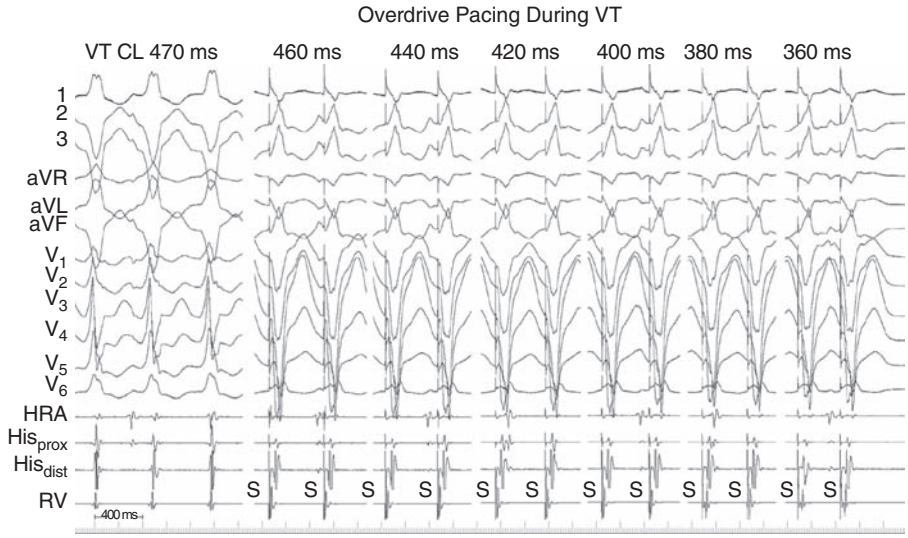

Figure 26-4

In Fig. 26-4, all 12 ECG leads of VT are shown at *left* (470 ms cycle length) as well as 2 complexes of pacing from the right ventricular outflow tract during VT at several different cycle lengths (including 460 ms, just 10 ms faster than the VT). It is evident that, no matter what cycle length of pacing during VT is used, QRS complexes are identical, indicating absence of fusion and strongly suggesting that macroreentry is not present (thus, a focal process). This evidence, taken with the suggestion of overdrive suppression as well as centrifugal pattern of electroanatomic activation mapping (shown later), led to a diagnosis of a focal ventricular tachycardia.

Mapping and Pacemapping

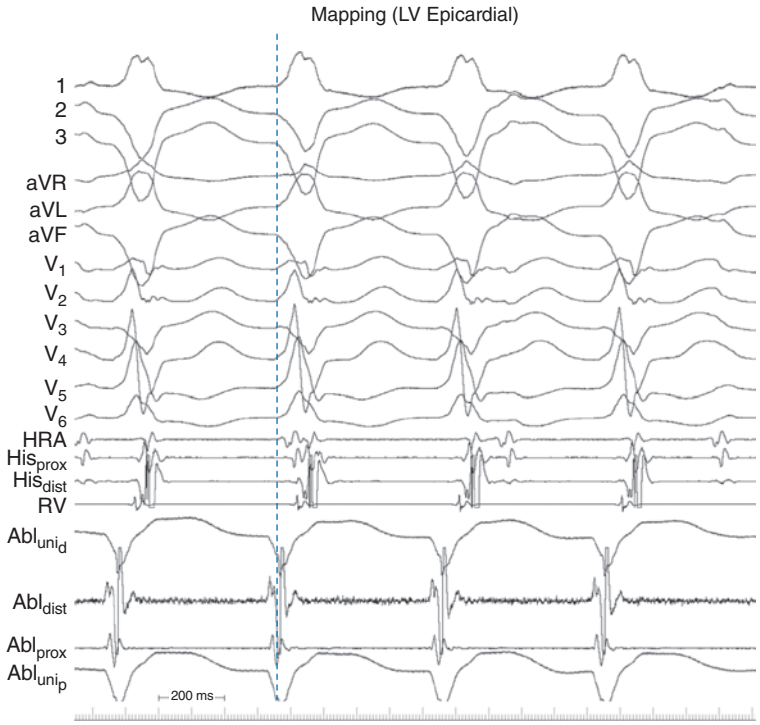

Figure 26-5

Having established a diagnosis of a focal VT, a site is sought with late diastolic activation (20 to 40 ms before the QRS onset), and a "QS" configuration in the unipolar recording. Thorough and extensive mapping of both right and left ventricular endocardial surfaces did not reveal any sites with timing before the QRS onset. With the "QS" configuration in the inferior ECG leads, in the absence of known infarction, pericardial access was obtained for epicardial mapping. The electrogram shown in Fig. 26-5 is from a site on the inferior left ventricular wall, halfway between apex and base, on the epicardial surface. Its features match those of the ideal target site noted previously; the QRS onset is denoted by a *dashed line*.

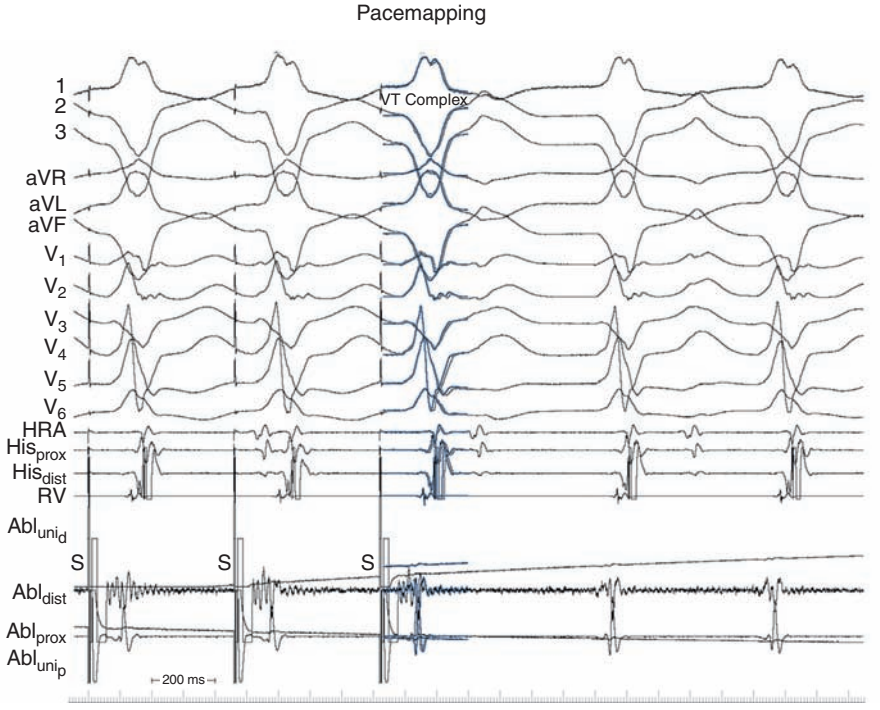

Figure 26-6

Pacing at this epicardial site (Fig. 26-6) produced a perfect 12-lead ECG (and intracardiac) match with a VT complex (superimposed in *blue*). This corroborates the activation mapping information. Note a relatively short stimulus-QRS interval, also consistent with a focal process.

Ablation and Postablation Pacing at Site

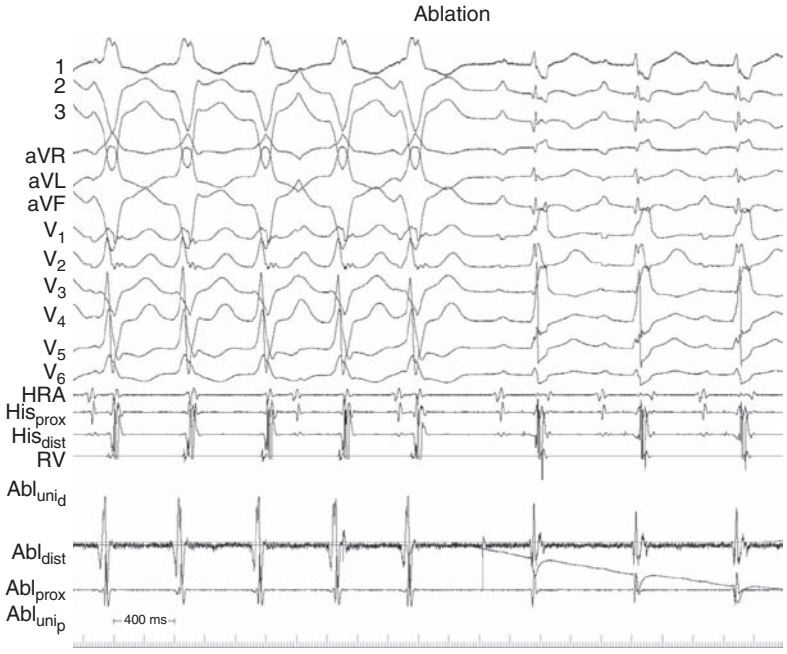

Figure 26-7

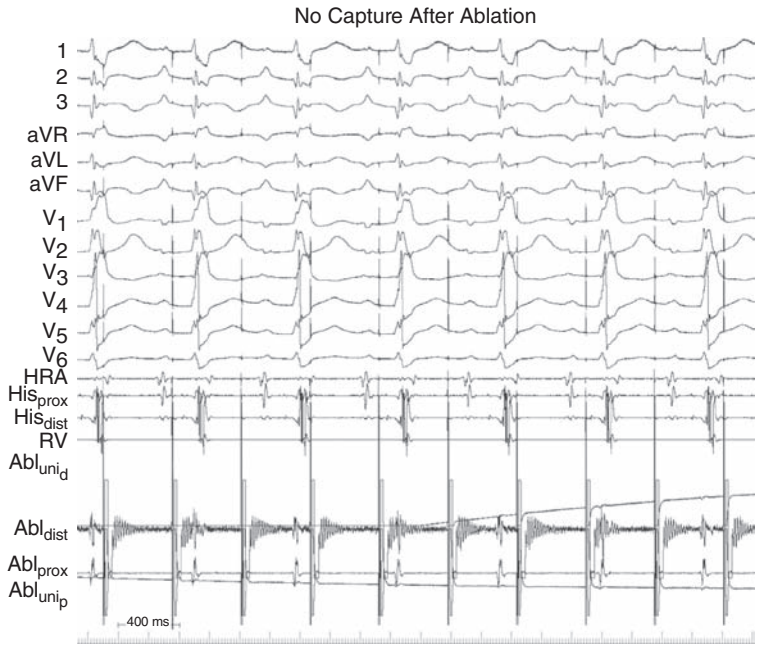
During radiofrequency (RF) energy delivery at the site of earliest activation mapping, tachycardia abruptly terminates to sinus rhythm (Fig. 26-7). The arrhythmia did not recur. Several other RF applications were administered in the same area to consolidate the damage.

Figure 26-8



High-output stimulation at the site of ablation shows inability to capture, indicating destruction of excitable tissue in that area (Fig. 26-8). The patient had no further arrhythmias during the course of his hospitalization, during which left ventricular function gradually recovered almost completely (ejection fraction 40% to 45%). He regained full neurologic function and was discharged home.

Before ablation, it is usually important to perform coronary arteriography to avoid injury to a nearby vessel during RF delivery; in this case, because the patient was unlikely to survive unless the VT was controlled, right coronary arteriography was not performed before RF delivery but was done later in the procedure, showing >1 cm from the ablation zone to the posterior descending artery.

Electroanatomic Mapping (Activation and Voltage)

Figure 26-9

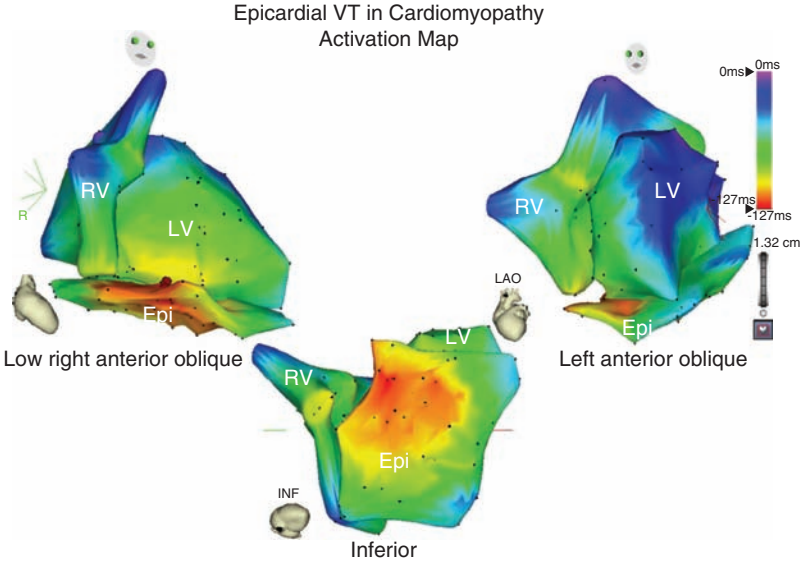


Fig. 26-9 displays electroanatomic activation mapping during ventricular tachycardia of right and left ventricular endocardial surfaces as well as the epicardial surface. *Red coloration* indicates the region of earliest activation, on the inferior wall at the junction of right and left ventricles.

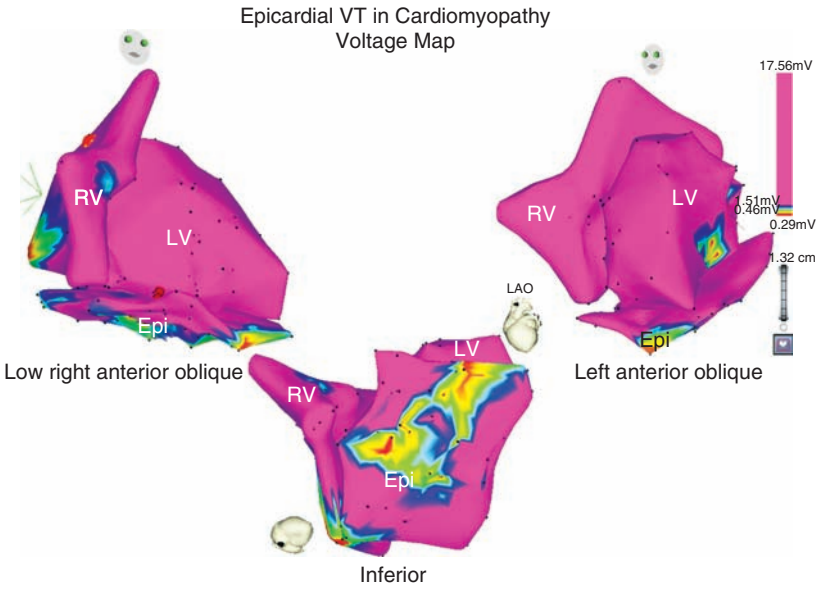

Figure 26-10

Electroanatomic voltage mapping of right and left ventricular endocardium, and epicardial surface of the inferior wall are shown in Fig. 26-10. *Purple color* indicates normal voltage; *red,* very low voltage/scar. The latter was limited to a very small area on the inferior wall of the left ventricle.

Summary

- Patients with nonischemic cardiomyopathy may have different types of VT:
  - Myocardial macroreentry—endocardial versus midwall versus epicardial
  - His-Purkinje reentry (bundle branch reentry [BBR])
  - Focal discharge (myocardial, Purkinje)
- Investigation and mapping attention should be focused:
  - To determine VT mechanism, thus how the ablation target should appear
  - At areas of low voltage/scar (perivalvular)
  - At His-Purkinje system (possibility of BBR)
- Electroanatomic mapping can help:
  - Determining areas of prior damage/scar
  - Delineation of potential channels for ablation
  - Tag sites with abnormal potentials for subsequent targeting
  - Planning and constructing lines of ablation

27 Ventricular Tachycardia in Dilated Cardiomyopathy

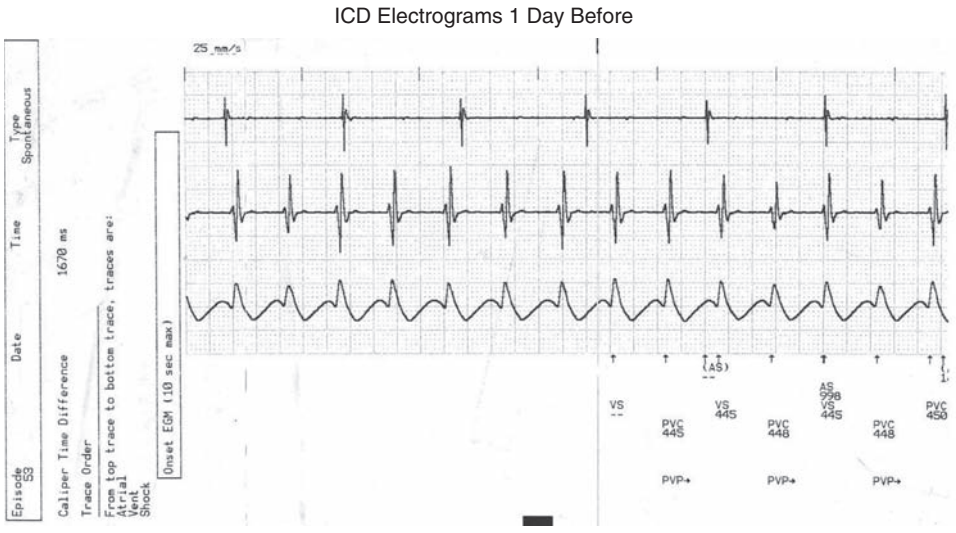
Case Presentation

The patient was a 74-year-old man with increasingly frequent implantable cardioverter-defibrillator (ICD) shocks. In 2009, poor left ventricular (LV) function was noted in the setting of prior (small) myocardial infarction (MI). Single-chamber ICD was implanted (primary prevention). In 2012, there was the first appropriate shock for ventricular tachycardia (VT), and amiodarone was initiated. There were more palpitations and shocks. Antitachycardia pacing (ATP) was modified, and there were more episodes and shocks. Mexiletine was added to amiodarone. There were more palpitations and shocks. In 2014, he was referred for electrophysiology (EP) study and possible ablation. Echocardiogram revealed poor LV systolic function (diffuse); there was no LV thrombus. ICD interrogation: repeated episodes of VT, cycle length (CL) 440 ms, not terminated with ATP (requiring shock).

ICD Stored Electrograms from 1 Day Before Ablation

What Else Do You Need to Know Preprocedure? [Fig. 27-1]
What Will Be the Procedural Strategy?

Figure 27-1

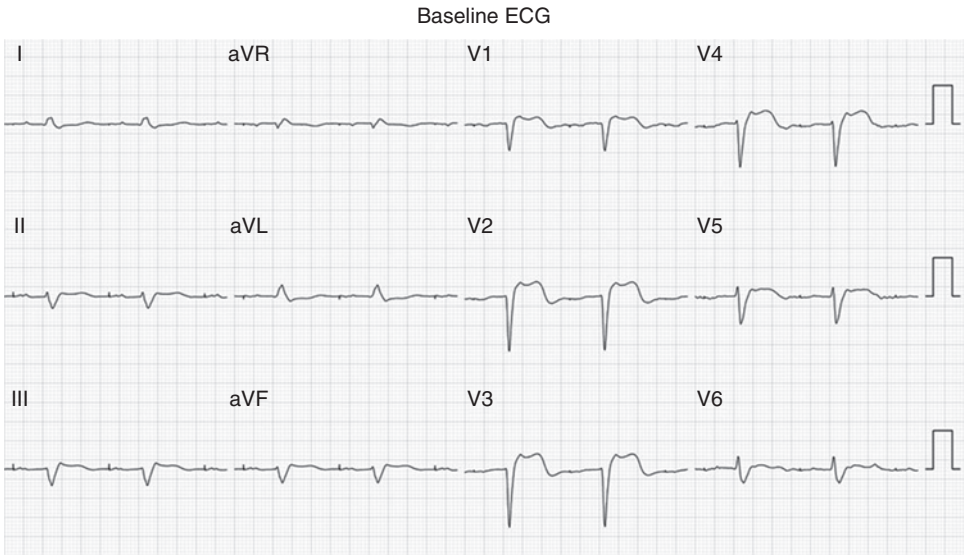


What other studies might be useful? Echocardiogram (exclude LV thrombus, demonstrate regional wall motion abnormalities) or magnetic resonance imaging (identification of scar regions), if your institution will do these in patients with ICDs.

ICD electrograms (Fig. 27-1) can be useful to sort out which of possibly several induced arrhythmias at EP study "match" the spontaneously occurring VT.

Which catheters to use? CS can be helpful for anatomic/fluoroscopic landmark as well as showing interesting electrograms in cases of VT arising from the basal region.

Baseline ECG and Intracardiac Recordings



Can You Interpret as far as Infarction? [Fig. 27-2] Anything to See?

Figure 27-2

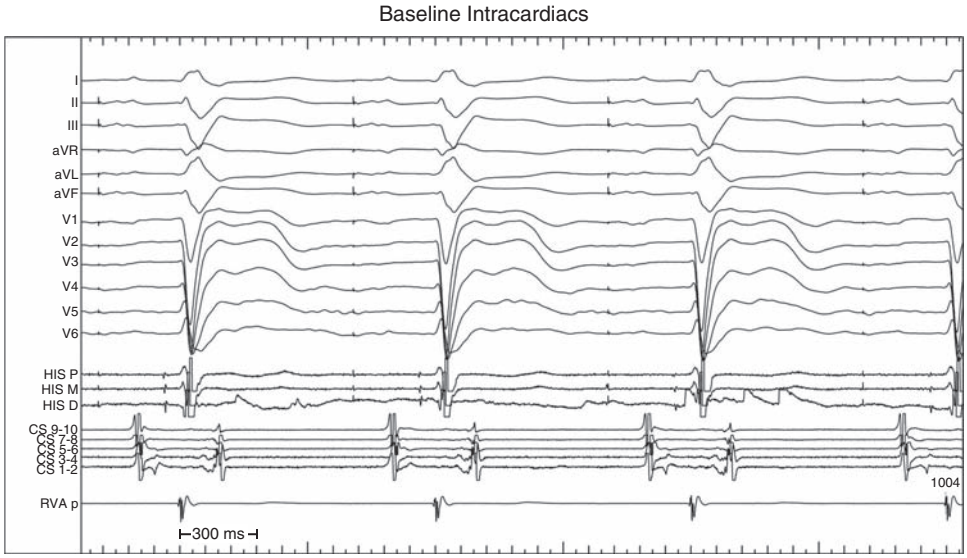


Figure 27-3

ECG during atrial pacing with conduction (Fig. 27-2) shows a wide QRS without clear infarct pattern. Ventricular electrograms (Fig. 27-3) on coronary sinus recordings are very late in the QRS complex—maybe it means something, maybe it doesn't.

Ventricular Pacing Baseline

Is Retrograde Conduction Present? [Fig. 27-4]

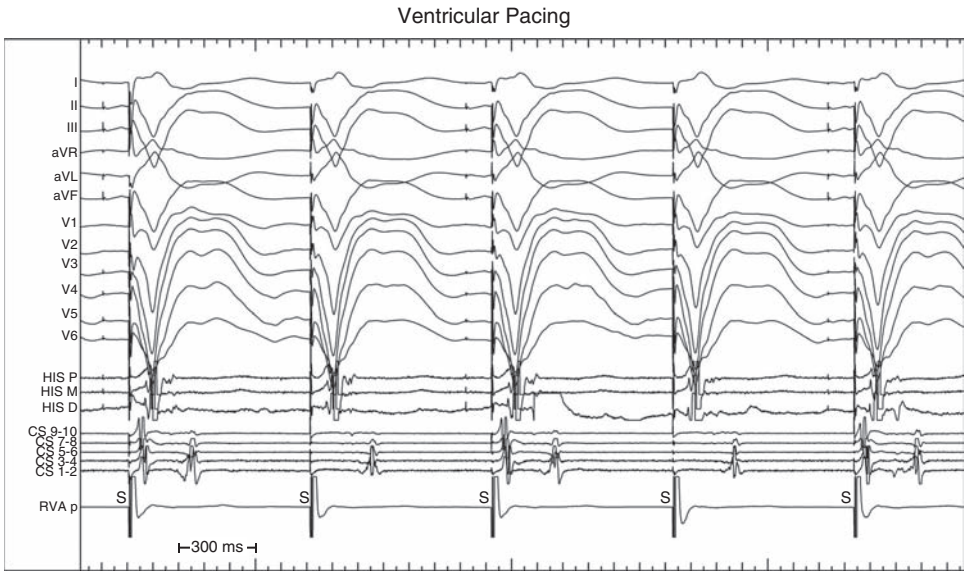

Figure 27-4

Potentials in the coronary sinus recordings that follow each QRS shown in Fig. 27-4 are actually very delayed ventricular signals, not atrial. True atrial signals are driven by atrial pacing from the ICD, and occur immediately after 1st, 3rd, and 5th ventricular stimulus artifact. Thus although retrograde conduction is probably not present, it is difficult to interpret.

VT Initiation and Attempt to Terminate

Is This the VT We're Looking For? [Fig. 27-5]

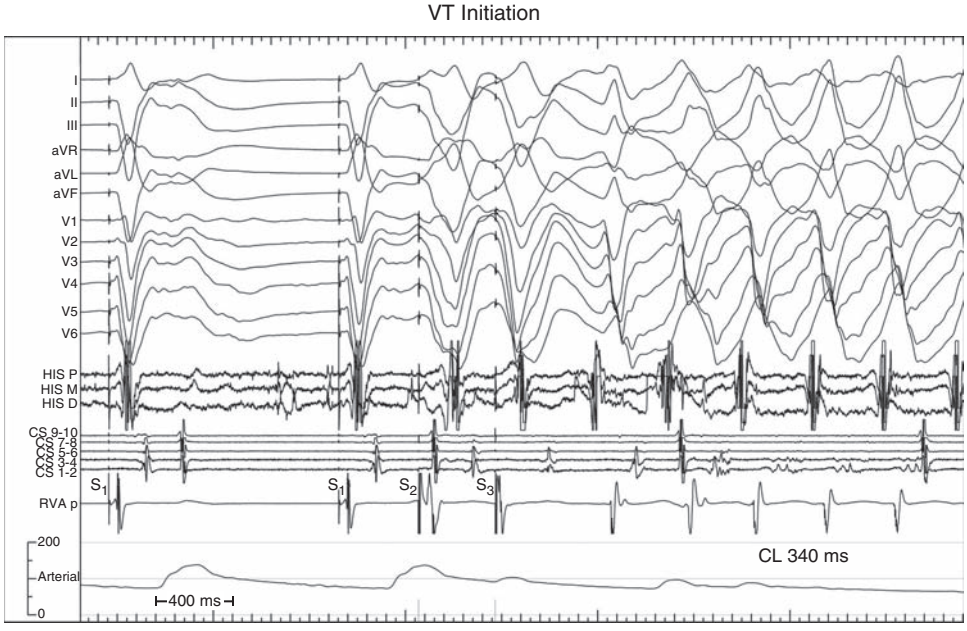

Figure 27-5

VT was initiated with double extrastimuli. The spontaneous tachycardia cycle length was 430 ms; it would be difficult for this one (340 ms) to be the same VT (Fig. 27-5).

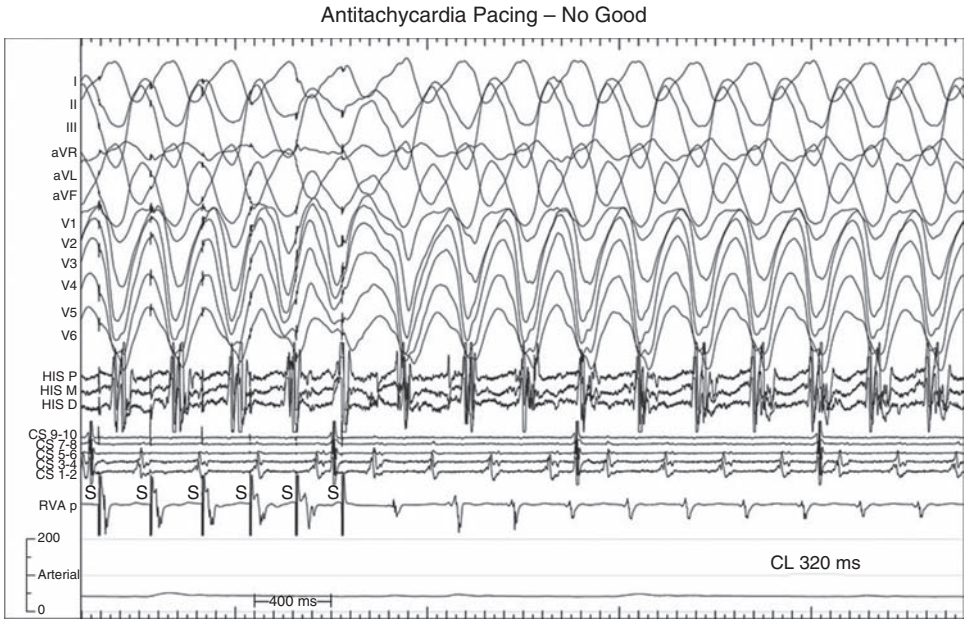

Figure 27-6

Overdrive pacing fails to terminate the rapid VT. At least this phenomenon (Fig. 27-6) is consistent with his clinical behavior—acceleration with antitachycardia pacing.

Why No QRS?

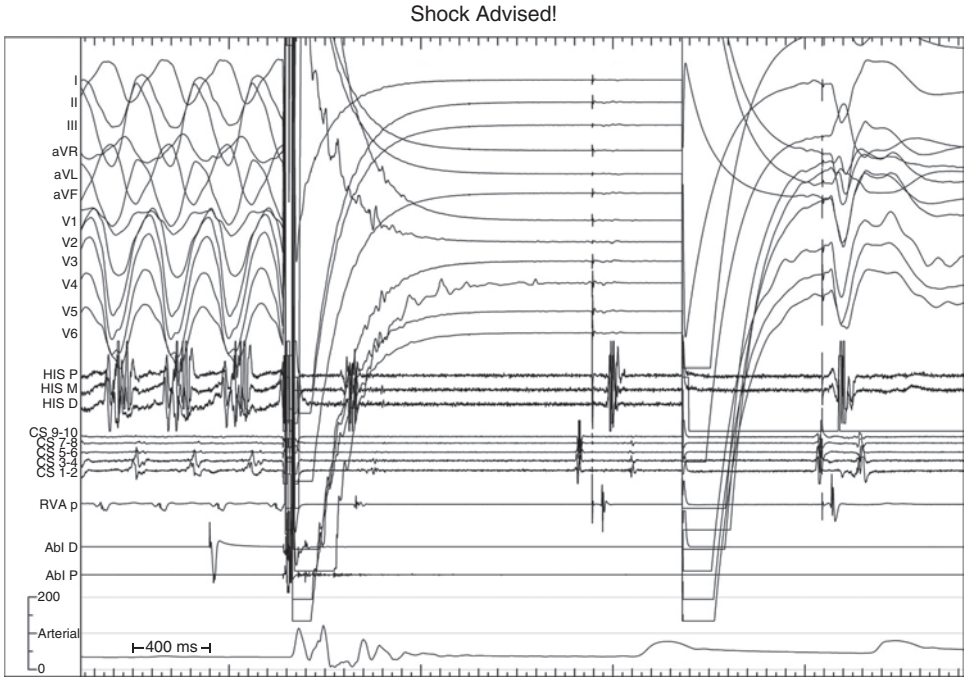

Figure 27-7

In Fig. 27-7, shock terminates rapid VT, but a stimulus from the device after the shock does not seem to capture the ventricle (no QRS complex). There really is one (note ventricular electrogram in RVA signal) and there is a systolic wave in the blood pressure recording, but surface ECG amplifiers have not reset.

VT Reinitiation

Is This the VT We're Looking For?

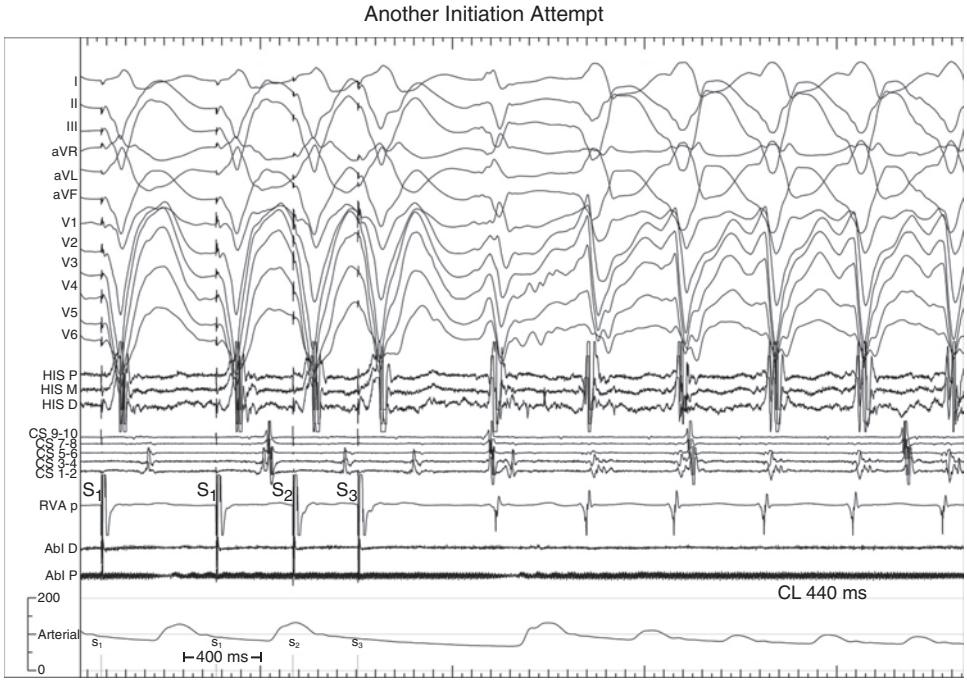

Figure 27-8

Another attempt is made to initiate VT. The VT shown in Fig. 27-8 has a cycle length very similar to the one that occurred spontaneously and is very likely the VT we are seeking.

Comparison of ICD Electrograms from This Episode and Prior Episode

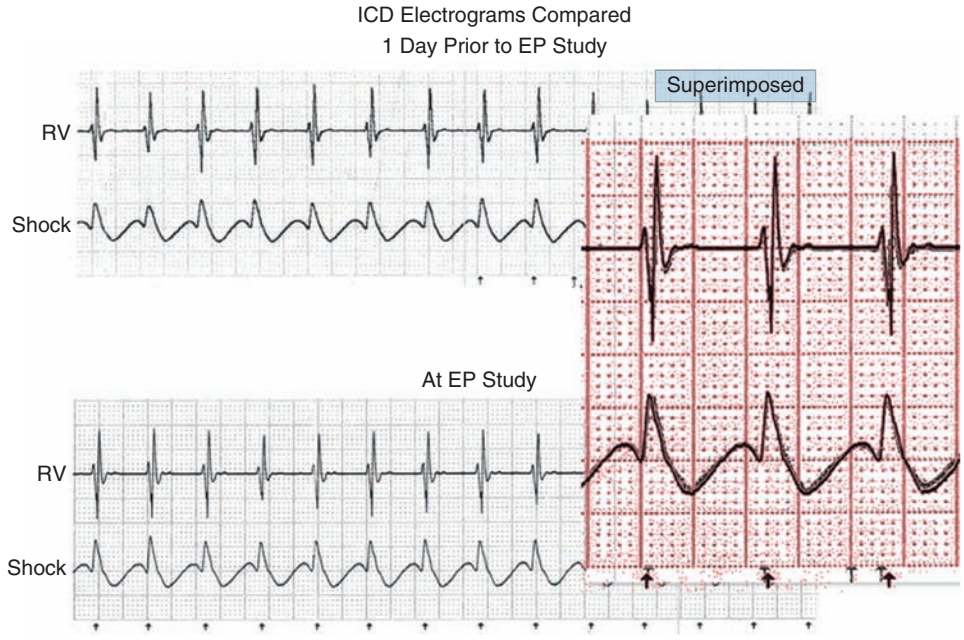

Figure 27-9

In Fig. 27-9, real-time electrograms from EP study (at bottom) are compared with those from the stored episode (at top); they are identical. Thus the induced VT corresponding to these electrograms is the same as the spontaneously occurring VT.

ECG of Target VT

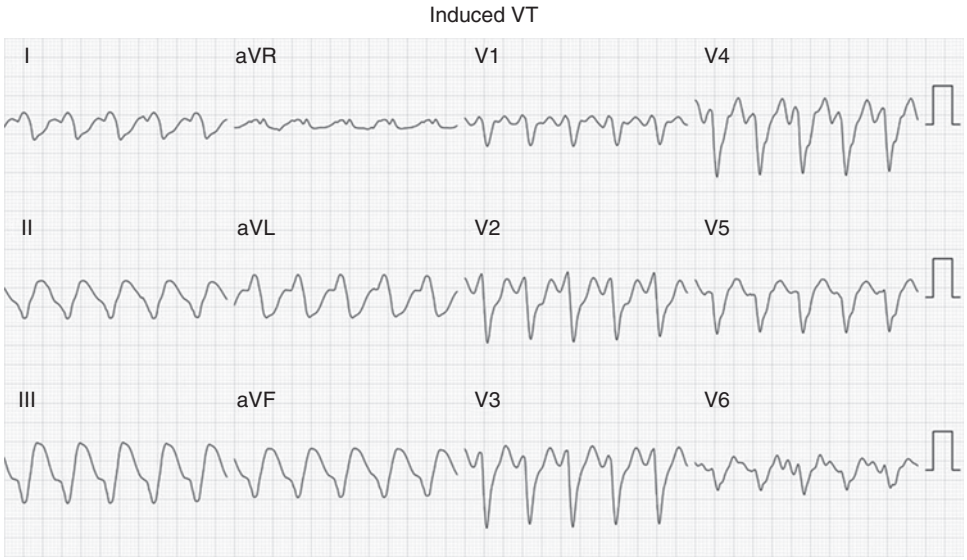

Figure 27-10

In Fig. 27-10, a 12-lead ECG of the induced VT has a left bundle branch block, leftward superior axis. It has findings that suggest a relationship to an inferior scar, though other features (poor R-wave progression) might suggest an apical exit site.

Comparison and Critique of Different Mapping Sites During VT

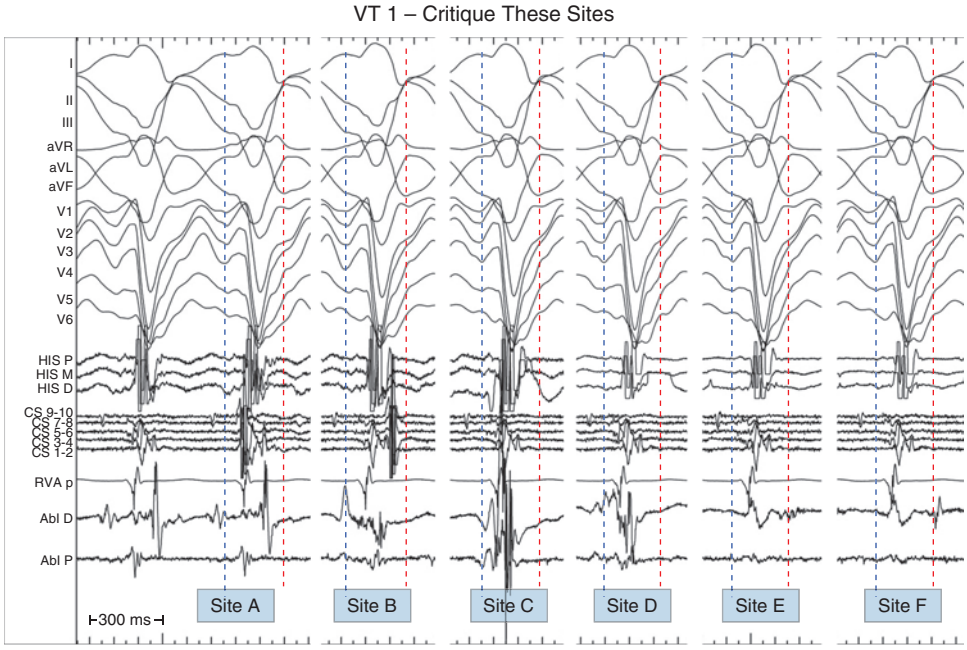

Figure 27-11

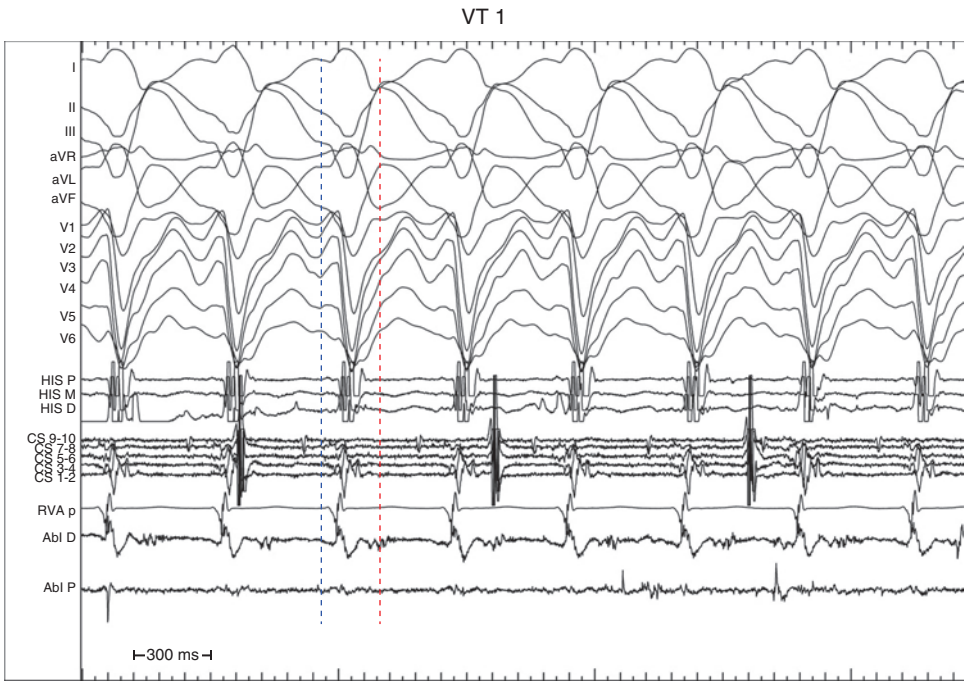
Fig. 27-11 displays several mapping sites (*dashed blue line* denotes onset of the QRS complex; *dashed red line,* the end):

A—late diastolic recording looks a little far-field; near-field component occurs during QRS complex
B—fragmented signal during QRS complex, but other portion is barely presystolic
C—high-amplitude, intra-QRS signal, of no interest
D—fragmented signal, with far-field late diastolic component
E—fragmented signal in early diastole—more interesting
F—discrete potential in early diastole—more interesting

Critique This Site . . .

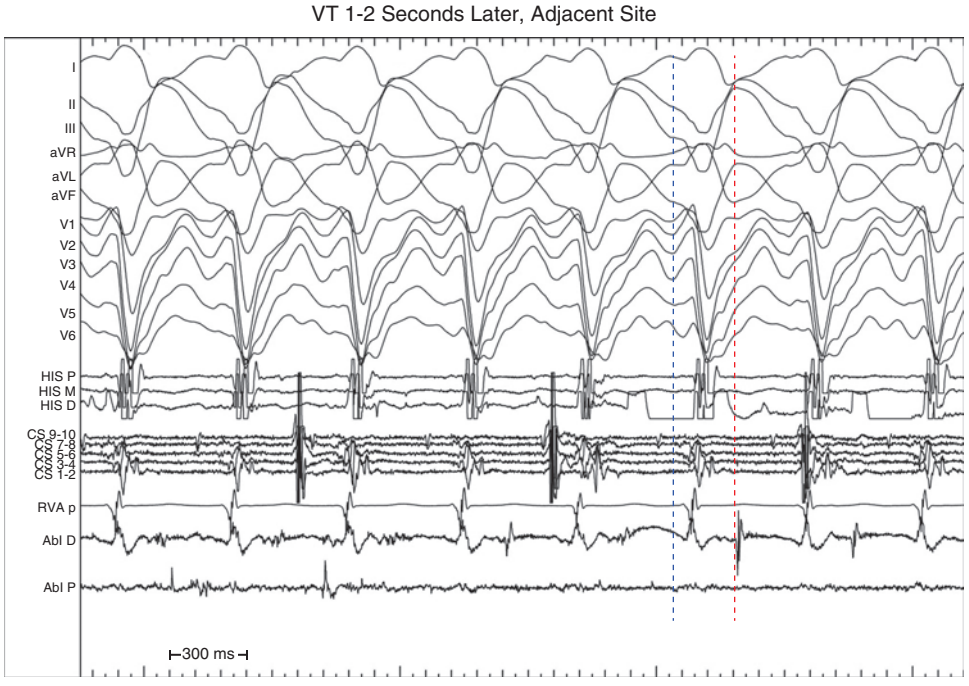
Figure 27-12



The site in Fig. 27-12 is only mildly interesting; though it has a systolic component (inside QRS complex), there is a fragmented portion extending into early diastole.

Critique This Site . . .

Figure 27-13



Recordings from just a few millimeters away have an interesting early diastolic component (Fig. 27-13), showing that potentially important sites may be extremely close to sites that are not very interesting (Fig. 27-12). This underscores the importance of detailed mapping.

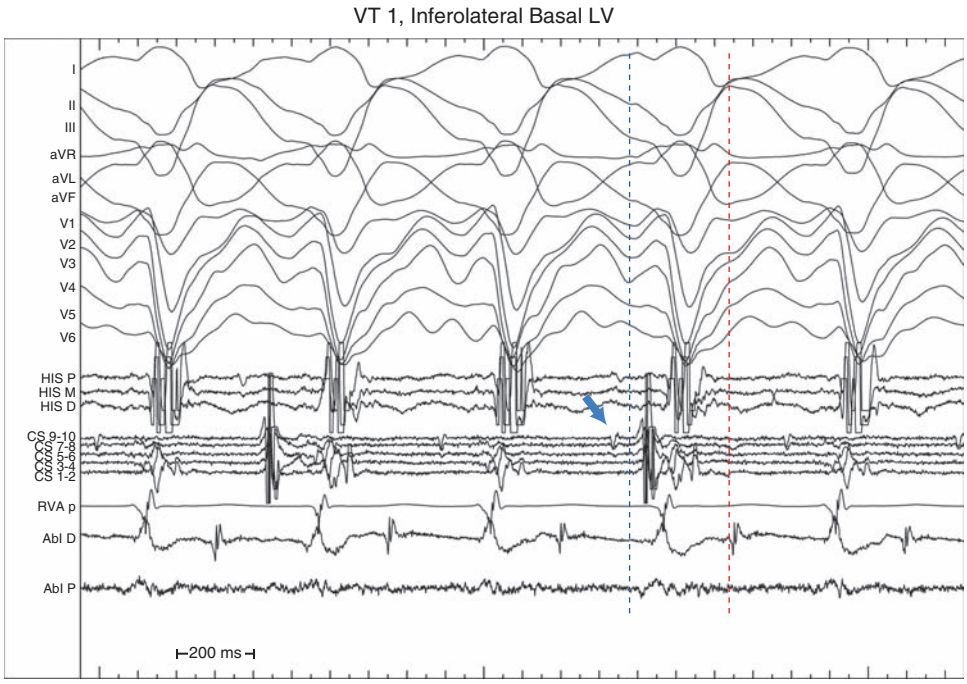


Figure 27-14

All the time we have been mapping, coronary sinus recordings have shown mid-late diastolic potentials (blue arrow) when adequately gained (Fig. 27-14).

What's Going on Here? [Fig. 27-15]

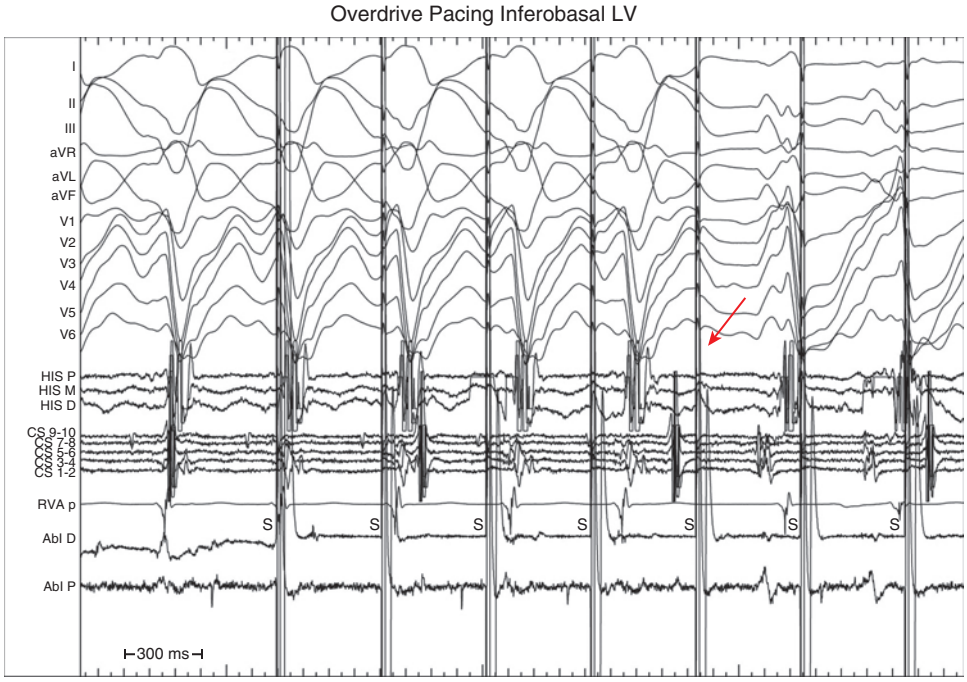

Figure 27-15

An attempt at overdrive pacing during VT results in termination of VT without apparent propagation *(arrow)*; actually, the impulse captures and propagates in the opposite direction as shown by the longer stimulus-QRS and complete change in polarity of the resulting QRS complex (Fig. 27-15). If this is a reproducible phenomenon, it has significant implications regarding the site (within the protected isthmus essential for VT continuation).

Critique This Site . . .
0.15 mV [Fig. 27-16]

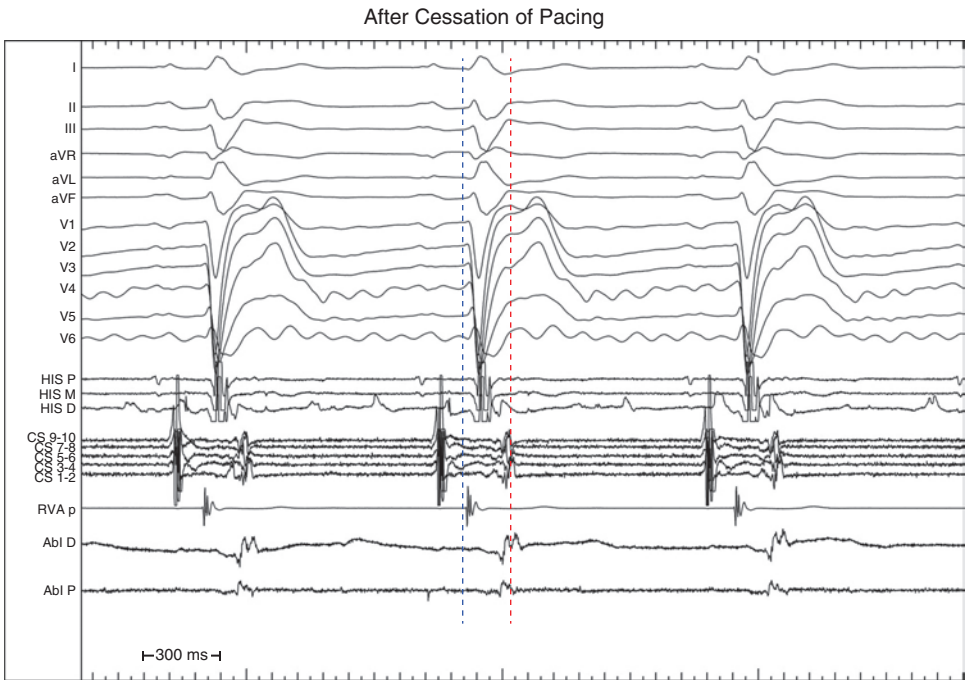

Figure 27-16

The site at which VT terminated with a nonpropagated stimulus is shown in Fig. 27-16 during sinus rhythm—not a very impressive site. This illustrates one of the problems with sinus rhythm/substrate mapping (poor sensitivity).

Comment on Capture at This Site . . . [Fig. 27-17]

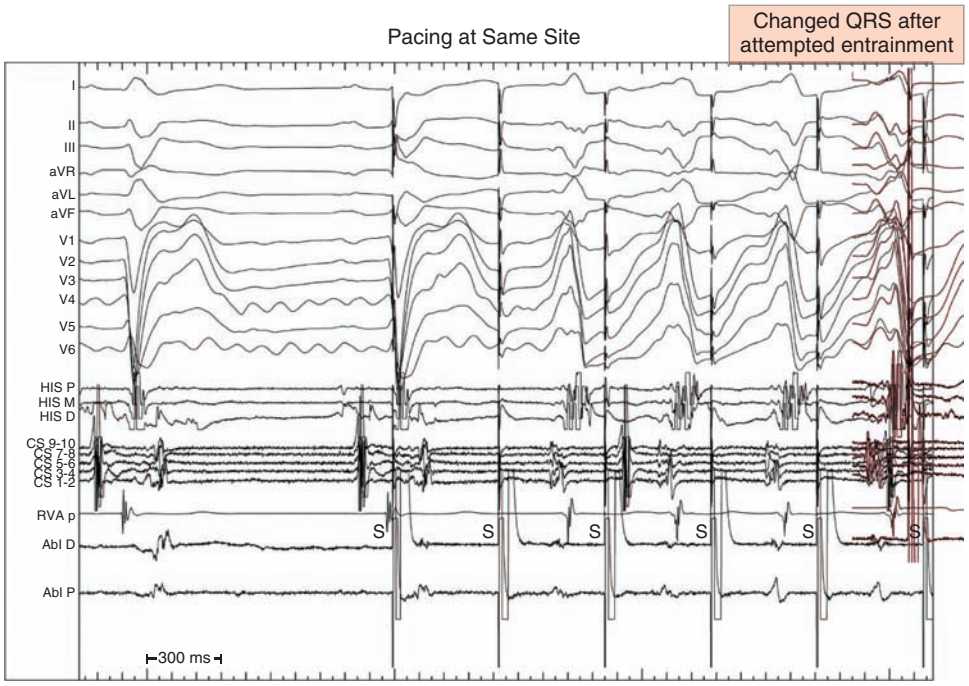

Figure 27-17

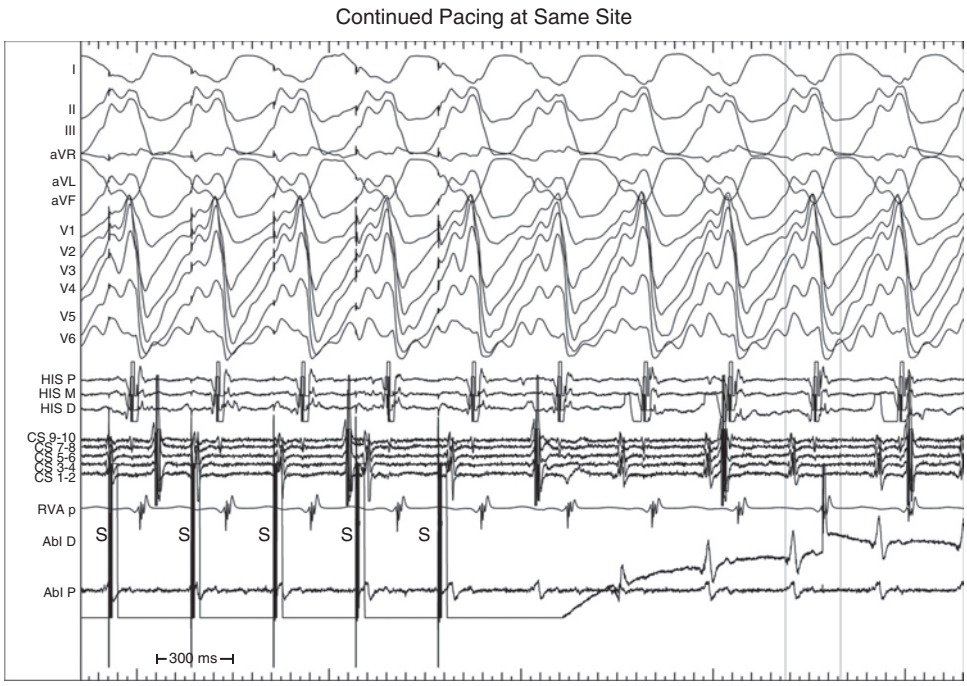
Stimulation at this same site (Fig. 27-17) results in a QRS complex very similar to that obtained during overdrive pacing during VT. The interpretation is that it is electrically a shorter distance to propagate in this direction (which would be toward the entrance of the circuit) than toward the exit (that would result in the same morphology as the first VT).

Pacing Induces VT-2



Comment on Capture at This Site . . . [Fig. 27-18]

Figure 27-18

As pacing continues in Fig. 27-18, it is clear that another VT has been initiated (note lack of correlation between stimulus artifacts and QRS complexes on the left of the figure).

ECG of VT-2

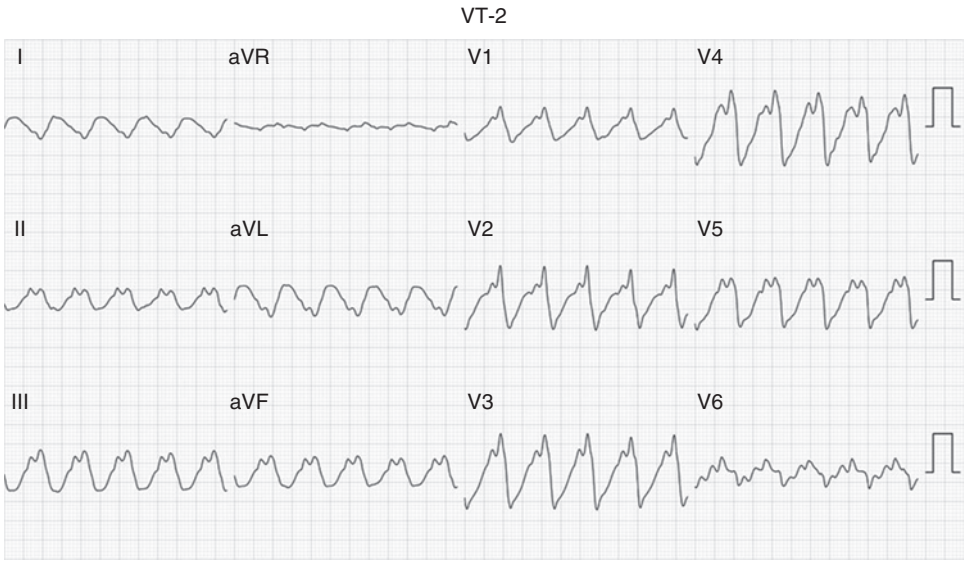


Figure 27-19

Fig. 27-19 shows a 12-lead ECG of the second induced VT.

VT-2, Pacing, and Sinus Rhythm at One Site

Critique This Site . . . and Where Is It? [Fig. 27-20]

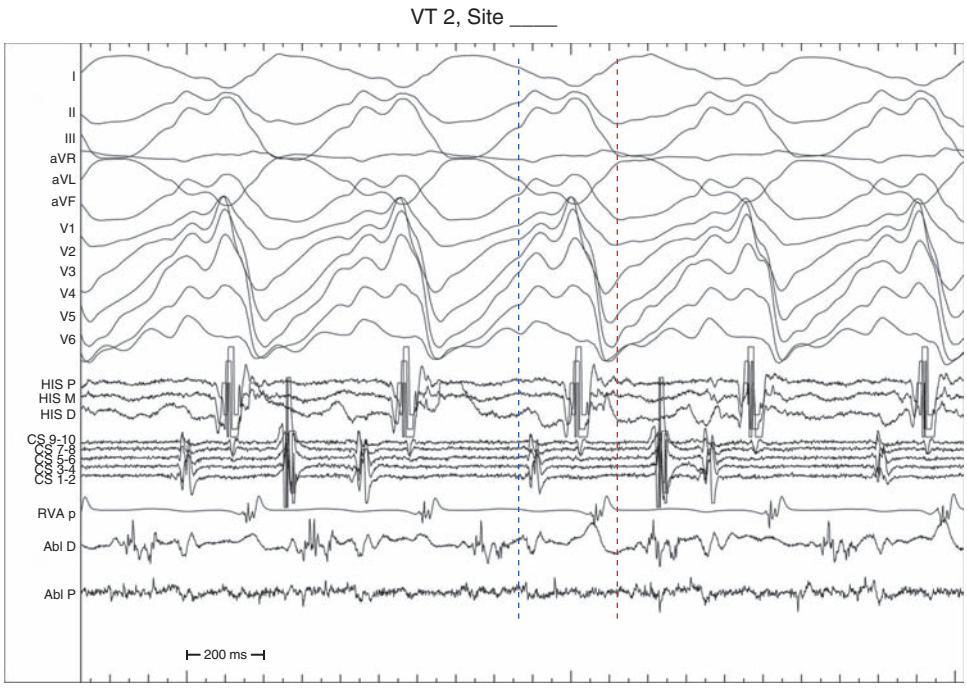

Figure 27-20

Fig. 27-20 shows a mid-diastolic potential, from the basal lateral LV.

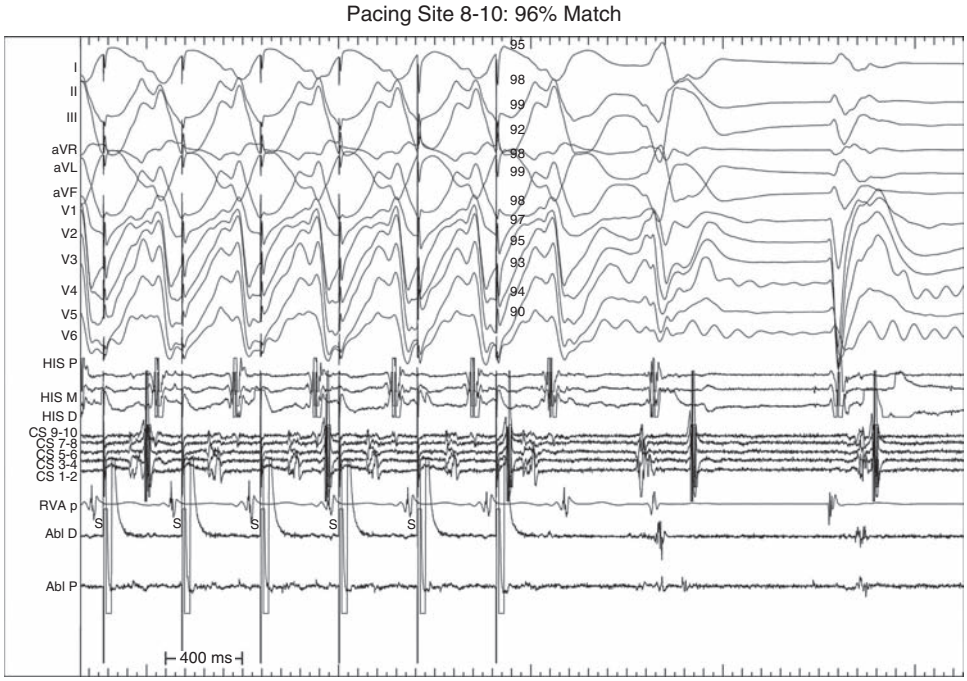

Figure 27-21

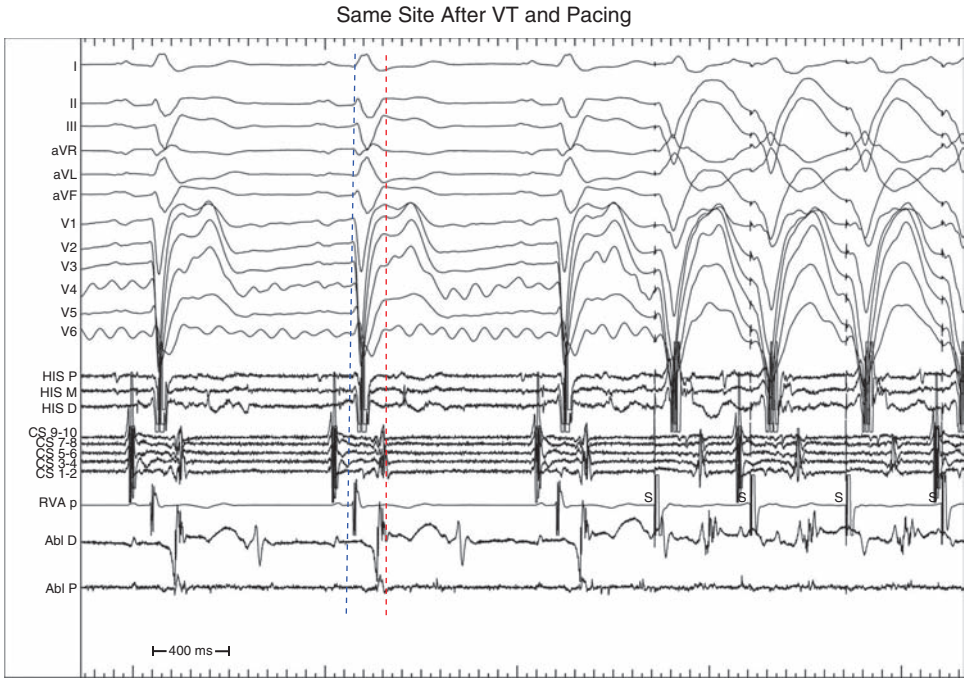
Pacing at a basal lateral side produces a 96% computer match of the morphology of VT-2 (Fig. 27-21).



Critique This Site . . . [Fig. 27-22]

Figure 27-22

Fig. 27-22 shows the sinus rhythm recordings from the site of pace match and diastolic signal during VT-2—not very impressive (no fragmentation or late potential). Pacing the right ventricle, however, unveils a highly fragmented and delayed electrogram. This shows the importance of pacing-induced changes in signal characteristics when looking for local abnormal late activities (LAVA).

Reinitiation of VT-1

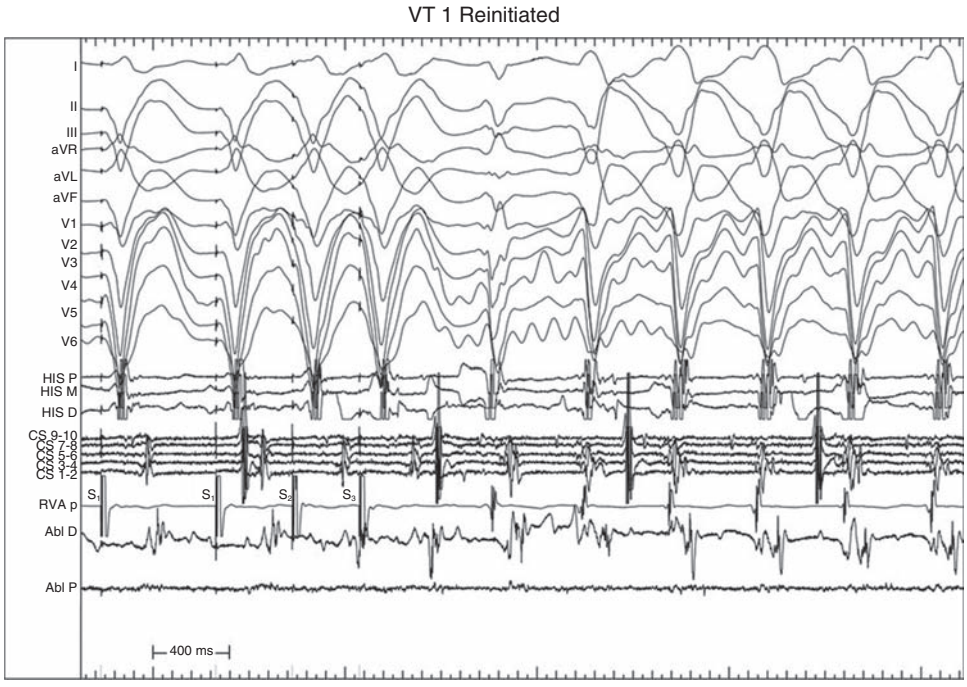


Figure 27-23

In Fig. 27-23, VT was reinitiated to test whether the stimulus that terminated VT without global capture ("nonpropagated termination") was a real phenomenon or chance occurrence (ie, spontaneous change).

Single Extrastimulus Terminates VT-1, Spontaneous Reinitiation, and Further Testing at This Site

What's Going on Here?

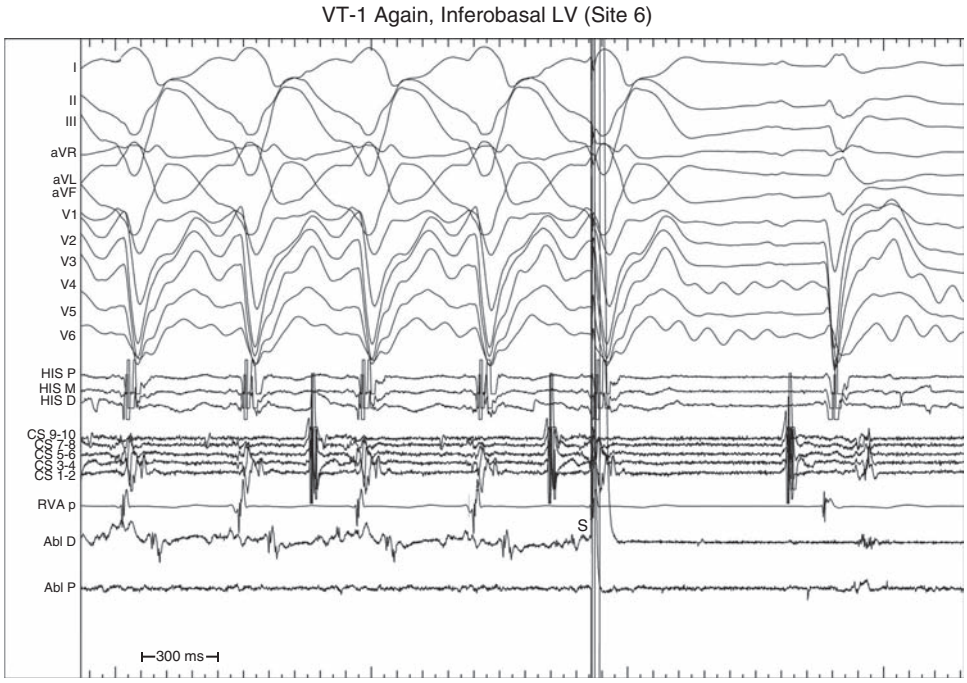

Figure 27-24

At a site very near where an attempt at overdrive pacing terminated VT without propagation, a single extrastimulus terminates VT (Fig. 27-24). This signifies that this is an excellent site for ablation.

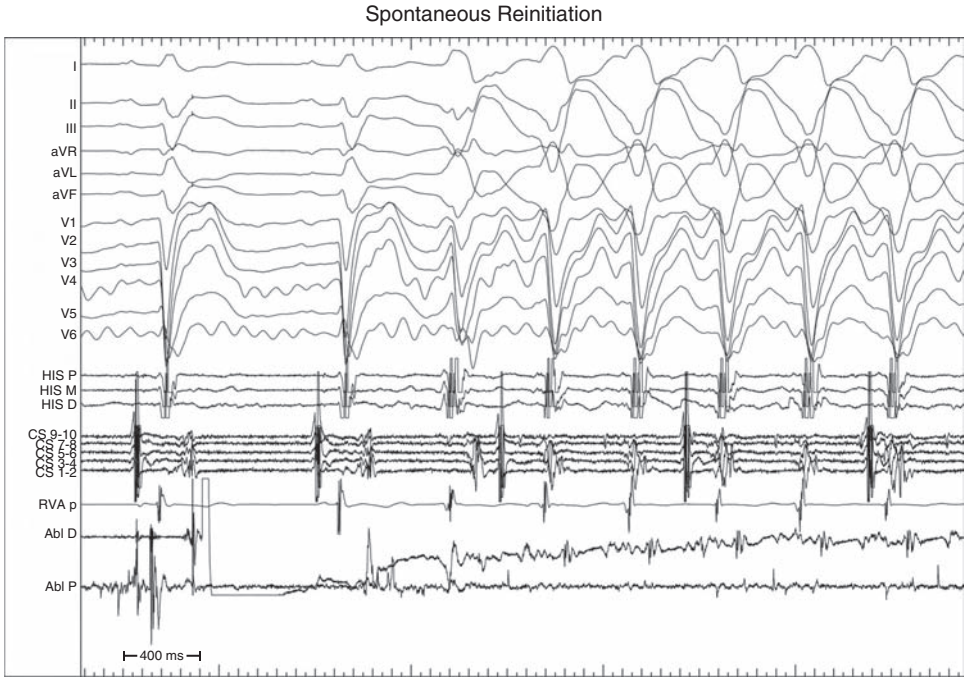

Figure 27-25

Spontaneous initiation of VT occurs when the catheter is at this site, as shown in Fig. 27-25.

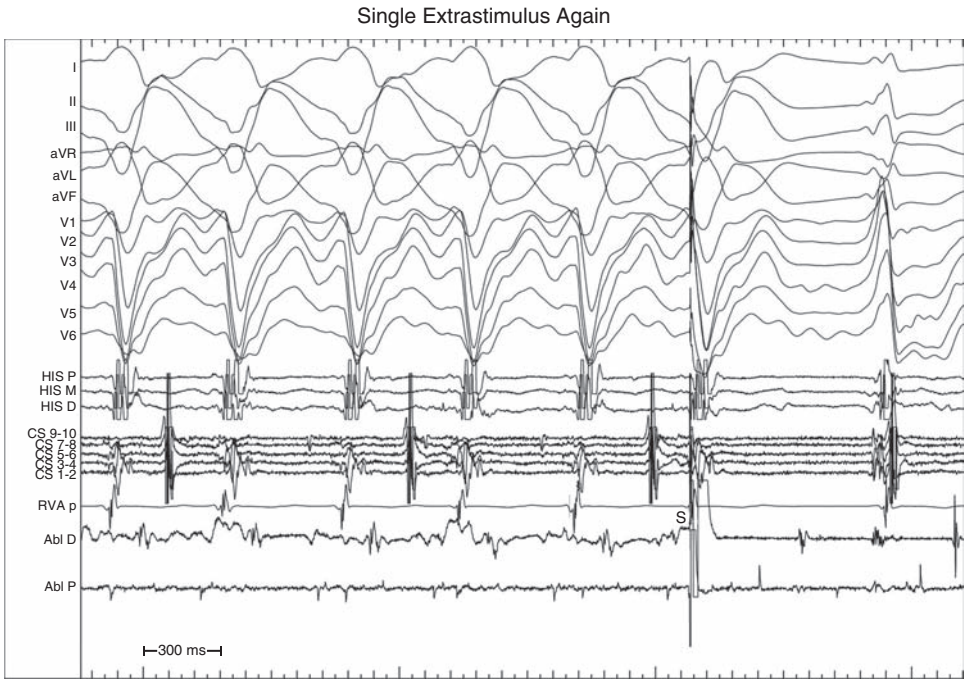

Figure 27-26

Just to prove the point, another single extrastimulus (S) terminates VT without propagation (Fig. 27-26).

Critique This Site . . .

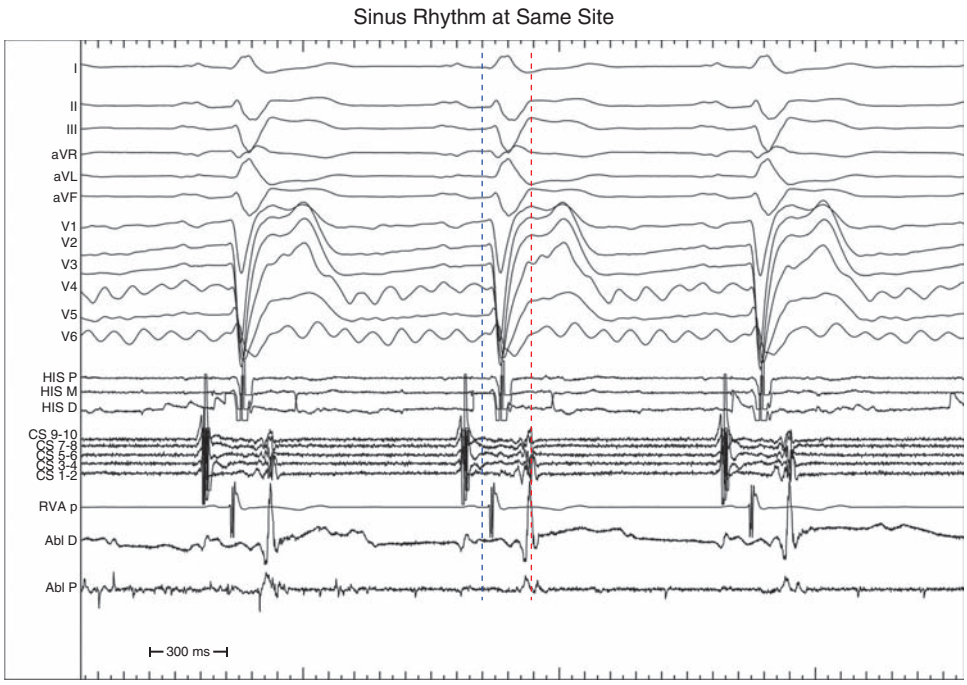

Figure 27-27

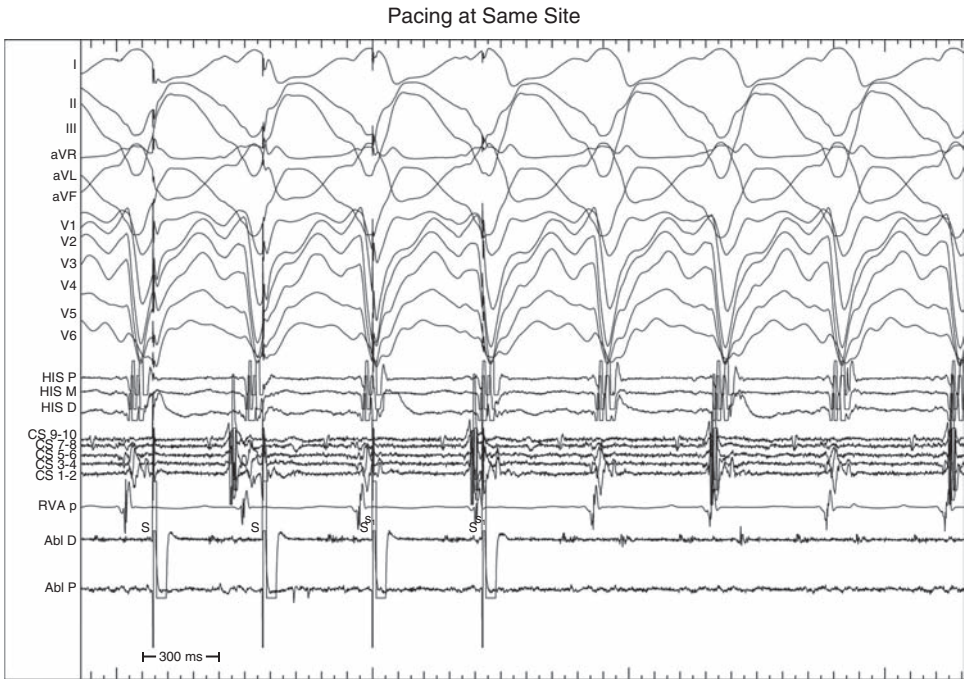
A nondescript electrogram is evident during sinus rhythm at the site at which VT was terminated by a single extrastimulus (Fig. 27-27).

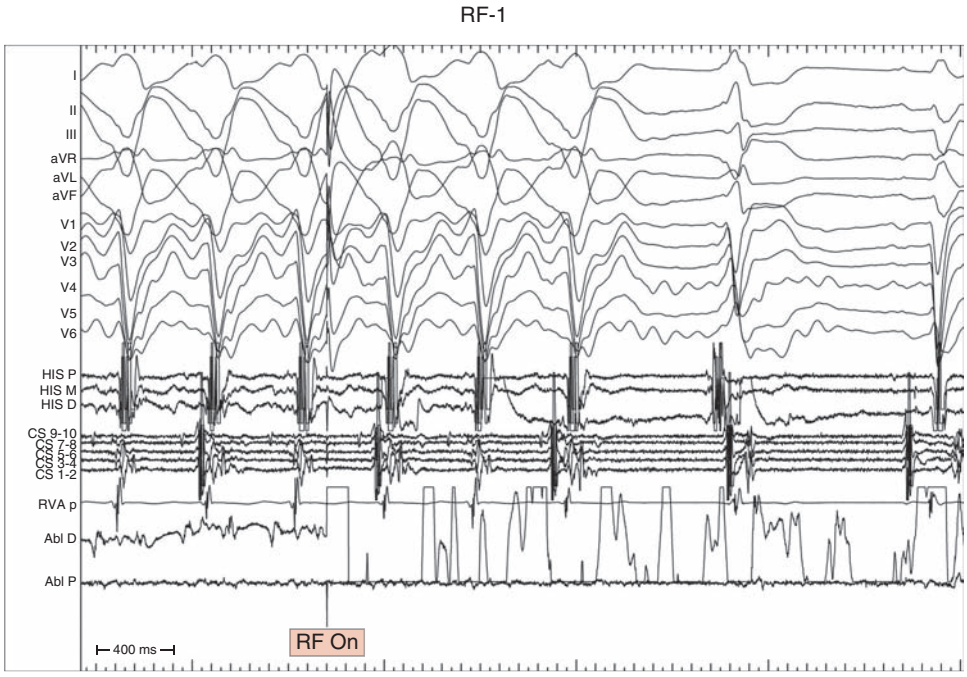
Figure 27-28



As shown in Fig. 27-28, pacing at this same site reinitiates the same VT.

Ablation and Subsequent Pacing at This Site in VT-1

Figure 27-29



Rewarding our hard work is nearly immediate termination of VT with radiofrequency application at this site (Fig. 27-29).

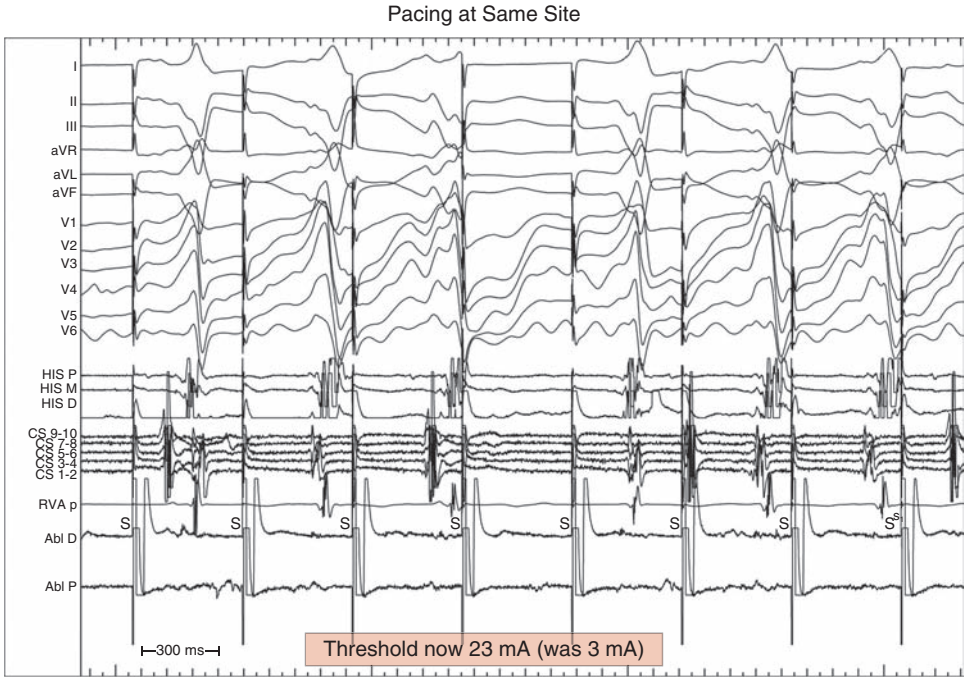


Figure 27-30

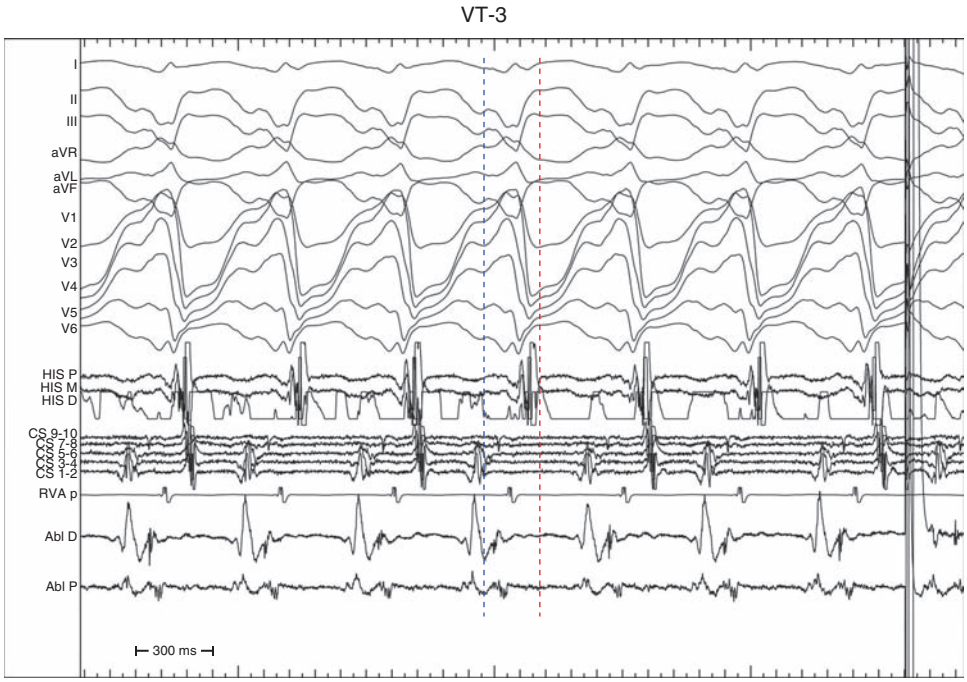
VT cannot be reinitiated; a quick check of the pacing threshold at this site after ablation shows it to be markedly elevated (Fig. 27-30).

Initiation and Ablation of VT-3

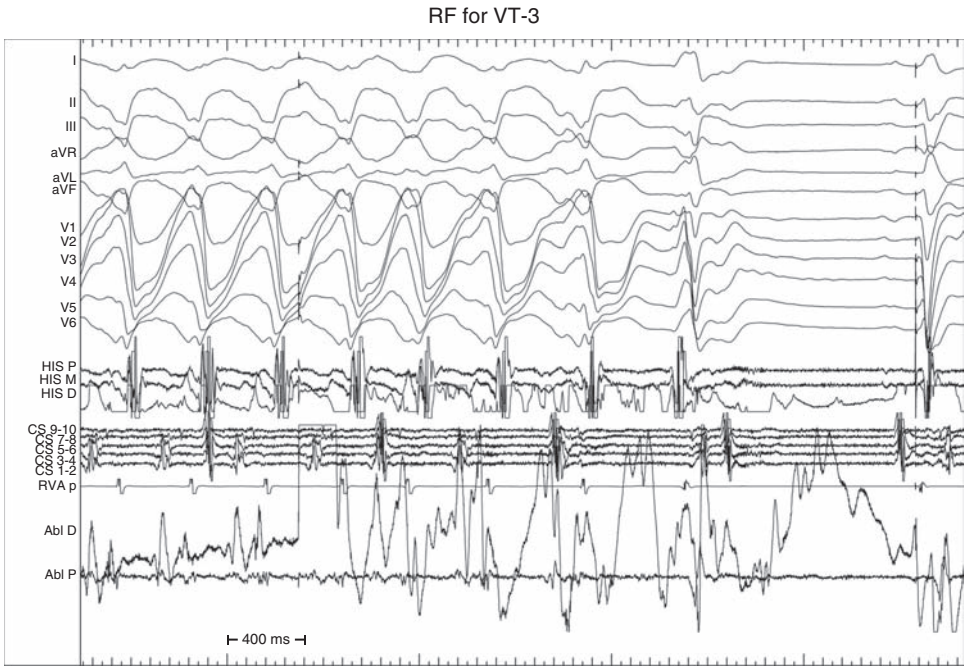


Critique This Site . . . [Fig. 27-31]

Figure 27-31

However, as can be seen in Fig. 27-31, another VT can be initiated.

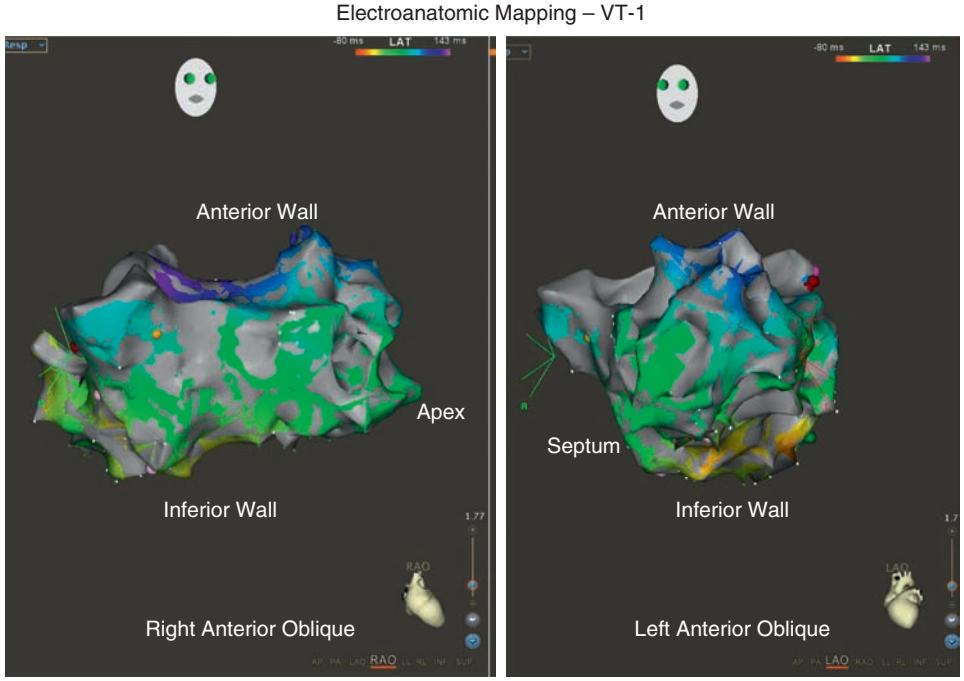
Figure 27-32



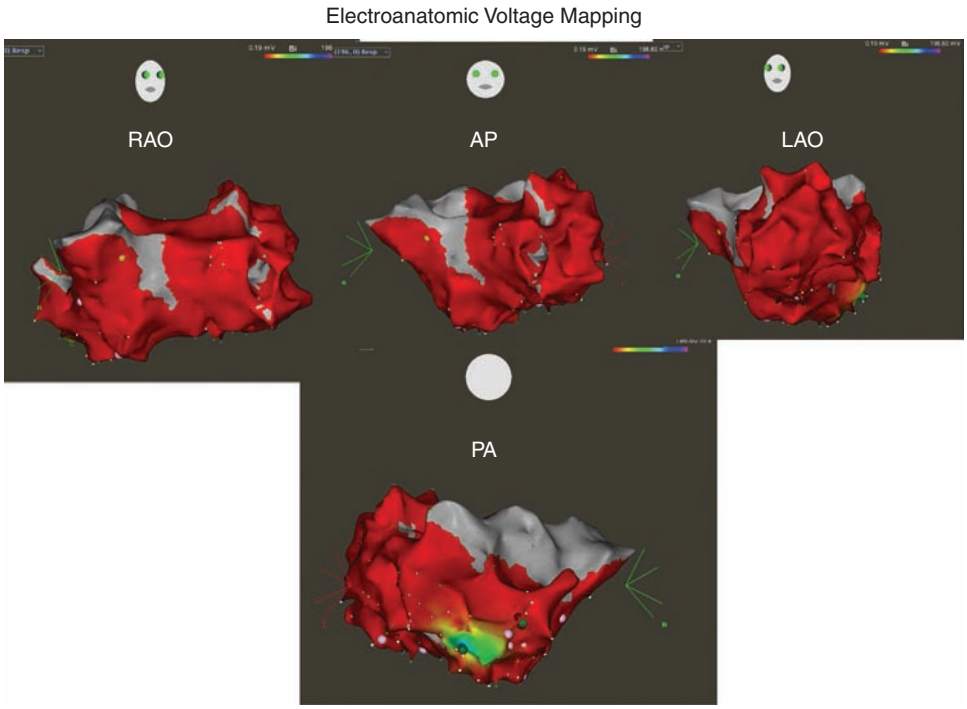
After applying several of the same pacing maneuvers, the VT displayed in Fig. 27-32 is terminated with radiofrequency energy at a site of diastolic activation.

Electroanatomic Mapping Findings

Figure 27-33



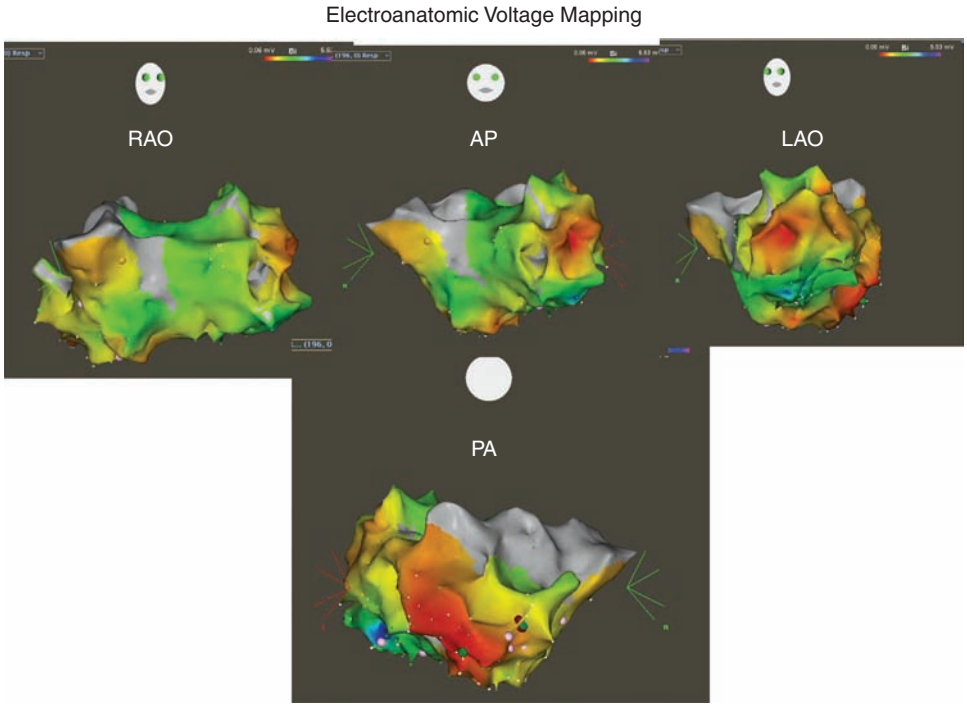
Standard views of the electroanatomic activation map, shown in Fig. 27-33, suggest a region of interest in the inferolateral basal left ventricular free wall (*red* and *orange* areas).



Why So Much Low Voltage? [Fig. 27-34]

Figure 27-34

In Fig. 27-34, it looks like the entire ventricle, except for a small portion (near where we ablated!), has very low voltage. This does not make sense; the ablated area (diseased) should have low voltage (*red*) while other areas should have more normal voltage (*purple*).

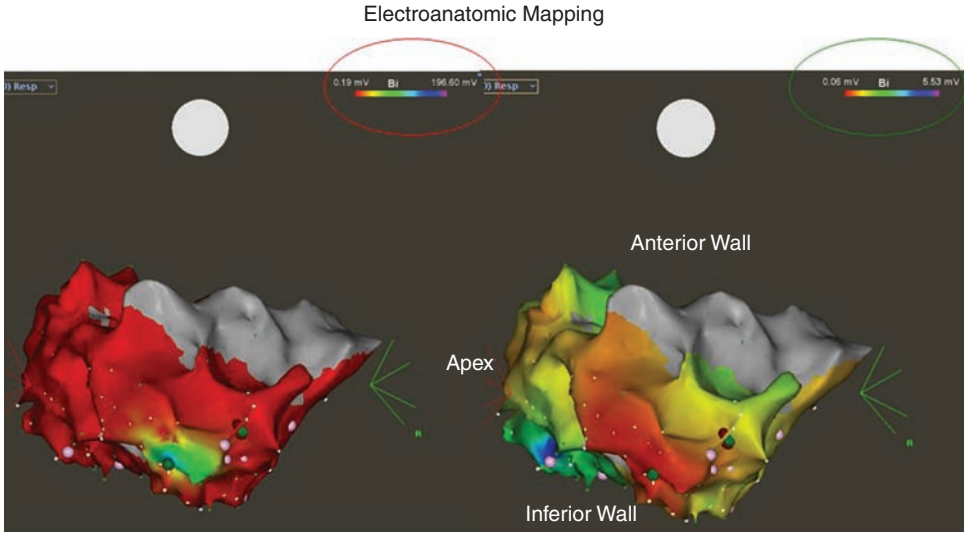


Why Such Different Voltage?

Figure 27-35

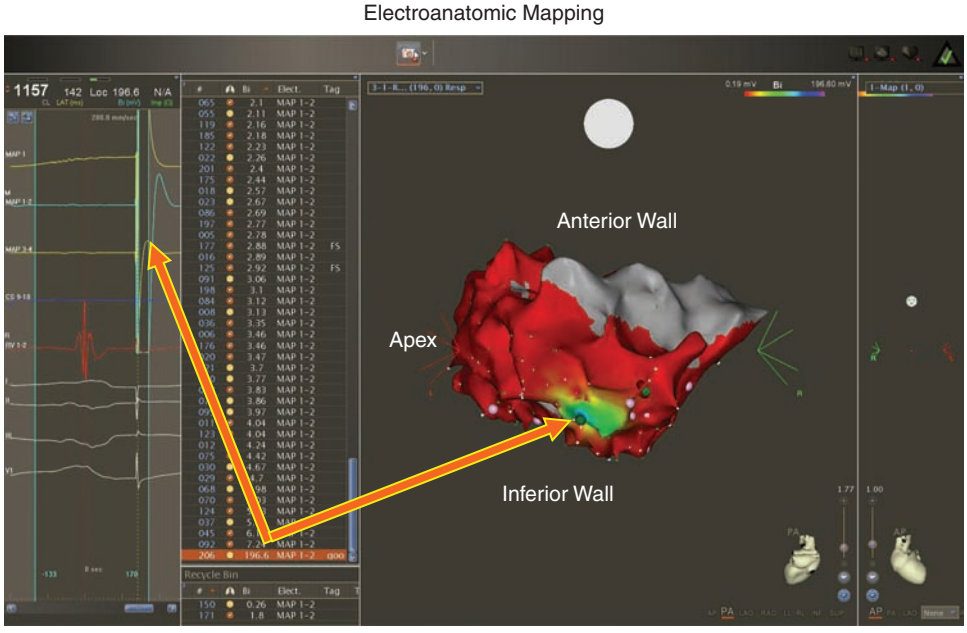
The problem is, a single site of the posterior wall had an extremely high voltage, making everything else seem extremely low (Fig. 27-35).

Figure 27-36



At left of Fig. 27-36 is the original voltage map; at right is the edited voltage map (after adjudicating the computer-designated voltage at one site).

Figure 27-37



In Fig. 27-37, the point with the falsely high voltage was because of a stimulus artifact.

This *single point* in the voltage map threw everything else off (195 other points that were correct).

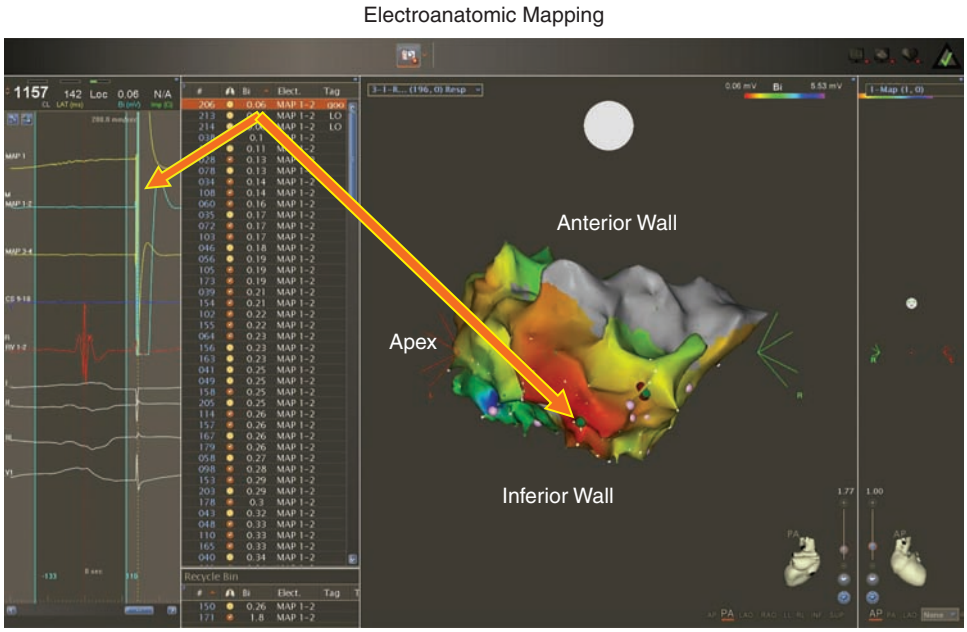


Figure 27-38

In Fig. 27-38 is the correct voltage at that site, obtained by simply sliding the window of interest enough to exclude the stimulus artifact that was causing a problem.

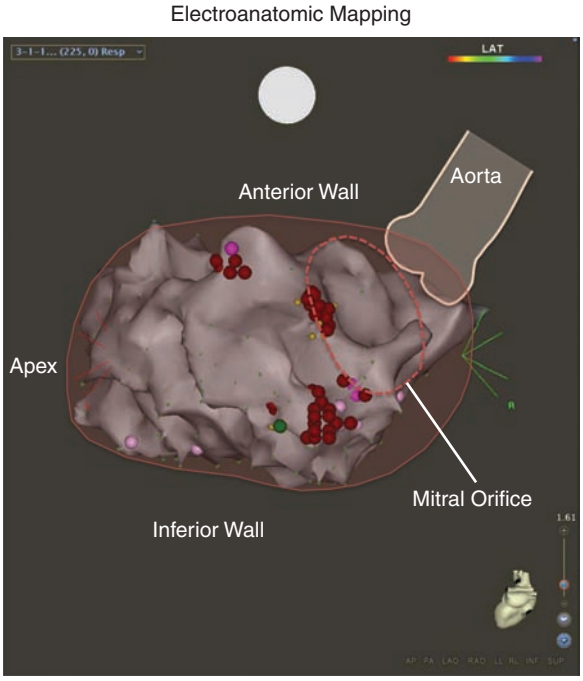

Figure 27-39

In Fig. 27-39, the electroanatomic map as well as ablation sites *(red dots)* are projected on a silhouette of the left ventricle and aorta in a posterior view of the heart.

Summary

- Sometimes it is hard to know what the target area is likely to be (preoperative imaging, ECG in sinus rhythm or VT can help)
- The pathophysiology of VT in dilated cardiomyopathy is fundamentally the same as other scar-based VTs (like post-MI VT); this patient had a small prior MI but LV dysfunction out of proportion to it
- Having *some* information about the spontaneous VT (ICD recordings) can be very useful in deciding what to target
- Serendipitous findings (nonpropagated stimulus terminating VT) are very valuable and should not be ignored
- Voltage mapping can be great but *just one incorrect point* can make interpretation completely wrong

Bundle Branch Reentry Ventricular Tachycardia

28

Case Presentation

A 56-year-old man with inferior wall myocardial infarction (MI) in May 2010 was referred for catheter ablation because of frequent implantable cardioverter-defibrillator (ICD) activity. At the time of his MI, he had percutaneous coronary intervention to the mid-right coronary artery. Left ventricular systolic function was poor at the time and remained so; he underwent biventricular ICD placement for primary prophylaxis of sudden death. Within months, he began experiencing frequent antitachycardia pacing (ATP) and shocks from his ICD because of rapid ventricular tachycardia (VT). Amiodarone was administered; he still received frequent ATP and some shocks, despite additional device reprogramming. He underwent electrophysiology (EP) study and ablation, at which time abnormal electrograms on the left ventricular anterior septum were identified. Only nonsustained VT episodes with multiple left bundle branch block (LBBB) morphologies could be induced. Extensive ablation of anterior septal sites was performed. Unfortunately, even after the procedure, he continued to have episodes of VT requiring ATP or shocks. He was given more amiodarone but still required frequent ATP for treatment of VT. He was referred for repeat ablation.

Baseline ECG (Paced) and Intracardiac Recordings

Figure 28-1

The baseline ECG during atrial and biventricular pacing yields few clues as to where mapping attention should be focused (Fig. 28-1).

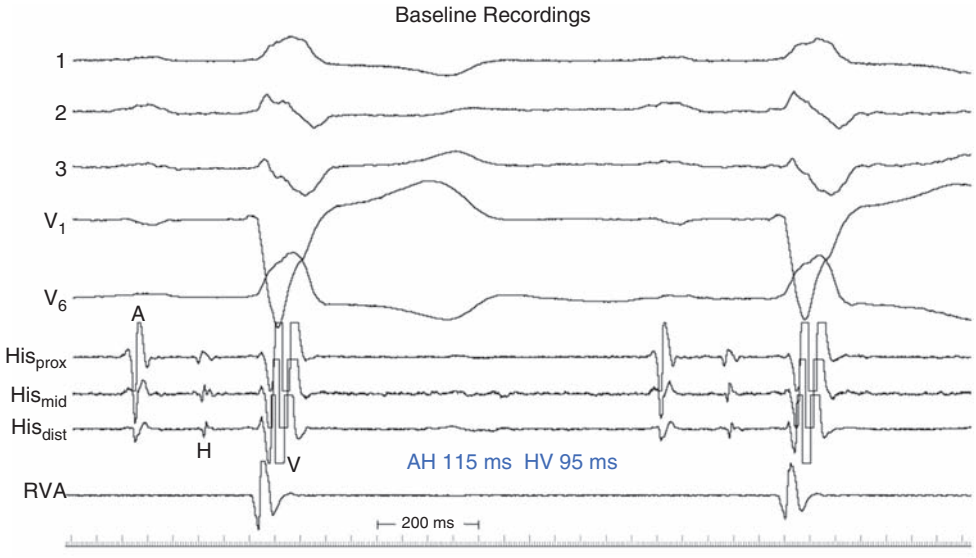

Figure 28-2

When the device was reprogrammed to a backup pacing mode, sinus rhythm with intact AV conduction is revealed. In Fig. 28-2, LBBB is present with intervals as shown.

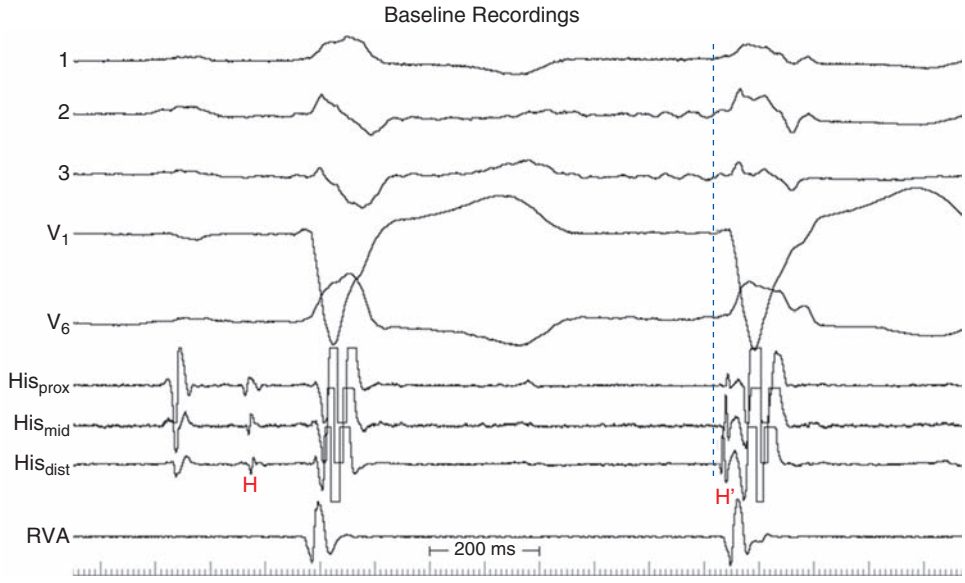

Figure 28-3

In Fig. 28-3, a spontaneous premature ventricular complex occurs that conducts retrogradely over the His bundle (H′, propagated distal to proximal). As early as the retrograde His occurs relative to the QRS onset *(dashed line)*, it must have conducted from the right bundle branch.

Ventricular Stimulation and VT Induction

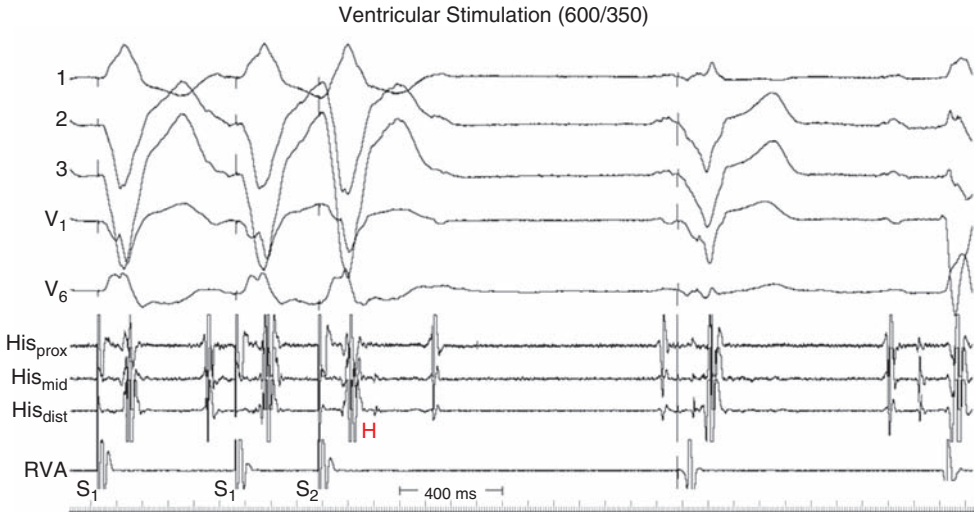

Figure 28-4

With ventricular extrastimulus testing, a His potential (H) is seen "out the back" (retrograde block in RBB with transseptal propagation to the LBB and then to the His bundle) in Fig. 28-4.

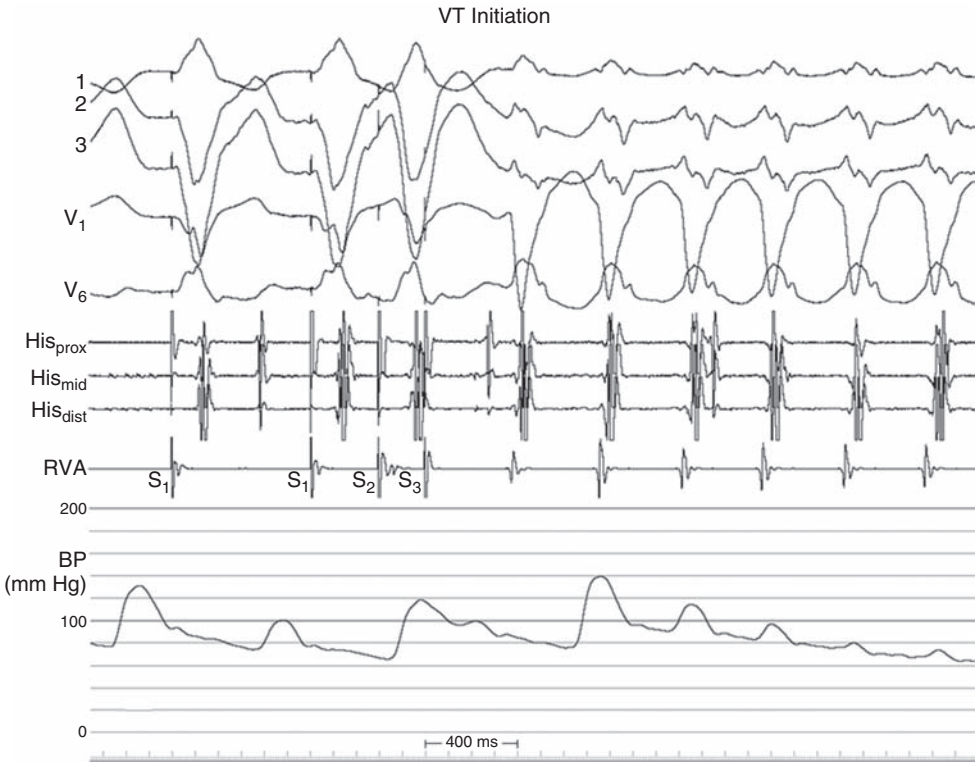

Figure 28-5

With double ventricular extrastimuli, rapid VT is induced; blood pressure is very poor and pacing termination was necessary within a few seconds after this recording (Fig. 28-5) was made.

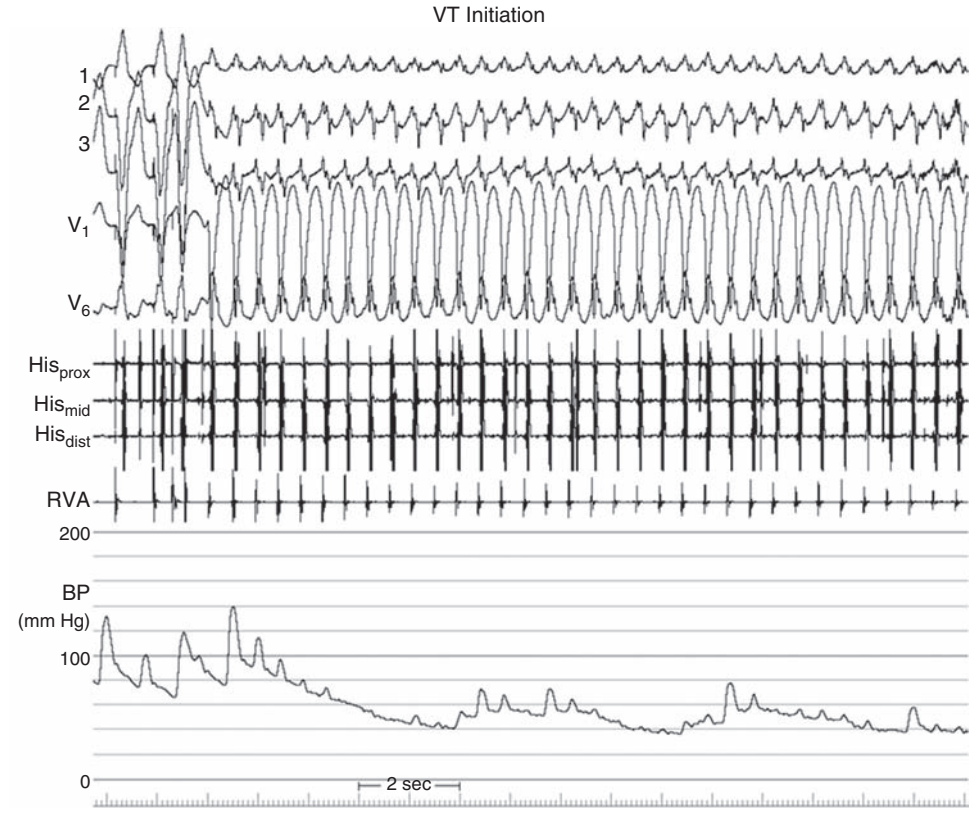

Figure 28-6

Fig. 28-6 presents the same events at a slower sweep speed and clearly shows the poor blood pressure response during induced VT.

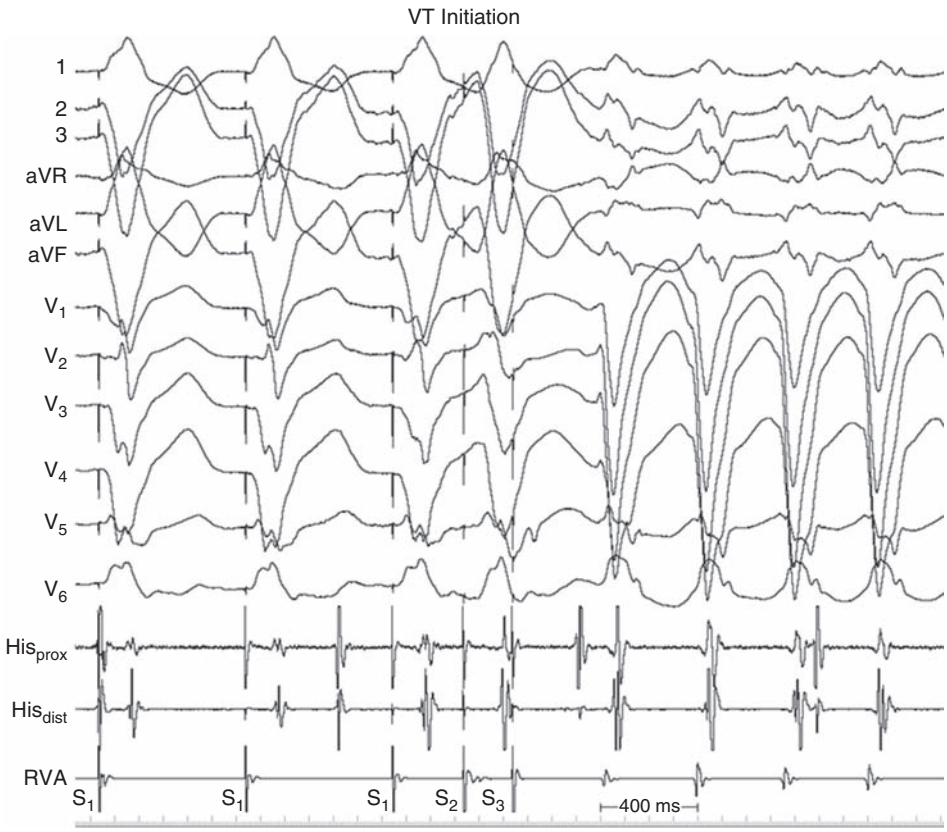

Figure 28-7

In Fig. 28-7, the same events as in the prior figure are shown, but this time displaying all 12 ECG leads. Of note, there is no His potential visible during VT.

VT ECG

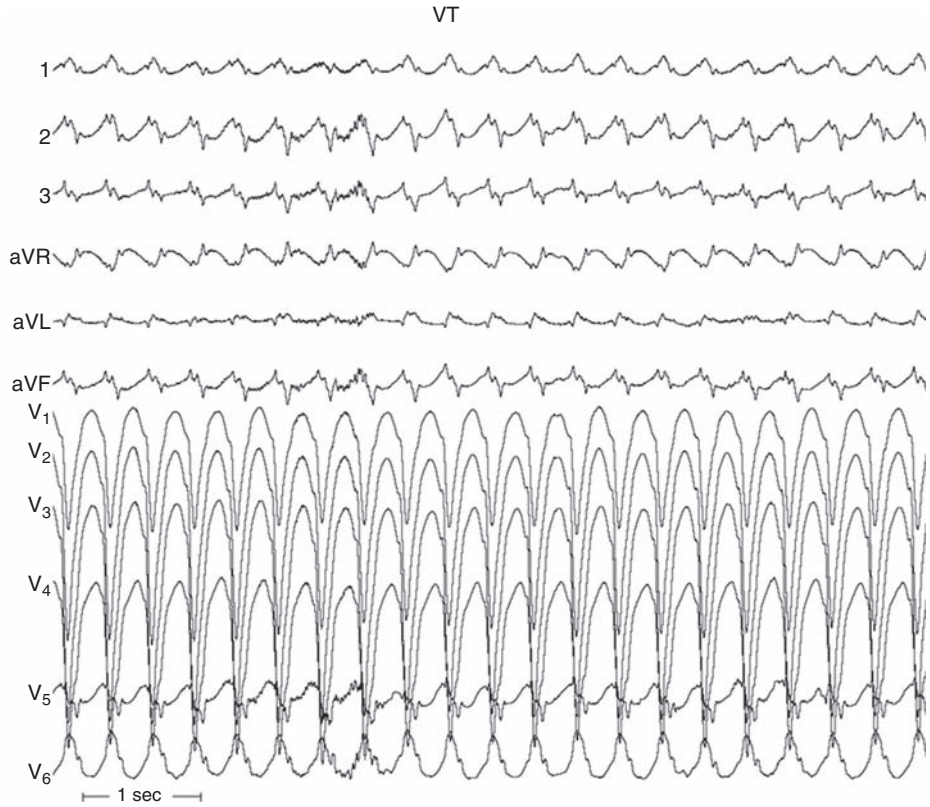

Figure 28-8

The full 12 leads of ECG during this induced VT are shown in Fig. 28-8, having an LBBB morphology (similar to what was described as having been initiated at the previous procedure).

VT Termination

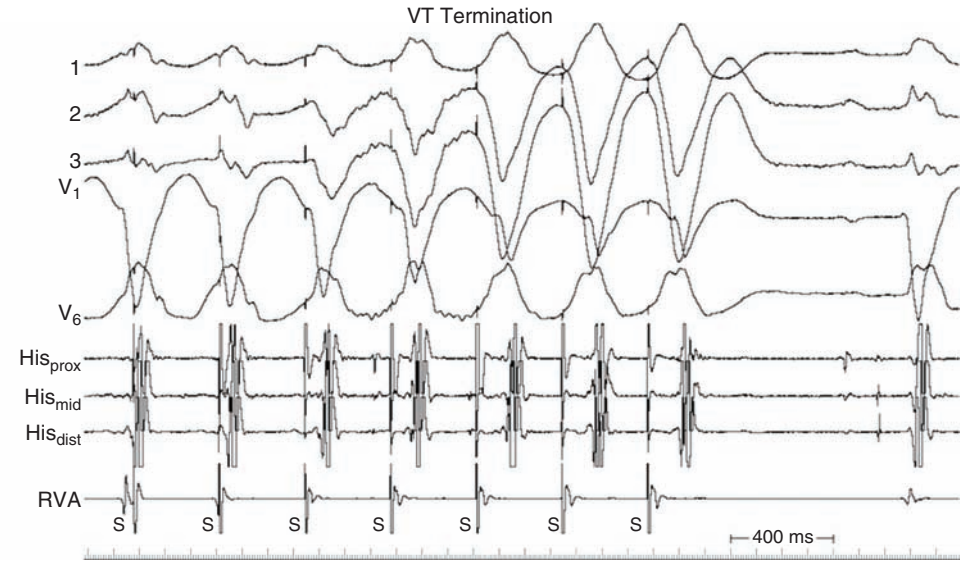

Figure 28-9

Fortunately, a single burst of ventricular pacing was able to terminate VT to sinus rhythm (Fig. 28-9). The situation at this time is as follows: VT is inducible but severe hypotension during VT precludes activation mapping under the current conditions. He had already undergone extensive substrate mapping and ablation, with little beneficial effect. Options at this point include the following: adding an inotropic agent to support blood pressure and

reinitiate VT; add procainamide or amiodarone to slow VT rate, hoping for better hemodynamic stability, and attempt activation mapping if VT is tolerated; use pacemapping to guide ablation; repeat substrate mapping and ablation; perform epicardial mapping and ablation; discontinue procedure and come back another day with mechanical hemodynamic support (percutaneous ventricular assist device, etc.)

Baseline ECG (Nonpaced)

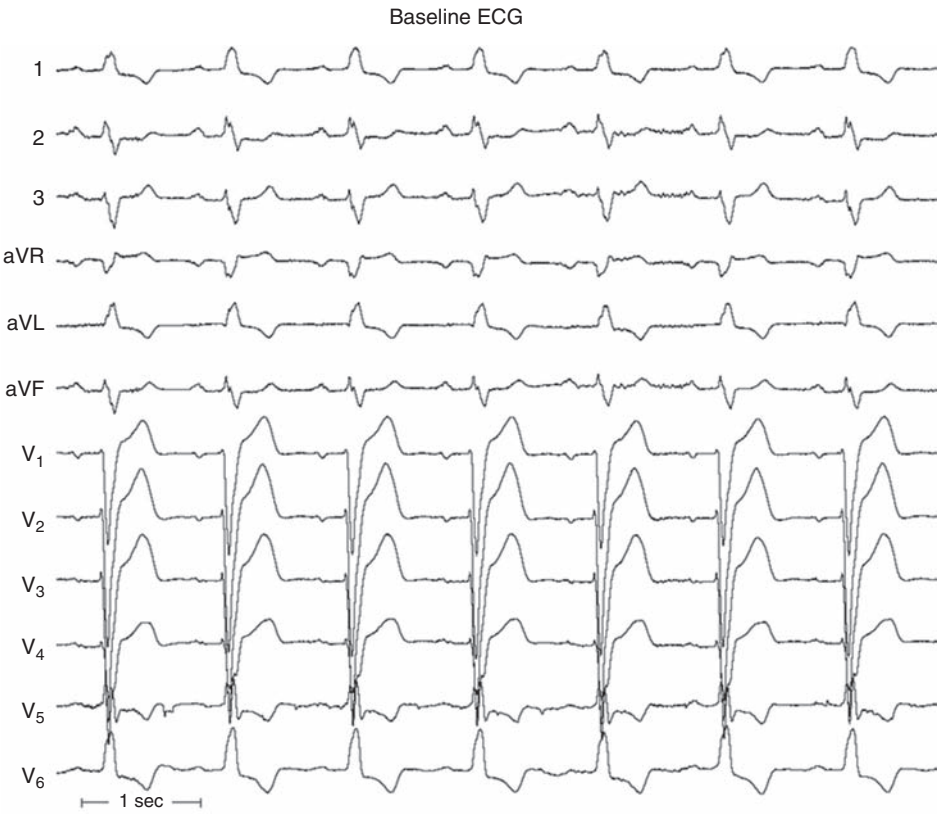

Figure 28-10

Before proceeding, it is worth a look back at what has already been learned in the procedure, starting with the nonpaced ECG at the beginning; this shows a LBBB morphology (Fig. 28-10).

Baseline Intracardiac Recordings Again

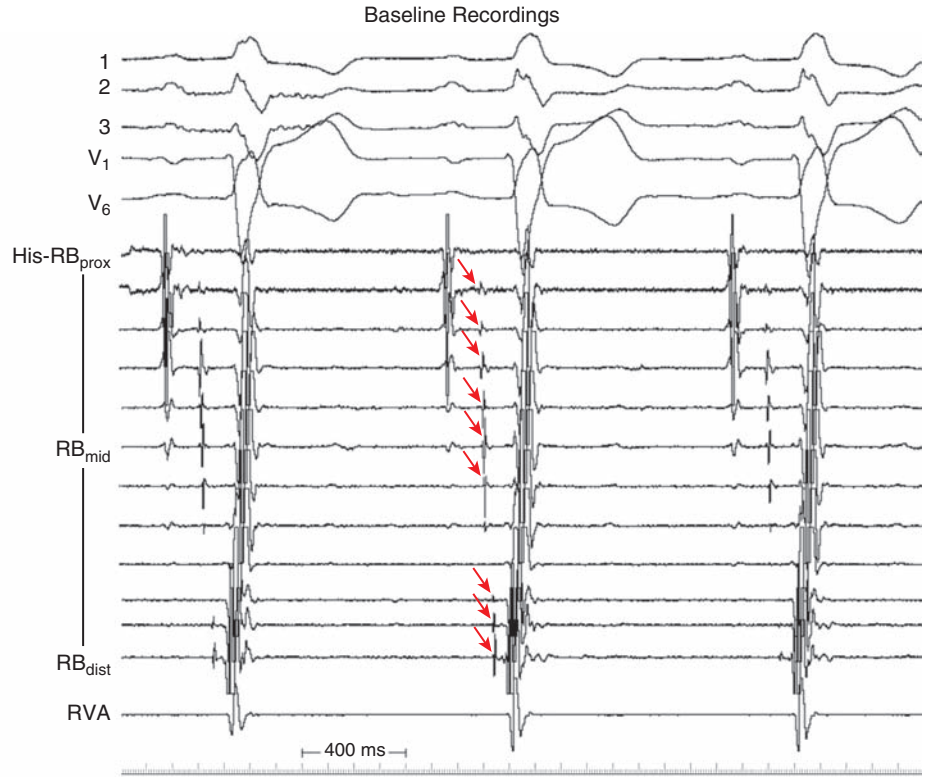

Figure 28-11

Another look back at sinus rhythm before induction of VT shows additional recordings made at the time, but not displayed earlier (Fig. 28-11). A decapolar catheter had been placed roughly in the usual His recording position, extending into the right ventricle along course of the right bundle branch; in addition, the quadripolar catheter usually used for recording the His bundle was placed more distally on the right ventricular aspect of the interventricular septum. Recordings from these two catheters are labeled His-RB_{prox} through RB_{dist}, and show small potentials representing His and RBB recordings *(arrows)*.

VT Initiation Again

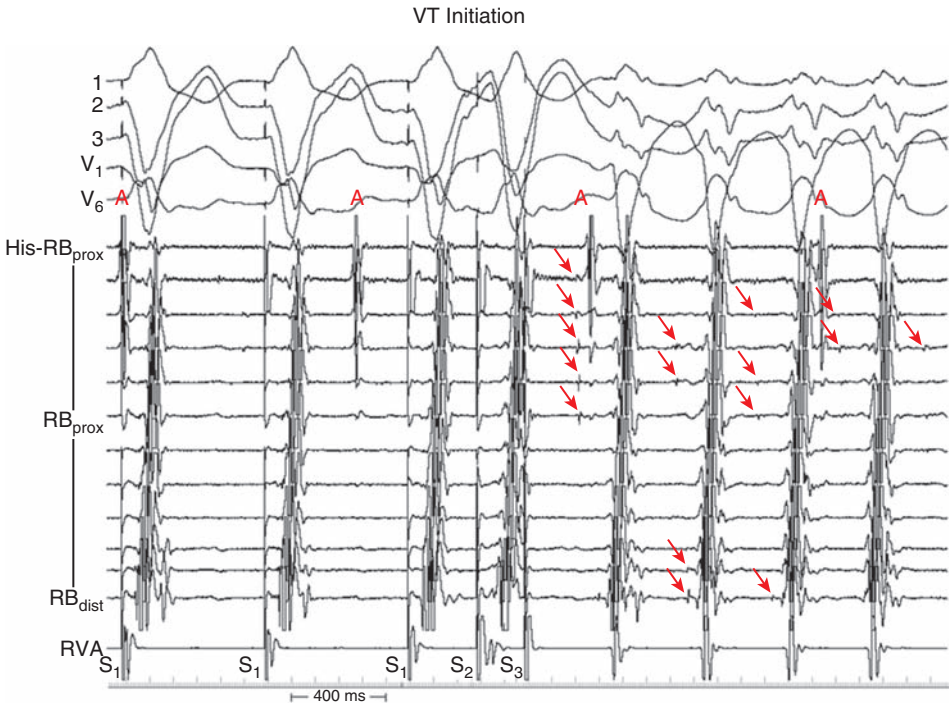

Figure 28-12

Another look back at induction of VT shows the additional recordings described in the prior figure that were made at the time, but not displayed earlier (Fig. 28-12). Recordings from these two catheters show small potentials *(red arrows)* during initiation of VT that are consistent with His and bundle branch potentials; the HV here is about 110 ms (in sinus rhythm, 95 ms). The mere presence of His potentials during VT does not allow a diagnosis of bundle branch reentry (because these are frequently seen in all forms of VT), but is consistent with it. Dissociated atrial electrograms are also seen (*A*).

VT Compared with Sinus Rhythm ECGs

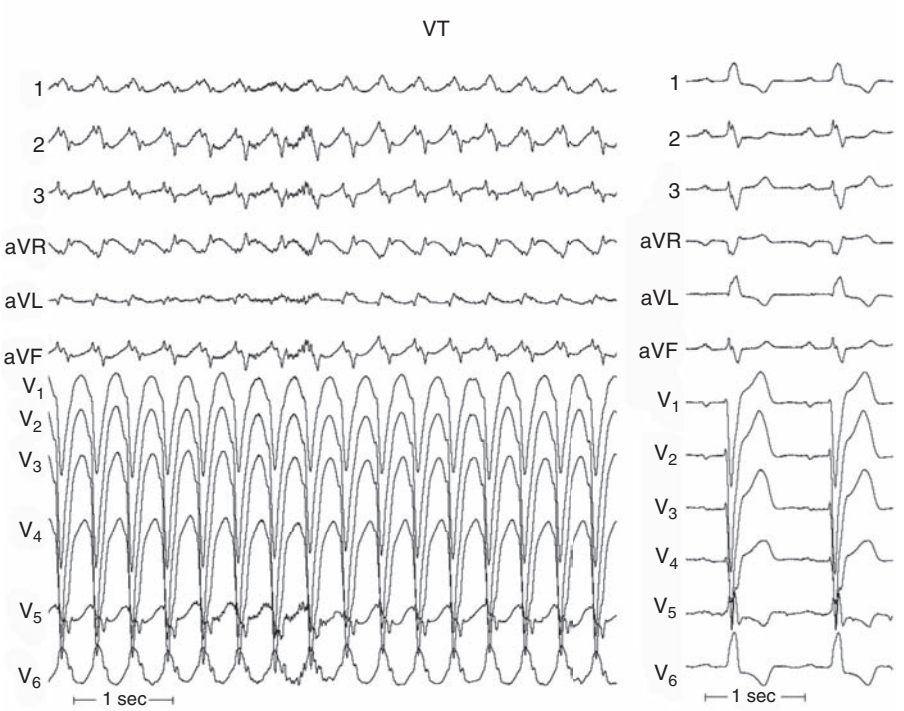

Figure 28-13

Another look at the 12-lead ECG of VT (in Fig. 28-13) shows similarities to the nonpaced QRS (at right) at the beginning of the procedure.

His Recordings During VT

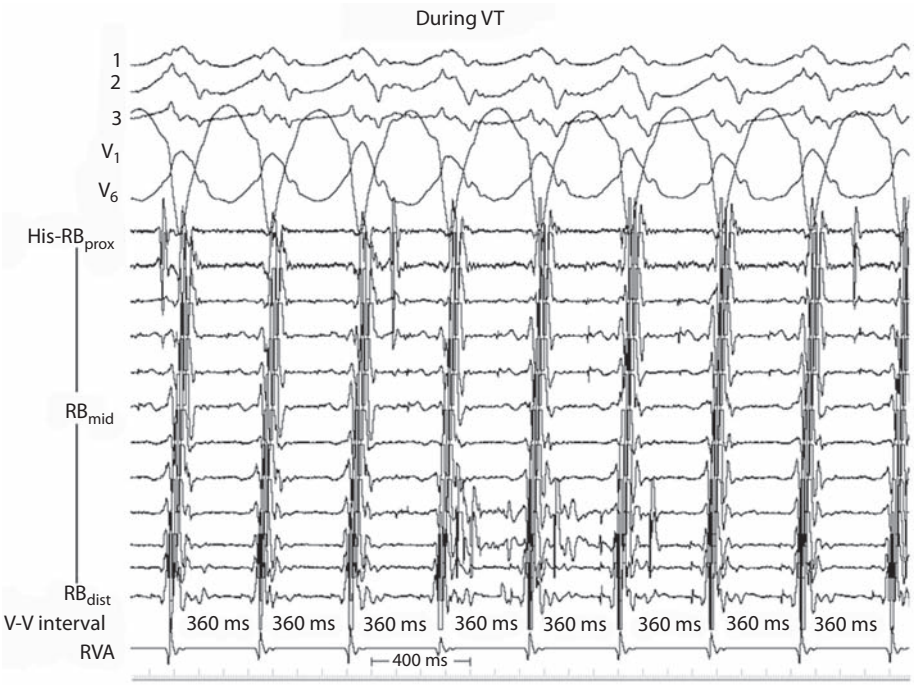

Figure 28-14

A few seconds after initiation of VT, but before pacing termination, the recordings in Fig. 28-14 were made. All intervals appear constant, affording no opportunity to test which signal leads others.

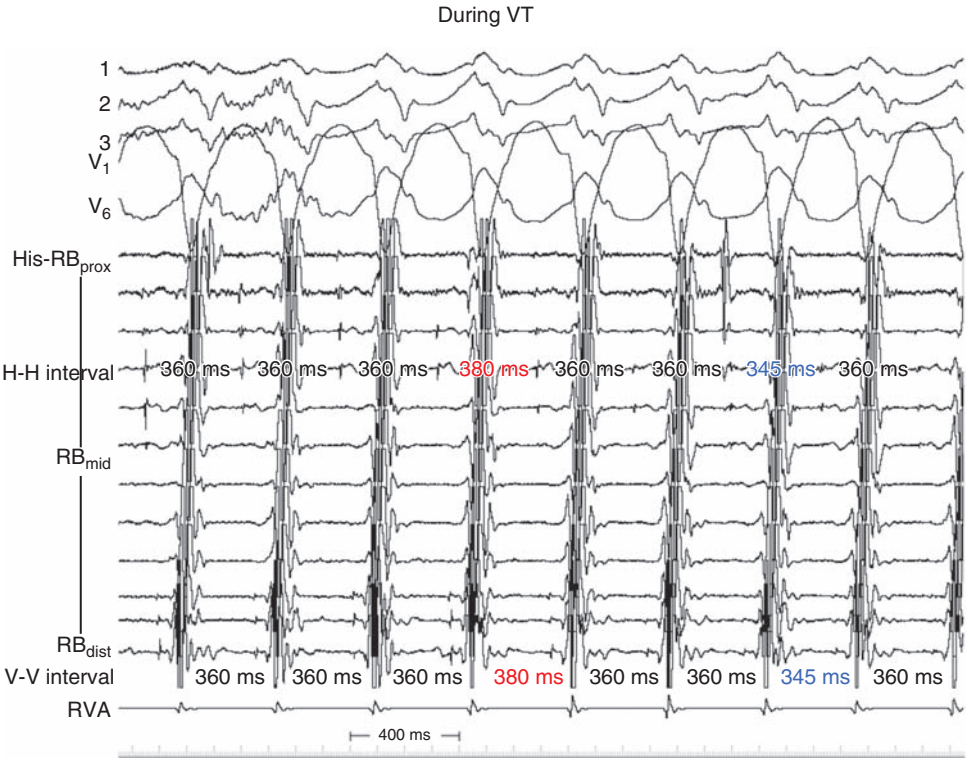

Figure 28-15

A few seconds still later, immediately before pacing termination, some irregularity of VT cycle length is seen (Fig. 28-15); it appears that changes in H-H intervals as shown precede changes in V-V intervals, strongly indicating that His-Purkinje activation drives the VT.

Ablation Site

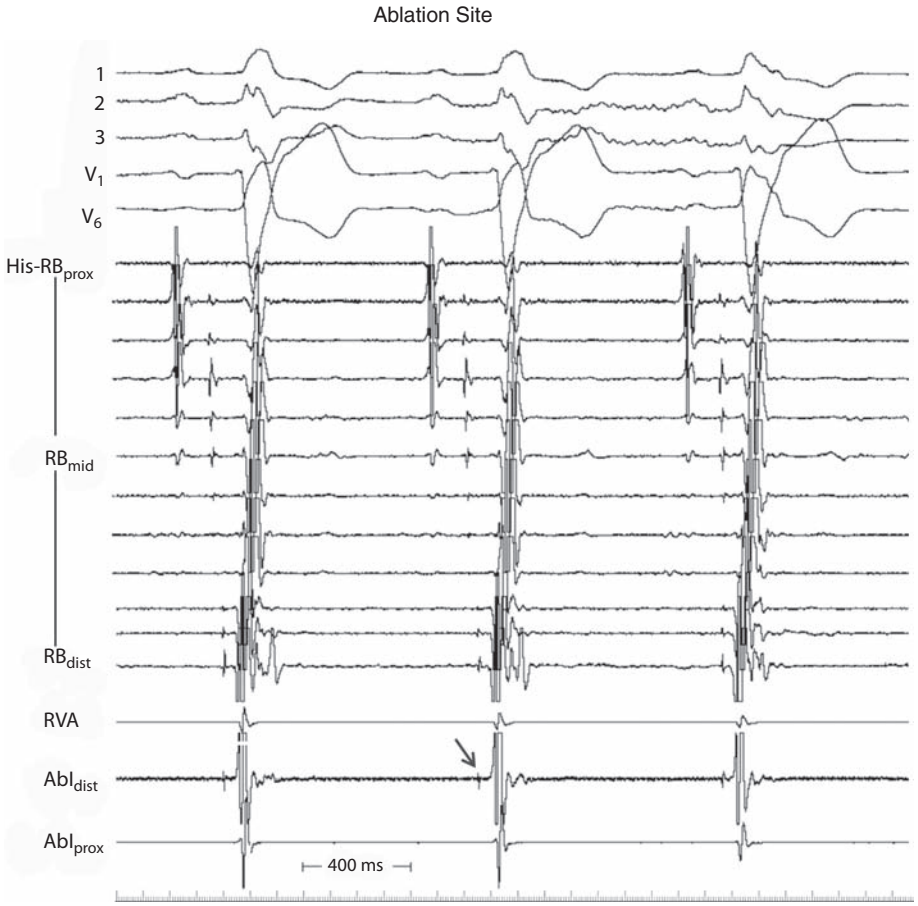

Figure 28-16

With all the data taken together (LBBB in sinus rhythm and similar morphology in VT; long HV baseline and during VT; H-H changes preceding V-V changes during VT; early activation of the RV apex during VT), a diagnosis of bundle branch reentrant VT was made and the RBB was targeted for ablation. Further maneuvers (attempted entrainment from RV) were not attempted because of hemodynamic instability during VT. In Fig. 28-16, a very small, sharp RBB potential *(arrow)* is evident in the ablation recording. These are often of very low amplitude and may be missed if the signal gain is not adequate.

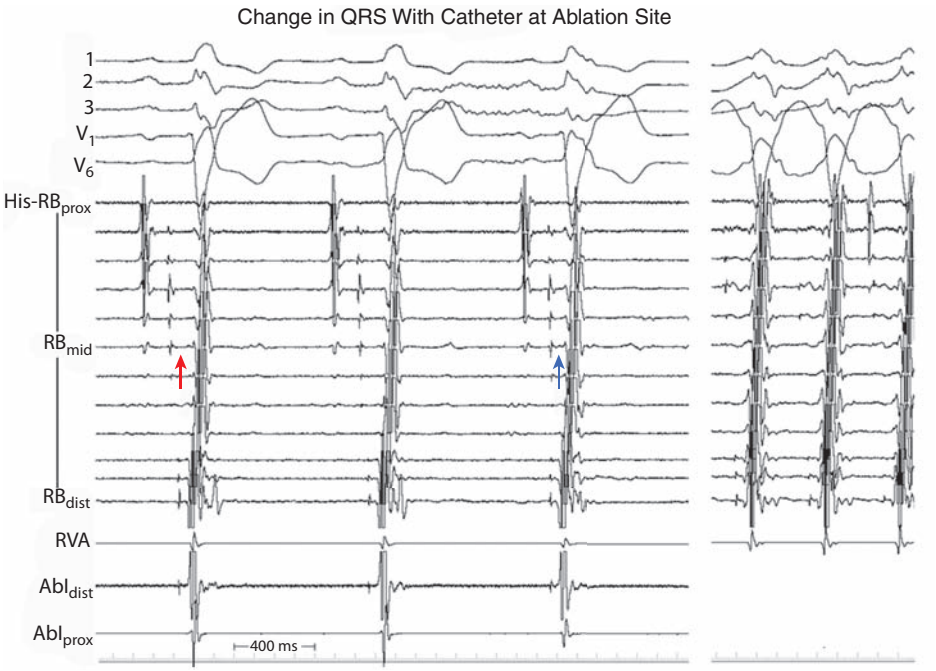

Figure 28-17

Catheter pressure at the ablation site (Fig. 28-17) appeared to cause mild prematurity of the RBB potential (shorter HV interval at *blue arrow* than *red*). Of note, this was accompanied by a slight change in the QRS complex, making it still more like the VT complexes (shown in the right panel). This is likely related to change in the site of breakout from the RBB to initiate ventricular activation.

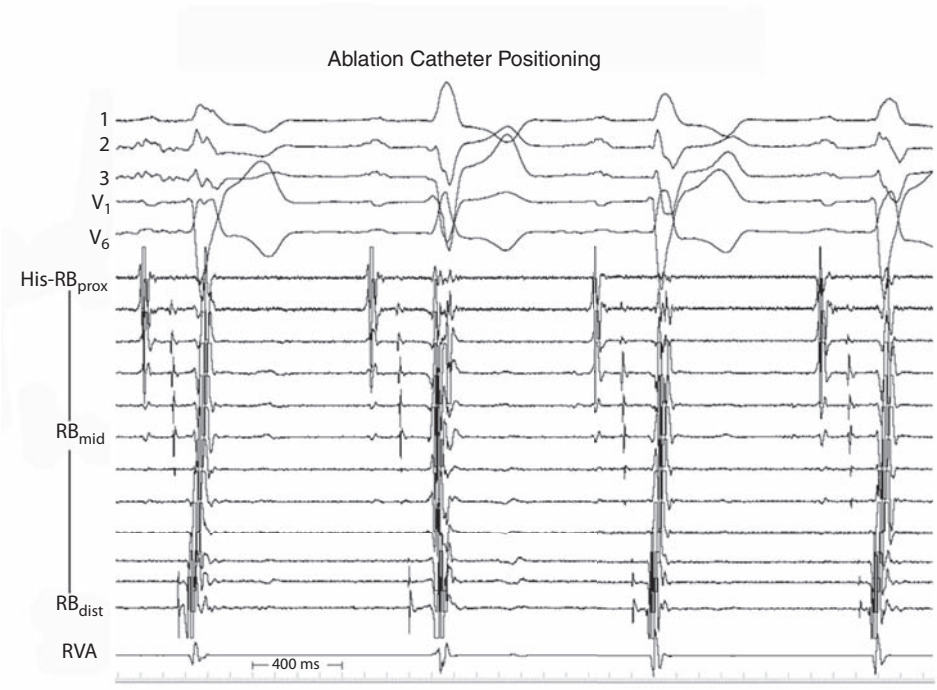

Figure 28-18

Additional catheter manipulation caused further changes in QRS complex and RBB-local ventricular activation times as shown in Fig. 28-18.

RF Ablation

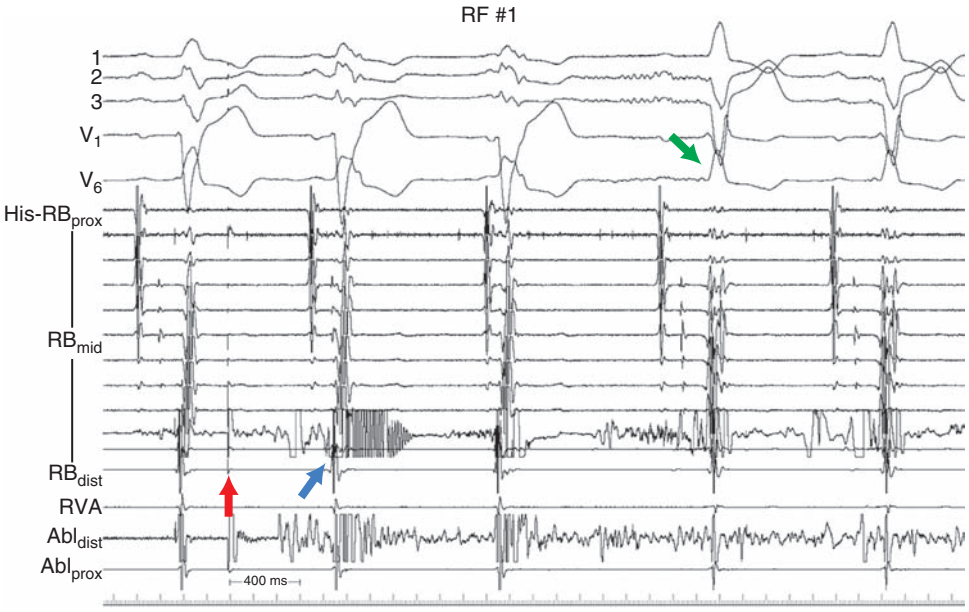

Figure 28-19

Radiofrequency (RF) energy (Fig. 28-19, delivery starting at *red arrow*) results in an accelerated rhythm *(blue arrows)* from the ablation site followed by elimination of conduction over the RBB *(green arrow)*. As is very often the situation in similar cases, RBBB in the presence of preexisting apparent LBBB does not result in complete heart block, but reveals very slow anterograde conduction over the left bundle branch (showing RBBB with a long HV interval).

Final ECG

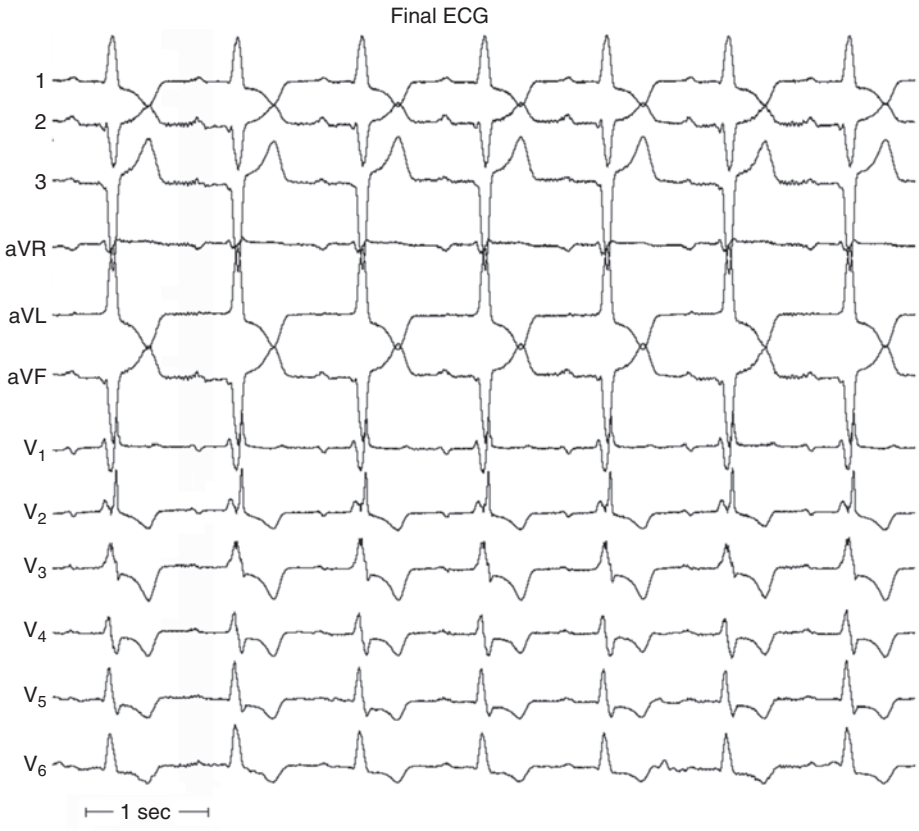

Figure 28-20

The final 12-lead ECG shows RBBB with left axis deviation.

After ablation, repeat ventricular stimulation showed no inducible ventricular arrhythmias; the patient's ICD was reprogrammed to atrial sensed biventricular pacing. After over 2 years of follow-up, no arrhythmias were detected by the ICD (Fig. 28-20).

Other Examples of Bundle Branch Reentry

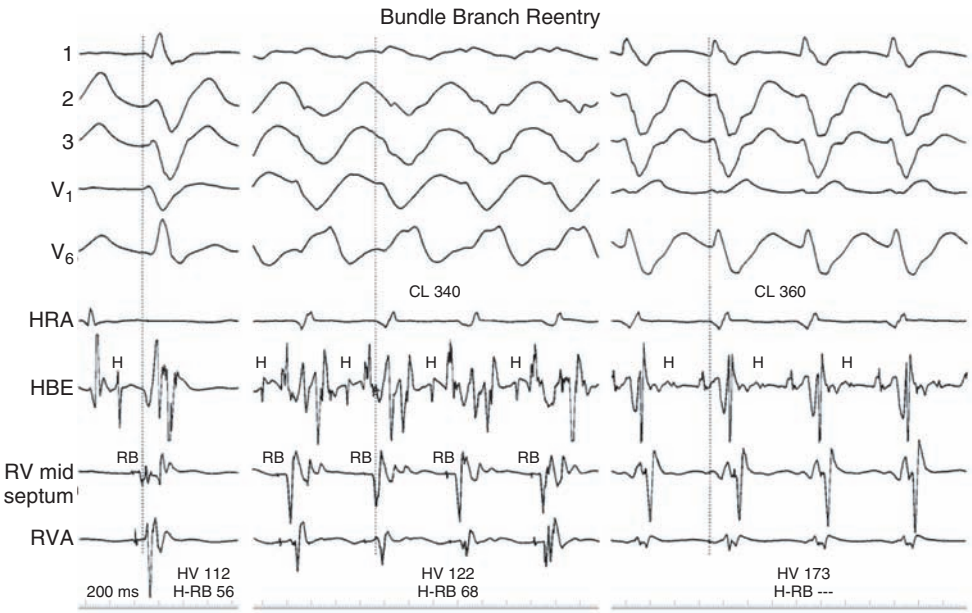

Figure 28-21

In a different patient, two episodes of bundle branch reentry (BBR) with opposite directions of circulation in the His-Purkinje system are illustrated in Fig. 28-21 with sinus rhythm at left, typical LBBB-type BBR in center, and RBBB-type BBR at right. Note relative timing of His and right bundle (RB) branch recordings.

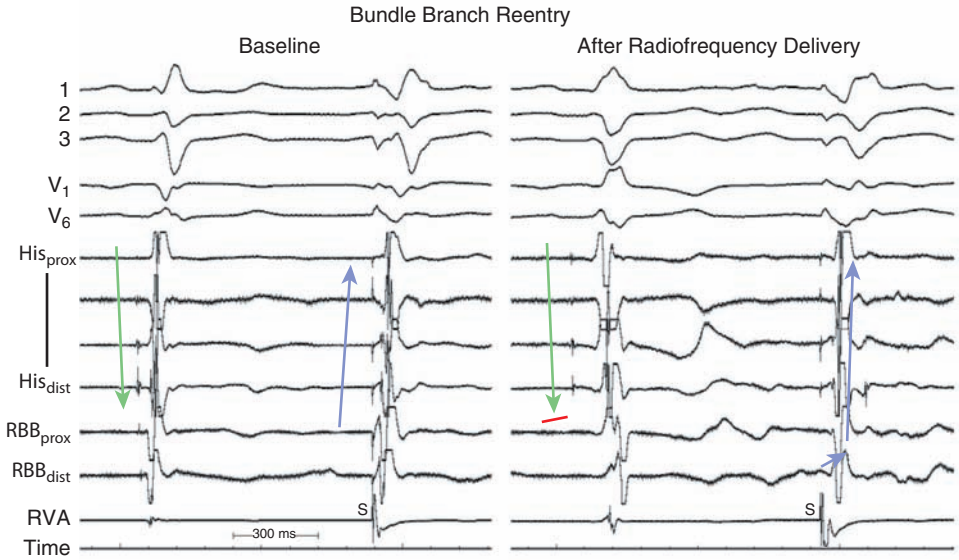

Figure 28-22

In yet another case of BBR, recordings along the RBB are shown in Fig. 28-22 before (baseline) and after RBB ablation, in sinus rhythm (complex at left in each panel) and right ventricular pacing (complex at right in each panel). *Green arrow* indicates anterograde propagation in the RBB during sinus rhythm (blocked after ablation, *red line*), whereas the *blue line* indicates retrograde propagation over the RBB. After ablation, retrograde RBB activation is dramatically delayed (appears after the local ventricular electrogram).

Summary

- Bundle branch reentry is not uncommon in patients with dilated cardiomyopathy
- At least a moderate level of suspicion is necessary for preparing correct recordings to make diagnosis
  - Multiple His + RB recordings are essential (ideally, LB also)
  - Standard catheter setup may easily miss the diagnosis
  - Look for spontaneous variations in VT cycle length (if preceded by H-H changes, BBR is diagnosed)
- Ablation of RB may unmask slow, but present, conduction over the LB with a very long HV interval
- Other myocardial VTs are present in at least 30% of patients, generally necessitating ICD placement (if not already present)

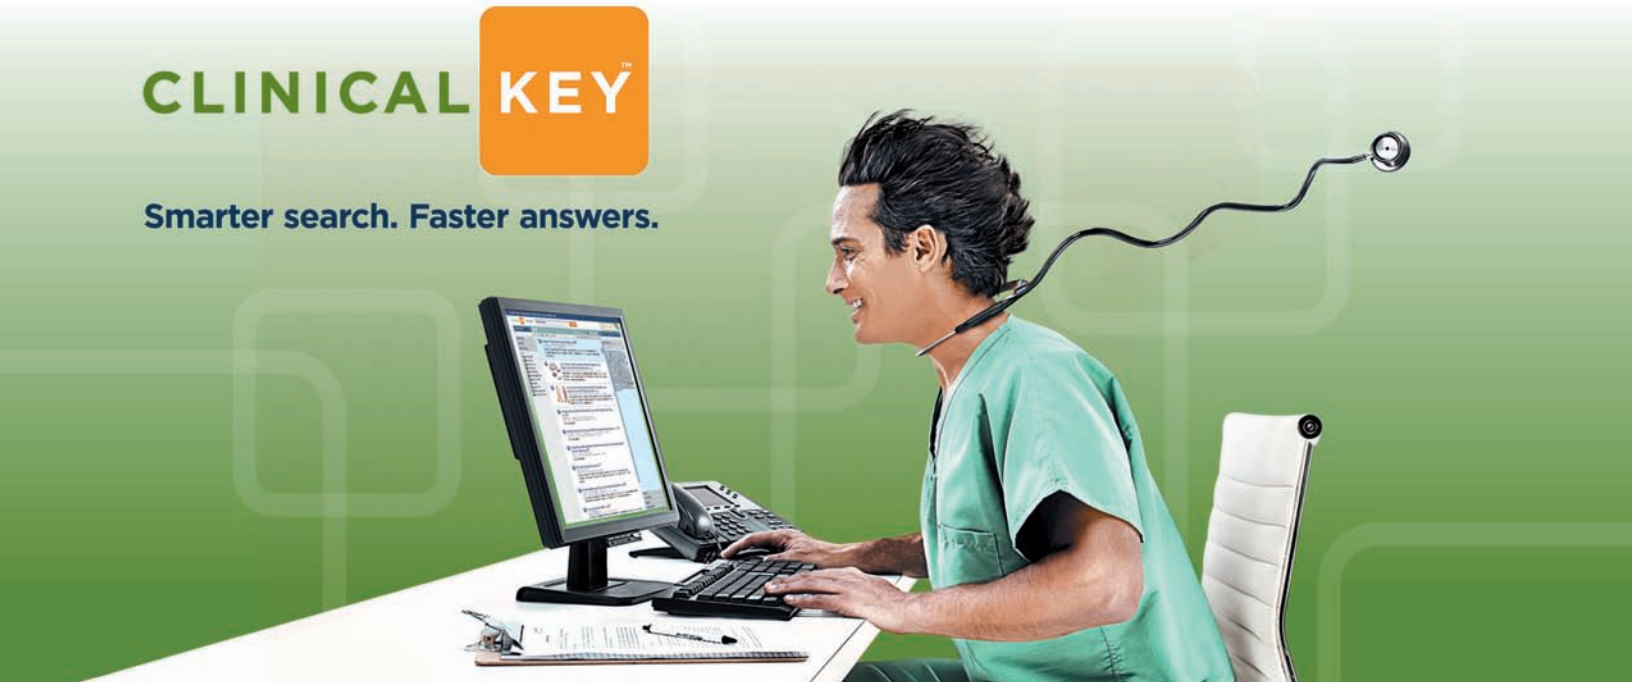
CLINICAL KEY

Smarter search. Faster answers.



Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit ***ClinicalKey.com*** for more information and subscription options.

Foreword

Clinical Handbook of Cardiac Electrophysiology, written and edited by Benedict M. Glover and Pedro Brugada, is a unique book. As the authors acknowledge in the preface, many excellent textbooks have been published on this topic. However, Glover and Brugada make the point that few provide a practical synopsis to bridge the chasm separating basic physiology, anatomy, and pharmacology from its practical application. That is the admirable goal of this book: to serve as the conduit between the basic scientist and beginner, for cardiology fellows, residents, and support personnel. The first three chapters lay a foundation for the rest of the book, including cardiac anatomy and basic electrophysiology (Chap. 1); the electrophysiology study, maneuvers, and ablation (Chap. 2); and electroanatomic mapping (Chap. 3). This book then embarks on a journey discussing the major cardiac arrhythmias including AV nodal reentrant tachycardia (Chap. 4), accessory pathway conduction (Chap. 5), atrial tachycardia (Chap. 6), atrial flutter (Chap. 7), atrial fibrillation (Chap. 8), ventricular tachycardia (Chap. 9), and antiarrhythmic drugs (Chap. 10).

I found this book to be authoritative and to the point with its main strength being the presentation at a level easily comprehended by the early learner. The many figures are very well done in that regard, very helpful and easily comprehended. This book will serve as an excellent stepping-stone for those who wish to delve further into electrophysiology mysteries, or as a final resting place for those contents with a basic understanding. Either way, *Clinical Handbook of Cardiac Electrophysiology* is an important contribution for learners.

Preface

Cardiac arrhythmia management has evolved as one of the most rapidly expanding fields within medicine. The development of catheter ablation has transformed the treatment of many arrhythmias, providing highly effective treatment options for the majority of tachyarrhythmias. There is also considerable research and development of more effective antiarrhythmic and anticoagulant drugs. Despite these huge technical advances, it is important to understand the basic principles of arrhythmia mechanisms in order to help make a diagnosis and chose an effective treatment strategy.

Although there are many excellent and detailed reference texts in this field, there are few handbooks which provide a practical overview bridging the gap between basic physiology, anatomy, pharmacology and interventional catheter ablations with precise details which should help in the intricate management of the patient.

This book covers all the important aspects of cardiac electrophysiology, presented in an easy-to-use format. For each arrhythmia, the aetiology, classification, clinical presentation, mechanism, electrophysiology set up (including precise set up and ablation parameters) and trouble-shooting are presented and demonstrated using illustrations, fluoroscopy images, ECGs and endocavity electrograms.

The overall aim of this book is to provide a logical and practical approach to cardiac arrhythmia management. We hope that this provides a useful resource and, importantly, helps to promote this wonderful sub-specialty.

This book is aimed at cardiac electrophysiologists, fellows, cardiologists, physicians, family practitioners, cardiology trainees, students, allied professionals and nurses. Given its succinct summary of electrophysiology, this should be available as a reference guide in the electrophysiology laboratory. We hope that this reaches a truly international audience and provides an important guide for those studying for heart rhythm exams.

Chapter 1
Cardiac Anatomy and Electrophysiology

Benedict M. Glover, Orla Buckley, Siew Yen Ho, Damian Sanchez-Quintana, and Pedro Brugada

Abstract Cardiac electrophysiology has rapidly moved from the mapping and ablation of accessory atrioventricular connections and ectopic foci to more extensive mapping and substrate modification. Training in cardiac electrophysiology requires a detailed knowledge of the anatomy and physiology of the heart. In order to understand the basis of cardiac electrophysiology it is important to discuss the different phases of the cardiac action potential, variability in morphology and duration throughout the heart and the most important ion channels and electrolyte shifts responsible for depolarization and repolarization of the cardiac cells. Electrophysiology continues to rely heavily on an understanding of these basic principles as well as the relevant anatomy of all cardiac chambers and surrounding structures. It is therefore fundamental to have a thorough understanding of cardiac anatomy as visualized on fluoroscopy, echocardiography, CT, MRI and 3 dimensional cardiac mapping systems.

The Cardiac Action Potential

Spontaneous depolarization of cells within the sinus node (SN) results in propagation of excitation throughout adjacent cells within the right atrium (RA) and left atrium (LA). The electrical impulse spreads through the atrioventricular (AV) junction into the His bundle, through the Purkinje network and then into the ventricular muscle where activation occurs from the septum spreading through the endocardium, mid-myocardium and finally the epicardium.

Each cardiac cell undergoes a process of depolarization and repolarization, which is recorded across the cell membrane as an action potential and occurs as a result of the relative concentration of ions (predominantly potassium, sodium and calcium) and electrostatic forces across the membrane. As shown in Fig. 1.1 this is composed of 5 components in atrial and ventricular myocytes and 3 components in the SN and AV node. The QTc on the surface ECG is an approximation of the mean duration of the ventricular action potential.

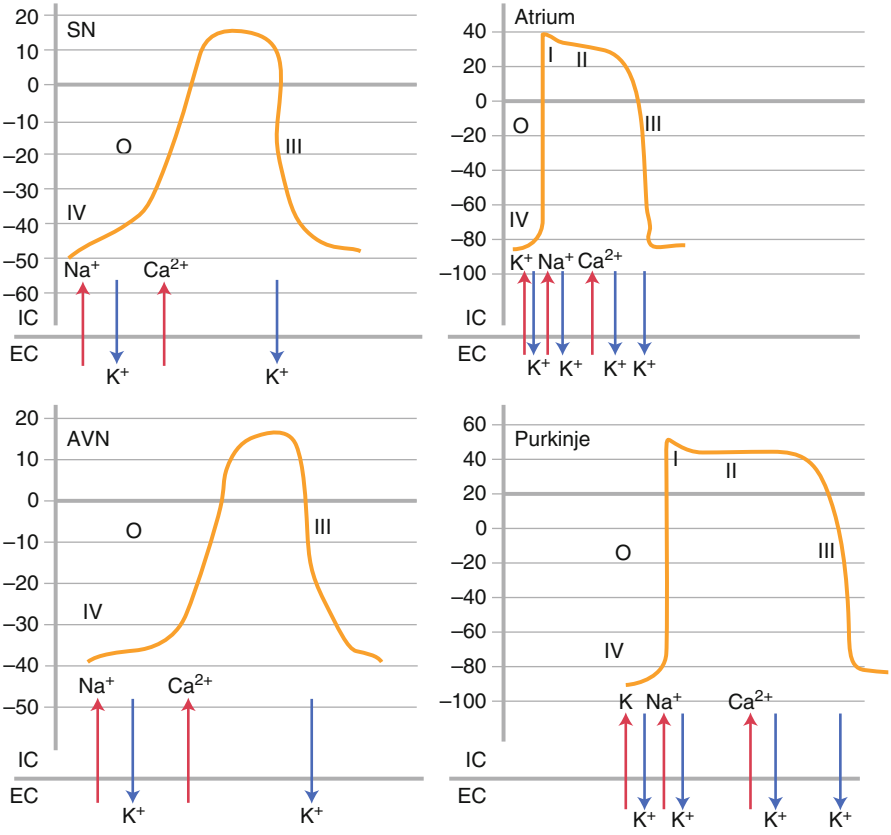

Fig. 1.1 Cardiac action potentials recorded from the SN (*top left*), atrium (*top right*), AV node (AVN) (*bottom left*) and Purkinje network (*bottom right*) and the predominant ionic currents responsible for theses changes in membrane potential (*IC* intracellular, *EC* extracellular, Na^+ sodium, Ca^{2+} calcium, K^+ potassium)

Phase IV is known as the **resting membrane potential**. This is recorded as −80 to −95 mV in atrial, Purkinje and ventricular cells. It is slightly less negative in the atrium than the ventricle. In the SN it is −50 to −60 mV and the AV node −60 to −70 mV. In both the SN and AV nodes there is a slow spontaneous diastolic depolarization which merges with Phase 0 resulting in spontaneous automaticity while Phase IV in other cells is generally more flat.

This is followed by **Phase 0** where the membrane potential becomes positive and is therefore known as **rapid depolarization**.

Phase I, **rapid repolarization** occurs in the atrium and ventricle but not in the SN and AV node. It is much more prominent in the Purkinje and epicardial cells.

Phase II is the **plateau phase** where the action potential becomes relatively flat and does not occur in the SN or AV node. It is followed by **Phase III**, which is known as **rapid repolarization** resulting in restoration of the membrane potential to the resting phase.

Phase IV (Resting Phase)

In the atrium and the ventricle this occurs largely as a result of the balance of potassium (K^+) across the cell membrane and is relatively flat with only a very slight slope.

K^+ is found in much higher concentrations in the intracellular space compared with the extracellular space. As a result of this there is an outward motion of K^+ leaving predominantly negative anions inside the cells at baseline.

This is counteracted during the resting phase by the inward rectifying current, (IK1). In general rectifier currents allow current to pass in a preferential direction. In the case of IK1 the transmembrane channel responsible allows the inward movement of K^+ at more negative potentials than the reversal outward K+ potential with less current movement at more positive membrane potentials [1]. This results in a very slight upward curve as the cell becomes less negative.

The resting phases in the SN and AV node are different from those recorded in the atrium and ventricle. As well as being less negative there is a continual slow spontaneous diastolic depolarization. This occurs as a result of the funny current (If) which plays the predominant role in this phase as opposed to the Ik1 current. This current is activated at voltages in the diastolic range resulting in a slow and steady inward Na^+ current (INa) which would normally occur in the depolarization phase in atrial and ventricular cells. There is also a slow outward movement of K^+ with the overall combined effect of a less negative cell membrane potential.

Phase 0 (Depolarization)

In the atrium and ventricle as a result of electrical stimulation from adjacent myocytes, a rapid inward sodium current (INa^+) results in the abrupt initial upstroke in the action potential known as Phase 0.

There are principally two Na^+ gates responsible for depolarization called the **activation** and **deactivation gates**. At the start of depolarization the activation gates are closed while the deactivation gates are open. As the action potential becomes less negative the activation gates tend to open rapidly allowing the inward movement of Na^+ while the deactivation gates tend to close slowly. This continues beyond zero voltage at which point the rate of Na^+ entry into the cell slows. As the deactivation gates close the fast Na^+ channels become inactive. These remain closed until Phase III of the action potential.

Depolarization in the SN and AV node does not occur as a result of INa^+ but rather as a result of calcium entry through the L-type calcium channels (ICaL) and T-type calcium channels (ICaT).

Phase I (Early Repolarization)

As the vast majority of the inward current deactivates, a rapid transient outward potassium current (Ito) results in early rapid repolarization. Phase I is much more prominent in Purkinje fibers and in epicardial myocytes and does not occur in the SN or the AV node.

Phase II (Plateau Phase)

The plateau phase occurs in the atrium and ventricles as a result of an inward movement of calcium ions (ICaL) combined with an outward movement of potassium (IKs, IKr and IKUr). As the voltage becomes less negative during depolarization the ICaL and ICaT channels become active.

ICaL channels are the predominant type found in cardiac myocytes and are activated when the voltage reaches −30 mV. ICaT channels which are less common in cardiac myocytes are activated at more negative voltages.

Overall ICaL activation begins in late depolarization. Ca^{2+} crosses from outside the cell where the concentration is higher relative to the inside.

K^+ shift is also partially responsible for the plateau phase. The balance of K^+ across the cell membrane is similar to that during the resting phase but the voltage is positive rather than negative which results in an outward movement of K^+ from the cell. The overall balance between the inward movement of calcium and the outward movement of K^+ results in the plateau phase. The transient outward current (Ito) is expressed in the atrium more than the ventricle. As a result of this there is a greater outward movement of K^+ versus the inward movement of calcium resulting in a shorter plateau phase.

Phase II does not occur in the SN or the AV node.

Phase III (Repolarization)

As the outward movement of K^+ exceeds the inward movement of Ca^{2+} the voltage becomes more negative resulting in repolarization. Although the delayed rectifier currents Ikr and Iks are activated during depolarization their action tends to be delayed and gradually increases during the plateau phase. Next to Ito the inwardly rectified K^+ current (Ik1) is also responsible for repolarization although this is more active as the voltage across the cell membrane becomes less negative and is responsible for the small bump seen in the action potential during repolarization.

All these K^+ currents are responsible for restoration of the K^+ balance. The Na^+ which entered the cell during depolarization is removed by the Na^+/K^+ ATPase enzyme while calcium which entered the cell during the plateau phase is removed by the Na^+/Ca^{2+} exchanger.

Repolarization in the SN occurs as a result of the rapid outward movement of K^+ as well as inactivation of the inward Ca^{2+} current making the cell more negative.

Refractoriness

Refractoriness describes the period after phase 0 of the cardiac action potential during which a stimulus does not result in a new depolarization.

There are three different types of refractory periods (RP): relative, absolute and effective.

The **relative RP** is the longest coupling interval resulting in local capture therefore marking the end of refractoriness.

The **absolute RP** is the longest coupling interval which does not result in local capture. The absolute and relative RP's are depicted in Fig. 1.2.

The **effective RP** is the longest coupling interval delivered which fails to propagate through the distal tissue.

In the clinical electrophysiology laboratory the RP is calculated by performing an **extrastimulus test**. In order to perform this the threshold for stimulation is measured in diastole by pacing at a fixed rate and decreasing the intensity of the pacing stimulus until capture fails.

Following a drive of eight beats at a fixed rate (to establish a steady state) a single extrastimulus is introduced at twice the diastolic threshold at shorter intervals until capture no longer occurs. This can be seen in Fig. 1.3 where pacing from the high RA is performed at a cycle length of 600 msec for 8 beats (drivetrain) in order to achieve a steady state followed by a decremental extrastimulus. In this example the first beat on the left is the final beat of the drive train. The extrastimulus occurs at a cycle length of 280 msec and captures the atria but fails to conduct over the AV node. This is considered to be the AV node ERP.

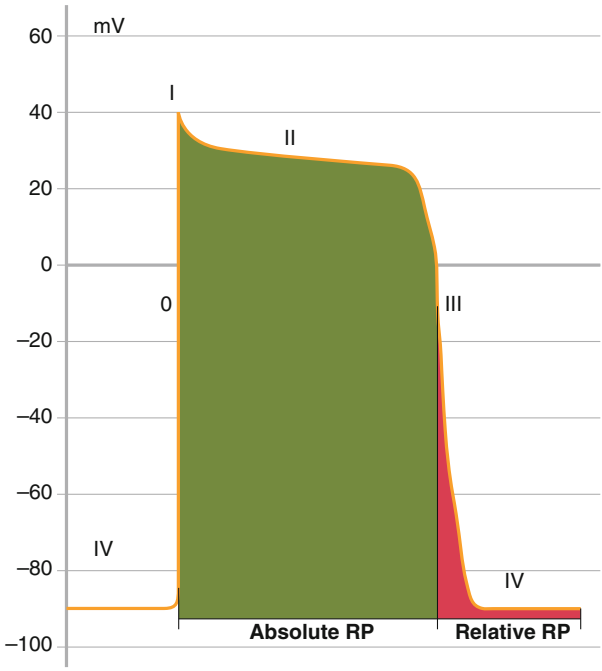

Fig. 1.2 Diagram showing the absolute RP and relative RP during the cardiac action potential. The absolute RP occurs from phase 0 until the transmembrane potential reaches -60 mV during phase III. During this time a stimulus will not result in depolarization. The relative refractory period follows this in which a high voltage stimulus may result in further depolarization

Arrhythmia Mechanisms

Arrhythmias may be classified as either **macro re-entry** or **focal**. Focal arrhythmias may be caused by **micro re-entry**, **enhanced automaticity**, **or triggered activity**.

Re-entry

A very common mechanism of clinical cardiac arrhythmia is re-entry. During re-entry a wave of excitation moves around a circuit which is determined anatomically, functionally or a combination of the two. A macro re-entry circuit which makes understanding of re-entry easy is the circuit during circus movement tachycardia in patients with the Wolf-Parkinson-White (WPW) syndrome (Fig. 1.4).

For re-entry to occur the following conditions have to be fulfilled:

1. There must be two or more pathways for conduction (for example the AV node and accessory pathway in WPW)
2. Unidirectional block in one pathway
3. Alternative conduction over the other pathway with sufficient delay as to retrogradely invade the formerly blocked pathway.

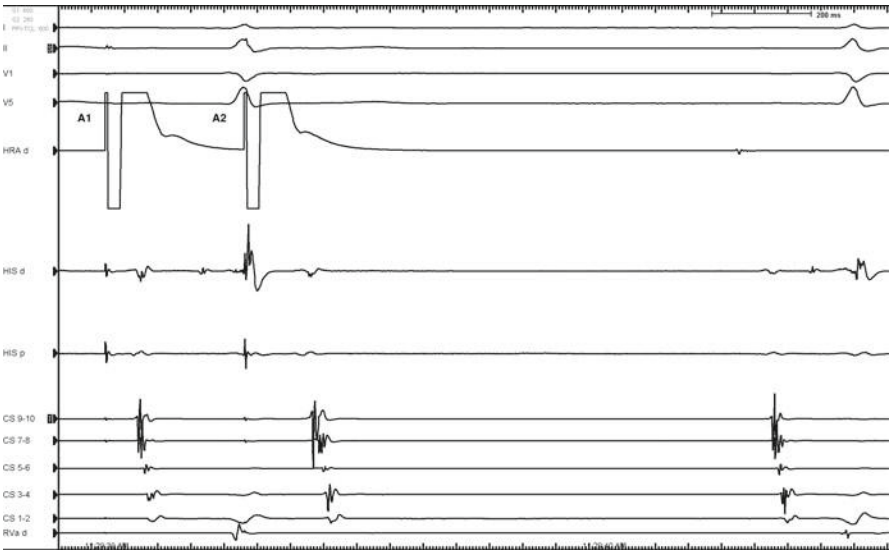

Fig. 1.3 Example of extrastimuli testing by pacing from the high RA (HRA d). The first paced beat on the *left of the image* is the final beat of the drive train where pacing is performed at 600 msec (*A1*). This beat conducts through the His to the ventricle via the AVN. This is followed by an extrastimuli which is performed at a progressively shorter cycle length. In this example this occurs at 280 msec (*A2*). Capture is seen on the high RA (HRA d) and the coronary sinus (*CS*) with lack of conduction through the AV node. This is considered to represent the AV node refractory period. (CS 9–10 is positioned in the proximal CS while CS 1–2 is in the distal CS, His d is positioned along the distal His, His p along the proximal His and RV a d is positioned in the RV apex)

For a re-entry circuit to sustain, the length of the circuit must be greater than or equal to the product of the conduction velocity and the refractory period termed the wavelength of the circuit. The pathways involved in these circuits must therefore have different conduction properties and refractoriness. A slow conduction pathway ensures that the wave of depolarization does not reach tissue which is refractory and thus terminate the arrhythmia.

Another requirement is the existence of a region of conduction block. This may be either anatomical or functional. Anatomical block may be structural such the tissue which exists between the slow and fast pathways in AV nodal re-entry tachycardia (AVNRT) or scar tissue in ischemic VT or functional such as occurs in typical atrial flutter. Functional block occurs as wavelets collide with each other and thus prevents the leading edge of the circuit stimulating refractory tissue resulting in termination of the arrhythmia. Most re-entry circuits involve a combination of structural and functional regions of block. A diagrammatic representation of a re-entry circuit is shown in Fig. 1.5.

The **wavelength of the circuit** is a product of the conduction velocity and the refractory period.

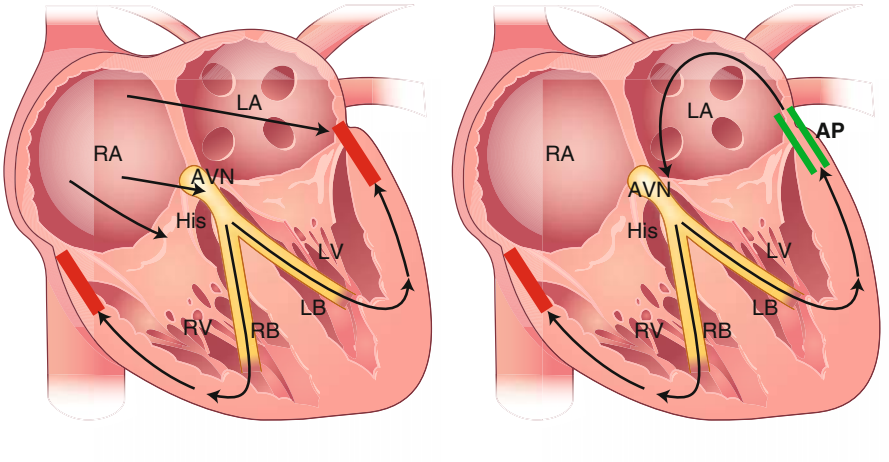

Fig. 1.4 Diagram showing the initiation of circus movement tachycardia (CMT) in a patient with WPW. In the *left image* conduction occurs antegradely through the AV node and is blocked retrogradely as there is no accessory pathway present. In the *right image* a re-entry tachycardia is demonstrated utilizing the AV node as the antegrade limb and the AP as the retrograde limb. *Arrows* indicate the predominant direction of conduction. The *red lines* indicate blocked conduction which prevents a re-entry circuit while the green lines indicate retrograde conduction over an accessory pathway. A denotes atrium, AVN is the AV node, V is ventricle and AP is the accessory pathway

Automaticity

Automaticity results from spontaneous depolarization during phase IV of the AP. Although this is a feature of automatic cells such as the SN, AV node, His bundle and Purkinje cells, if it occurs in other cells then it is considered to be abnormal (ectopic focus).

Spontaneous depolarization does not normally occur in atrial and ventricular myocytes but may occur as a result of various physiological or pathological changes which on a cellular level may result in a reduction in the expression or function of the IK1 channel [2].

Latent automatic cells are normally suppressed by SN activity and only become functional if the sinus rate becomes slower than the rate of spontaneous discharge of these cells. Some regions of increased automaticity are protected from SN discharge and therefore discharge independently of this. These cells which demonstrate evidence of entrance block with exit conduction are called **parasystolic foci** and tend to result in ectopic beats with intervals which are multiples of each other [2]. Incomplete entrance block may also occur resulting in entrainment of the focus at a defined rate resulting in ectopic beats with a fixed coupling interval.

One of the typical features of increased automaticity is the ability to overdrive pace at a rate faster than the tachycardia cycle length. This occurs as a result of an

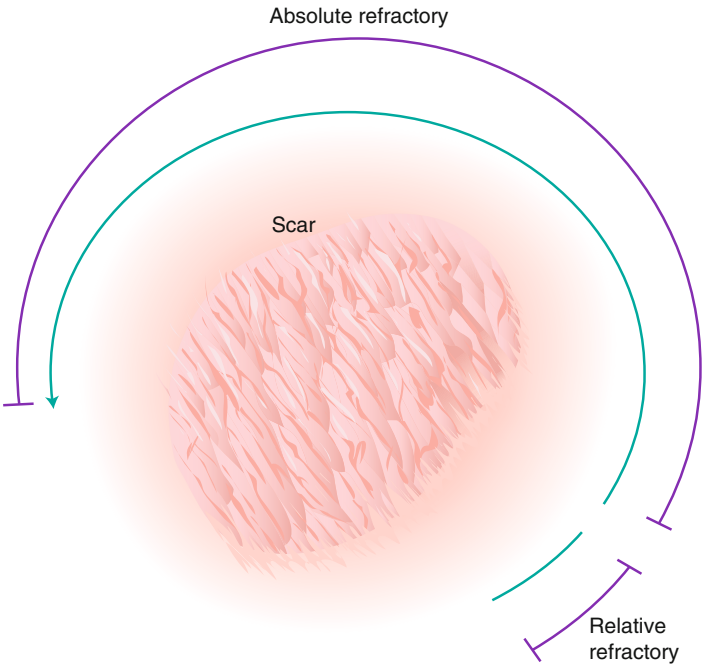

Fig. 1.5 Diagrammatic representation of a re-entry circuit circulating around a conduction barrier in this case scar. The region of tissue where the wavefront is propagating corresponds with tissue during the absolute RP. The tail of the wavefront corresponds with tissue during the relative RP

increase in the activity of the Na^+/K^+ ATPase pump resulting in the generation of a hyperpolarizing current which inhibits phase IV of the action potential [3].

Afterdepolarizations and Triggered Activity

Afterdepolarizations are defined as depolarizations which occur after Phase 0 of the cardiac action potential and may result in a spontaneous action potential known as a triggered response. These are divided into early afterdepolarization (EAD) or delayed afterdepolarization (DAD). These are depicted in Fig. 1.6.

EAD occurs during phase II and phase III while DAD occur after the cardiac action potential is complete. EADs tend to occur when there is an increase in the inward movement of positive ions during the plateau phase of the action potential.

DAD occur as a result of an increase in the inward movement of calcium. This can occur in the setting of digoxin toxicity or in conditions such as catecholamine induced polymorphic ventricular tachycardia (CPVT).

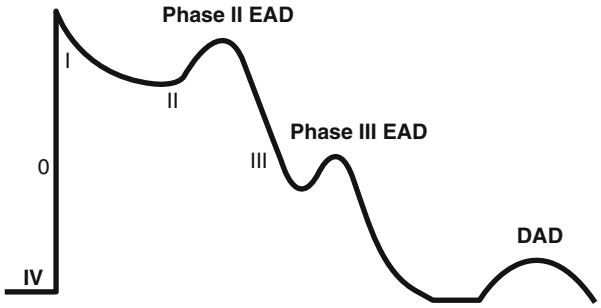

Fig. 1.6 Diagrammatic representation of phase II and phase III early atrial depolarizations (*EADs*) and delayed atrial depolarizations (*DADs*) at the end of the cardiac AP

Anatomy of the Cardiac Chambers

The cardiac chambers may be visualized prior to a complex ablation using computed tomography (CT) or magnetic resonance imaging (MRI) or during the procedure using fluoroscopy, echocardiography and electroanatomic mapping (EAM). The majority of procedures rely on a certain amount of fluoroscopic imaging and often our anatomical understanding is based on the locations of the catheters in various views. The most common views in the electrophysiology laboratory are the right anterior oblique (RAO), left anterior oblique (LAO), posterior – anterior (PA) and left lateral (LL). These views are shown in Fig. 1.7.

The RAO projection helps to demonstrate the postero-anterior (PA) location of a catheter within the cardiac chambers and shows the AV groove more clearly than the PA view. In this view the spine is on the left. Moving the catheter to the right results in a more anterior orientation while moving to the left is more posterior. The left cardiac border is formed by the RV outflow tract (RVOT) superiorly with the RV superior wall inferior to this and the LV apex at the apex. More steep RAO images result in a greater proportion of the RV being visualized with less LV present. The inferior wall of the RV forms the base of the image while the right cardiac border is formed by the posterior wall of the RA and posterior wall of the LA. The AV annular fat strip is best seen in the RAO projection. This 1 cm thick white line is formed as a result of the overlap of the ring of fat in the right anterior, septal and left posterior annulus and either marks the course of, or is slightly ventricular to the coronary sinus (CS). Any catheter posterior to the fat strip is in the atrium and anterior to this is in the ventricle.

In the LAO view the AV rings are viewed parallel to the image. The left cardiac border is formed by the LA superiorly and the lateral wall of the LV inferiorly. Steeper LAO views image more LA and less LV. The right cardiac border is formed by the right atrial appendage superiorly and the RV free wall inferiorly. In this view the spine is on the right side of the image. In the LAO projection anterior is to the left and posterior to the right.

In the PA view the left cardiac border is formed superiorly by the tip of the left atrial appendage (LAA) and the anterior wall of the left ventricle (LV) more inferiorly and the LV apex at the apex. The right heart border is formed by the superior

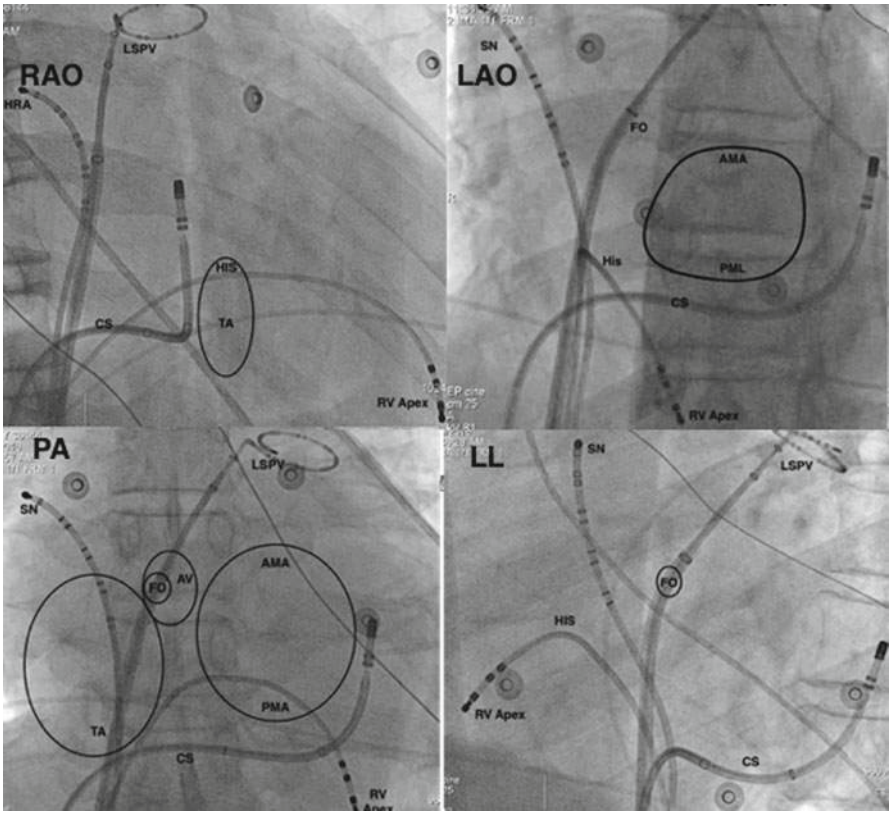

Fig. 1.7 The main fluoroscopic views used in the electrophysiology laboratory. All images have a catheter positioned in the coronary sinus (*CS*), RV apex, high right atrium (*HRA*) close to the sinus node (*SN*) and a catheter positioned across the fossa ovalis (*FO*) into the left superior pulmonary vein (*LSPV*). The location of the His is superimposed on the image. The tricuspid annulus (*TA*), mitral annulus (*MA*, anterior mitral annulus (*AMA*) and posterior mitral annulus (*PMA*)) and aortic valve (*AV*) are superimposed on the four views. The *top left view* shows the RAO projection, *top right* shows an LAO projection, *bottom left* a PA view and the *bottom right* shows a *left lateral view*

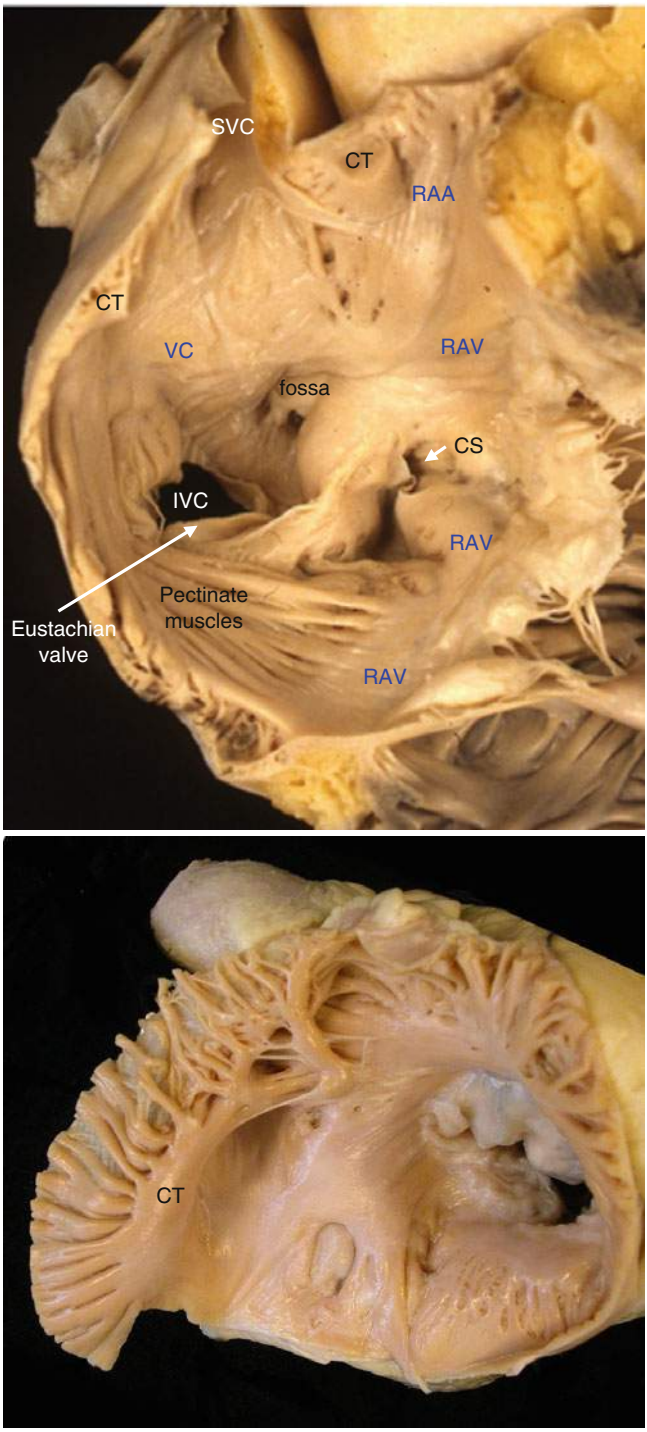
vena cava (SVC) to right atrial (RA) junction superiorly and the lateral wall of the RA inferior to this. The base is comprised of the inferolateral wall of the RV.

The LL view is very helpful in determining the anterior – posterior location of the catheter. This is useful for trans-septal access as well as for epicardial access in VT ablation.

The RA

The RA lies anterior, inferior and rightward from the LA and is composed of the venous component, appendage and vestibule. The anatomy of the RA is shown in Fig. 1.8.



SVC

RAV
CT

The superior and inferior vena cava drain systemic blood into the smooth-walled posterior venous component of the RA. Coronary blood flows through the CS into the RA through the CS os which is located between the inferior vena cava (IVC) and the tricuspid annulus (TA). The CS os is to a variable degree covered by the Thebesian valve which is a thin crescent shaped structure attached at the posterior and inferior boundary of the coronary sinus os. The degree of coverage varies but may practically occlude the CS os in up to 25 % of individuals [4].

The RA appendage is a triangular broad based structure composed of pectinate muscles originating from the **crista terminalis** and is generally where atrial pacemaker leads are positioned for stability. The crista terminalis is one of the most common regions responsible for focal atrial tachycardia's as well as acting as a functional electrical barrier essential for typical atrial flutter. It separates the pectinated appendage from the venous component (or intercaval area) of the atrial body. The latter is posterior whereas the vestibule which surrounds the atrial outlet leading to the tricuspid valve is anterior.

The SN

The SN is a collection of nodal cells within a tough matrix of connective tissue lying just below the epicardium and separated from the endocardium by a layer of atrial myocardium. It is located at the junction between the superior vena cava and the RA, at the antero-lateral quadrant marked by the crista terminalis (CT) (Fig. 1.8) and statistically measures 10–20 mm in length, 3 mm in width and 1 mm in depth but there is an enormous anatomical variation between individuals [5]. Cells in the SN tend to be much smaller than those in the RA measuring approximately 5–10 μm. Typical nodal cells known as P cells are located in the centre of the SN and are generally poorly organized myofilaments. There are fibroblasts and collagen fibers interspersed throughout the SN. There is a gradual transition between the SN and the RA with a disparity in conduction velocity between the cells thus preventing SN depolarization as a result of atrial depolarization [6].

Spontaneous phase IV diastolic depolarization starts at −65 mV until the activation threshold is reached at −40 mV resulting in rapid depolarization. The action potential of the SN differs from that of a Purkinje myocyte with a more gradual upslope and the absence of a plateau phase. Diastolic depolorization occurs as a

Fig. 1.8 Anatomy of the RA (*top image*) and the crista terminalis (*bottom*). The RA is antero-inferior to the LA and is composed of the venous component (*VC*), RA appendage (*RAA*) and RA vestibule (*RAV*). The superior (*SVC*) and inferior vena cava (*IVC*) are seen connected posteriorly into the RAV. The RA appendage is an anterior structure composed of pectinate muscles originating from the crista terminalis (*CT*). The coronary sinus (*CS*) is inferior and posterior. Superior and slightly posterior on the interatrial septum is the fossa ovalis. In the image below the crista terminalis is seen with pectinate muscles radiating out

result of activation of the If current. This operates in a voltage range more negative than normally occurs in the central pacemaker cells (less than −45 mV). It therefore has maximum activity during hyperpolarization and progressively increases opposing repolarization and then initiating diastolic depolarization [7].

The rate of diastolic depolarization in the SN is affected by both sympathetic adrenergic and parasympathetic muscarinic stimulation. This is predominantly affected by the If channel.

Sympathetic adrenergic stimulation results in an increase in the gradient and duration of diastolic depolarization with minimal effects on the overall action potential duration [8]. This occurs as a result of a shift in the activation curve to more positive voltages without a change in the conductance of the If channel as a result of an increase in intracellular cAMP [9].

The reverse occurs with parasympathetic muscarinic stimulation [10]. Slow inward Ca^{2+} channels are involved in the later phase of diastolic depolarization [8] as well as the upslope in the action potential. The transient T type Ca^{2+} channel is activated at more negative voltages and therefore opens first followed by the long lasting L component which opens during the upslope of the action potential [8].

The delayed rectifier Ik channel is the predominant potassium channel in the SN and contributes to repolarization allowing the following depolarization to be initiated.

Respiratory sinus arrhythmia occurs as a result of a reduction in the PP interval with inspiration and a prolongation of the PP interval with expiration. The maximum difference between the longest PP and shortest PP interval should be less than 160 ms. This phenomenon reduces with age.

Ventriculophasic sinus arrhythmia is seen in association with third degree AV block in which the PP interval surrounding a QRS complex is shorter than the PP interval not surrounding a QRS complex.

SN dysfunction encompasses sinus bradycardia, sinus pause, sinoatrial exit block, chronotropic incompetence and inappropriate sinus tachycardia.

Sinus bradycardia is a relatively common finding and in the absence of symptoms is generally of no clinical significance. A sinus pause is defined as the absence of a P wave for greater than or equal to 2 s (although generally not considered clinically significant unless greater than or equal to 3 s while awake or 5 s while asleep). If the duration of the sinus pause is a multiple of the PP interval, then sinoatrial node exit block should be considered. **Chronotropic incompetence** is defined as failure to achieve 70–80 % of maximal predicted heart rate (maximal predicted heart rate = 220-age) during peak exercise.

Inappropriate sinus tachycardia is a persistent elevation in heart rate greater than 100 bpm at rest with no obvious precipitating cause. There is an exaggerated increase in sinus rate with minimal activity and a reduction or normalization of sinus rate during sleep. The p wave morphology and axis are unchanged.

It is important to rule out all potential causes as well as other arrhythmias such as right atrial tachycardia close to the SN or SN re-entry tachycardia. Inappropriate sinus tachycardia is most likely multifactorial with a change in the overall autonomic supply to the SN which may include a reduction in the sensitivity to

anticholinergic effects or an increased sensitivity to adrenergic activity [11]. Pharmacological options for inappropriate sinus tachycardia include beta adrenergic blockers, nondihydropyridine calcium channel blockers and the selective If channel inhibitor ivabradine. Given the selective nature of ivabradine this has been shown to have a useful role in patients with symptomatic inappropriate sinus tachycardia unresponsive to beta adrenergic blockers and calcium channel blockers [12]. Further data is awaited whether this may be considered as first line treatment in this condition.

Catheter ablation for SN modification is an alternative strategy in select cases of inappropriate sinus tachycardia. The SN is often difficult to modify from the RA endocardium as there are multiple connections with sites of early activation between the SN and the RA. Additionally the bulk of the SN is subepicardial, has a significant amount of connective tissue, is often covered by thick muscle of the CT and there is a significant cooling effect from the SN artery. The usual area to target is the superomedial aspect of the CT targeting areas of local activation 15–60 msec ahead of the surface p wave looking for a reduction in the sinus rate to less than 90 bpm and a 20–25 % reduction in the maximum sinus rate with isoprenaline [13]. Although acute results are good long term maintenance is less successful [14]. High output pacing should be performed at sites being considered for ablation to avoid phrenic nerve injury. The need for a permanent pacemaker is unusual but a potential complication of this procedure.

Crista Terminalis (CT)

As shown in Fig. 1.8 this is a C-shaped structure which begins septally at the superior aspect becoming more anterior as it traverses the connection with the SVC and then moves posterior and inferior along the lateral wall of the RA towards the junction with the IVC [15]. The pectinate muscles which form the right atrial appendage span out from the CT. Approximately two thirds of focal atrial arrhythmias occur along this structure [16].

RA Conduction

Following discharge from the SN, conduction occurs through the RA using the muscular architecture of the atrial wall that comprises muscle bundles with well aligned working myocytes that preferentially carry the sinus impulse [17]. The notion of three specific internodal tracts is controversial because histologically specialized tissue tracts akin to the insulated ventricular conduction bundles have never been demonstrated anatomically.

Bachmann's bundle, which is also known as the anterior bundle is responsible for right to left atrial conduction. It is not a discrete bundle nor is it insulated with a

fibrous sheath. Instead, it is a muscle bundle with well aligned myocytes, superficially located across the anterior interatrial groove. Its rightward extension reaches superiorly to the area of the sinus node and inferiorly toward the right atial vestibule. Usually it is the most prominent interatrial bundle [18].

Cavotricuspid Isthmus (CTI)

This is the region of slow conduction in typical atrial flutter bounded anteriorly by the septal component of the TA and posteriorly by the Eustachian valve (EV) and the IVC (Fig. 1.9). Conduction in this region is slow due to the criss-cross arrangement of the myocytes and distal ramifications of the crista terminalis relative to the better aligned and circumferential arrangement of myocytes in the vestibule leading to the tricuspid valve (TV) [19].

In an LAO projection the ablation catheter is generally positioned in the mid isthmus in the 6 o'clock position. In the RAO position the catheter is moved from the right to the left keeping the catheter inferiorly. The EV separates the vestibular

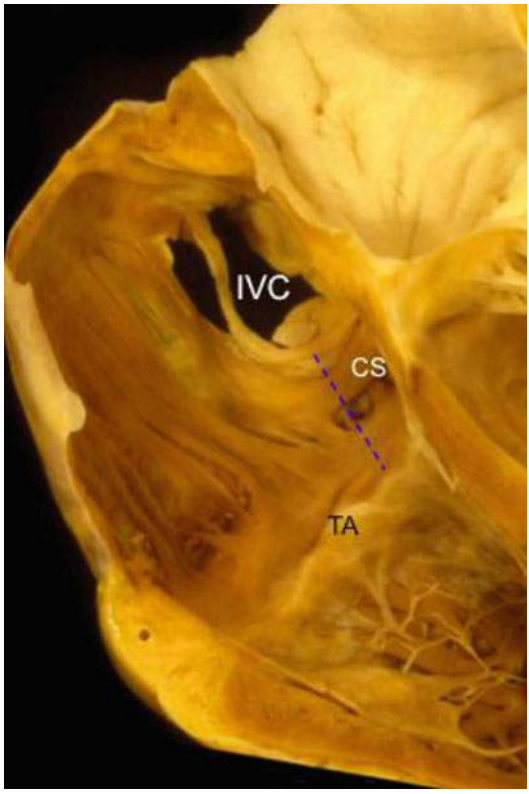

Fig. 1.9 Anatomy of the cavo-tricuspid isthmus (*CTI*). The CTI runs between the tricuspid annulus (*TA*) and the inferior vena cava (*IVC*). The dotted line shows a septal approach close to the coronary sinus (*CS*) which may be used as a line for catheter ablation in order to transect the isthmus

inferior RA from the inferior vena cava (IVC). The Eustachian ridge is an elevated region of tissue between the fossa ovalis and the coronary sinus in continuation with the insertion point of the EV. The Tendon of Todaro (TT) runs in this rim towards the AV node [18].

LA

The LA is posterior, superior and to the left of the RA. The tip of the left atrial appendage (LAA) contributes to the left side of the cardiac silhouette in a PA image. The LA is a smoother structure with the muscular appendage confined to a small tube-like structure arising from the superior and left side of the chamber. As shown in Fig. 1.10 the four pulmonary veins (PV's) drain into the posterior quadrants of the smooth-walled area, which is actually the most posterior region of the heart.

The left sided pulmonary veins are best seen in the LAO projection and are posterior to the left atrial appendage. The right pulmonary veins are best visualized in an RAO projection. The right superior pulmonary vein is posterior to the junction between the right atrium and superior vena cava.

The LA myocardial fibers extend over variable distances into the pulmonary veins. These connections are generally the targets for pulmonary vein isolation.

The LA wall is generally a thin structure and therefore care must be taken when manipulating catheters in this region. The lateral wall is approximately 3.9 ± 0.7 mm in thickness, the posterior wall 4.1 ± 0.7 mm, anterior wall 3.3 ± 1.2 mm and the roof 4.5 ± 0.6 mm when measured on cadaver heart specimens [19].

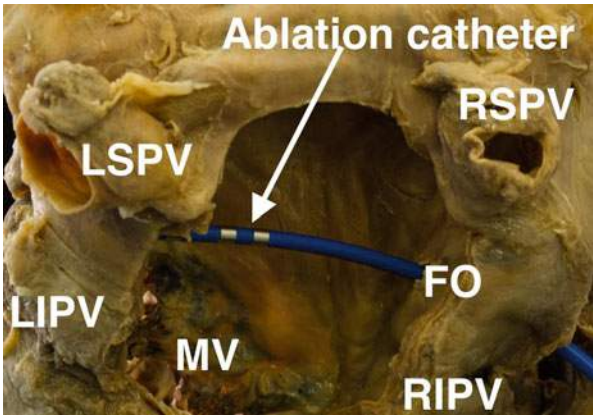

Fig. 1.10 Anatomy of the LA. This is seen from a posterior view. An ablation catheter is positioned via the intra-atrial septum at the location of the fossa ovalis. The left superior pulmonary vein (*LSPV*), left inferior pulmonary vein (*LIPV*), right superior pulmonary vein (*RSPV*) and right inferior pulmonary vein (*RIPV*) are seen as posterior structures in the left atrium. The mitral annulus (*MA*) is seen inferior to the LIPV

The LA is anterior to the esophagus. This is of real importance in terms of posterior wall ablation. The esophagus has a variable course in relation to the LA. There is also a variability in the thickness of the fibrofatty tissue between the LA and the esophagus. In clinical practice this generally results in the application of lower power (25–30 W) and shorter duration lesion in the posterior left atrial wall in order to attempt to minimize the possibility of esophageal injury.

Anterior to the LA is the ascending aorta which is an important consideration when performing trans septal access.

Atrio-Ventricular (AV) Junction

The compact AV node is the atrial component of the specialized AV junctional area and is located between the coronary sinus os and the septal leaflet of the tricuspid valve. It therefore lies inside the **triangle of Koch**.

It measures approximately 5 mm in length and is histologically quite complex. It is not insulated by connective tissue and therefore may potentially be damaged by RF application. The inferior extensions of the compact AV node also run within the triangle of Koch with the rightward extension (fast pathway) parallel to the tricuspid valve and the leftward extension (slow pathway) towards the coronary sinus. These extensions pass either side of the AV nodal artery and also are not protected structures. The histological appearances of these extensions are the same as the compact AV node and are involved in the AVNRT circuit [20]. The boundaries of the triangle of Koch are shown superimposed on an anatomic specimen in Fig. 1.11.

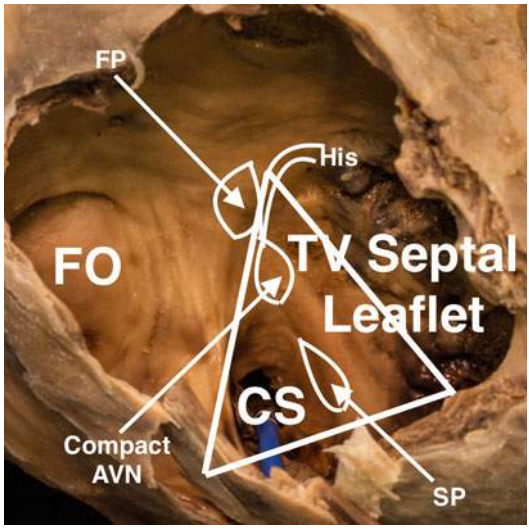

Fig. 1.11 Boundaries of the triangle of Koch superimposed on an anatomic specimen. This is formed by the coronary sinus (*CS*), septal leaflet of the tricuspid valve (*TV*) inferiorly and the tendon of Todaro anterosuperiorly. A catheter is positioned via the inferior vena cava (*IVC*) into the coronary sinus (*CS*). Also shown is the fossa ovalis, approximate location of the slow pathway (*SP*), compact AV node, fast pathway (*FP*) and His

His Bundle

The His bundle is a continuation of the compact AV node and with similar specialized cells although these are more parallel aligned [21]. It is better insulated than the AV node and therefore is not as easily damaged with RF, although this is still possible. The proximal bundle runs from the distal AV node into the fibrous tissue of the central body where it is termed the penetrating portion. Following this it emerges on the ventricular side of the fibrous body, sandwiched between the membranous septum and the muscular ventricular septum, Taking an initial course usually to the left side of the septum, it then bifurcates into the right bundle (RB) and left bundle (LB) branches, still insulated by fibrous tissue sheaths. The RB tends to have a more anterior origin in the membranous septum.

The CS

The CS is a tubular shaped structure which runs from either the Valve of Vieussens or in its absence the entrance of the vein/ligament of Marshall to the CS os where it enters the RA. It is approximately 7 cm in length [22] and 6–16 mm in diameter [23].

As shown in Fig. 1.12 the CS receives blood from the great cardiac vein that channels blood from its tributaries, the anterior interventricular vein, the middle cardiac vein, the left obtuse marginal vein, the right coronary vein and atrial veins of which the most well known is the vein of Marshall. The coronary sinus is generally surrounded by myocardial musculature which extends from the right and left atrial walls [24]. This musculature may extend for a further 2–11 mm along the great cardiac vein [25]. Distal to this the venous wall is not surrounded by musculature and therefore perforation through instrumentation is more likely.

The Valve of Vieussens rarely causes a significant obstruction to the advancement of a catheter but rather the acute bend in the vein beyond this or an advancement into a side branch are more common causes of cannulation problems. It is therefore better to slowly withdraw and rotate the catheter rather than to try to advance further.

The anterior interventricular vein courses from close to the LV apex and then continues into the great cardiac vein that into the left AV groove under the left atrial appendage [26]. Distally the great cardiac vein receives left atrial veins including the Vein of Marshall and more proximally ventricular veins from the anterior RV and LV and the interventricular septum.

The middle cardiac vein joins the CS close to the os. Occasionally it may also enter the RA directly. This vein runs along the diaphragmatic surface between the LV and RV with a close proximity to the right coronary artery and in particular the branch to the AV node. It may be used to map accessory pathways in the pyramidal space.

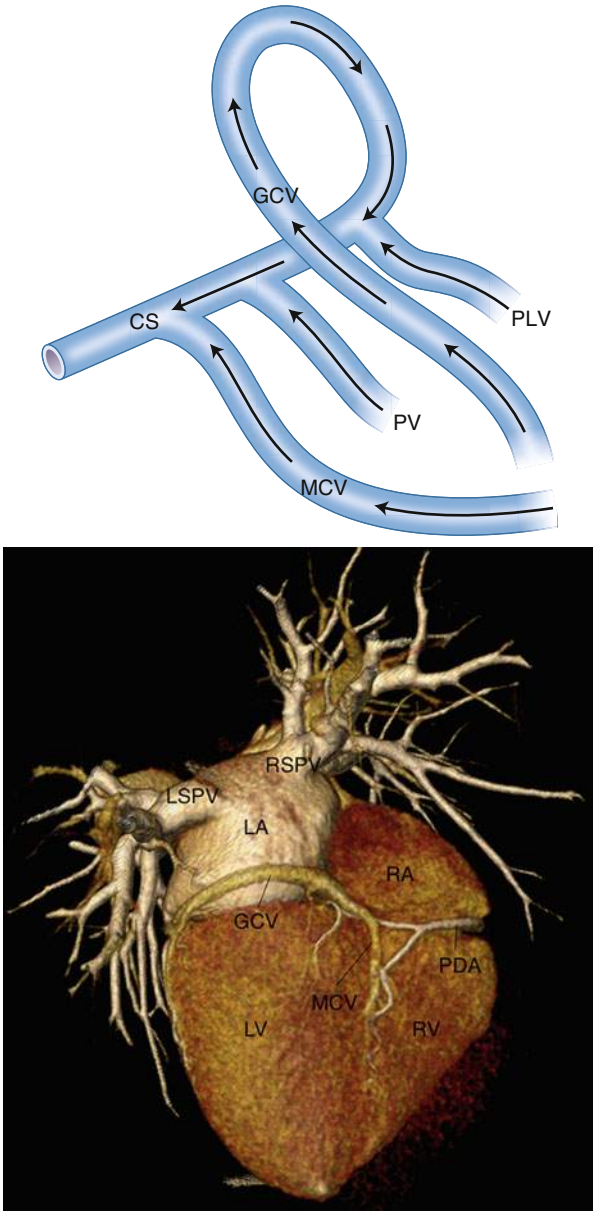

Fig. 1.12 The coronary sinus and its branches. The top image is a diagrammatic representation of the coronary sinus (*CS*) and its main tributaries the great cardiac vein (*GCV*), middle cardiac vein (*MCV*) as well as posterior veins (*PV*) and posterolateral veins (*PLV*) seen in an LAO view. In the image below this the CT shows the coronary sinus running along the inferior left atrium (*LA*) as the great cardiac vein (*GCV*). The middle cardiac vein (*MCV*) runs between the left ventricle (*LV*) and the right ventricle (RV). The posterior descending artery (*PDA*) is seen running between the right atrium (*RA*) and the right ventricle (*RV*). Also seen in this image is the left superior pulmonary vein (*LSPV*) and the rightsuperior pulmonary vein (*RSPV*)

LV Conduction System

The atrioventricular conduction bundle emerges from the central fibrous body to pass below the right and non-coronary cusps and continue into the branching atrioventricular bundle that gives origin to the RB and LB branches. The LB branch courses along the LV septal surface and divides into three fascicles (Fig. 1.13). The **anterior fascicle** which is **superior** runs towards the base of the anterosuperior papillary muscle, the **posterior fascicle** which is **inferior** runs towards the posteroinferior papillary muscle and in 60 % of cases a central or **septal fascicle** which runs to the mid septum. In the remaining 40 % of cases this area is supplied by the anterosuperior and posteroinferior fascicles.

Given that there are often more than two fascicles the term hemiblock is generally not accurate and fascicular block seems more appropriate.

Anterior fascicular block is more common than posterior fascicular block and results in a leftward QRS axis deviation poor R wave progression in V1–V3, with a negative QRS in II, III and aVF and positive QRS in lead I. There is also a tall R wave in aVL and aVR. The QRS is not broad.

Posterior fascicular block is less common due to the short and wide nature of this fascicle. The ECG features are a QRS axis greater than 100° with an rS morphology in leads I and aVL; and a qR pattern in leads II, III, and aVF. The QRS is not broad. Diagrammatic representation of both anterior and posterior fascicular bock are shown in Fig. 1.14.

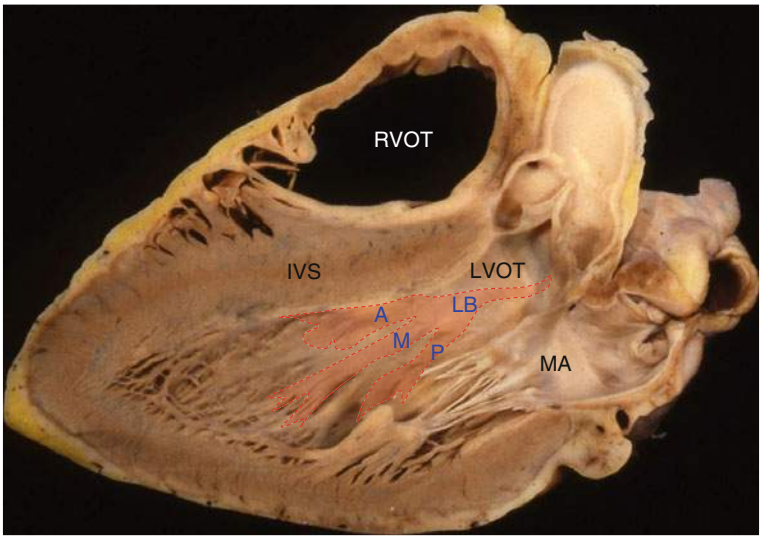

Fig. 1.13 Anatomy of the LV showing the walls of the chamber, interventricular septum (*IVS*), mitral annulus (*MA*) and left ventricular outflow tract (*LVOT*). Superimposed on this image are the approximate locations of the left bundle (*LB*), anterior fascicle (*AF*), posterior fascicle (*PF*) as well as the Purkinje system

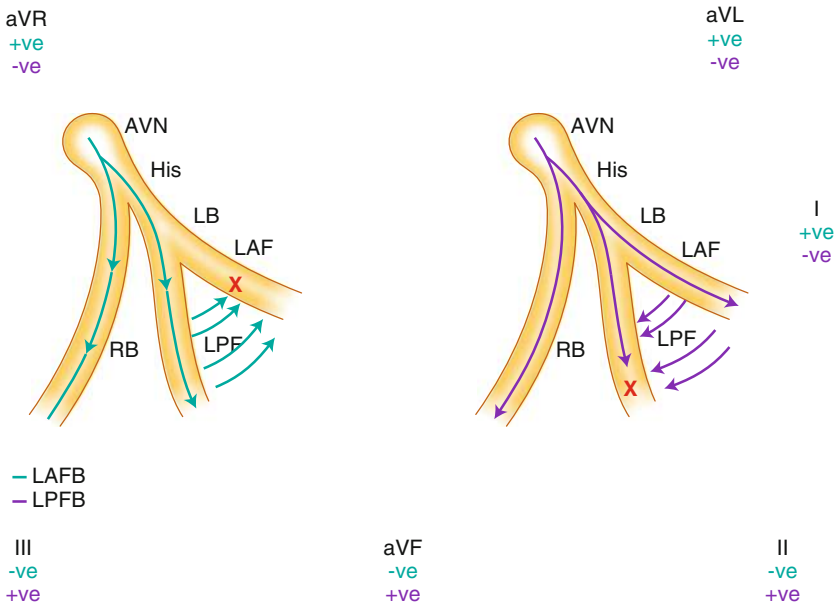

Fig. 1.14 Diagrammatic representation of left anterior fascicular block (*LAFB*) on the *left image* with activation in orange and left posterior fascicular block (*LPFB*) on the *right* with activation in *red* and the effects on the ECG limb leads

Septal fascicular block is the least clinically described of all the fascicular blocks. This may be due to the multiple ventricular connections of this fascicle making complete block of this fascicle less likely [27]. There is a variability in the ECG appearances. In general the changes noted are Q waves in V1 and V2 as a result of anteriorly directly right ventricular depolarization [28].

This may also cause a qrS in V1 and V2. There is also loss of q waves in leads V5, V6 and I due to loss or reversal of left to right ventricular septal activation. The QRS is not significantly broad because activation of the left ventricular free wall and apex occurs via the anterosuperior and posteroinferior fascicles.

Complete bundle branch block occurs as a result of either partial or complete structural or functional block in one of the two bundle branches resulting in a widening of the QRS greater than 120 ms as well as a change in morphology, which generally reflects conduction down the contralateral bundle with secondary repolarisation.

In **left bundle branch block** (**LBBB**) the initial activation is rightward and anterior resulting in small q waves in I, avL, and V6 with an rS in V2. Following this depolarisation spreads from the apex to the base and to the RV free wall and apex. During this process, septal activation is the pre- dominant force and therefore the vector is anterior and to the left, resulting in a wide slurred QRS in I, aVL and V6 (Fig. 1.15). Depolarization then occurs in a leftward and posterior direction through the LV. Finally, the anterior wall of the LV is depolarized.

RV Conduction System

The RV is anterior to the LV as shown in Fig. 1.16. The RB branch is an insulated bundle of specialized myocytes that runs as a direct continuation of the atrioventricular conduction bundle distal to origin of the left bundle branch. It penetrates the

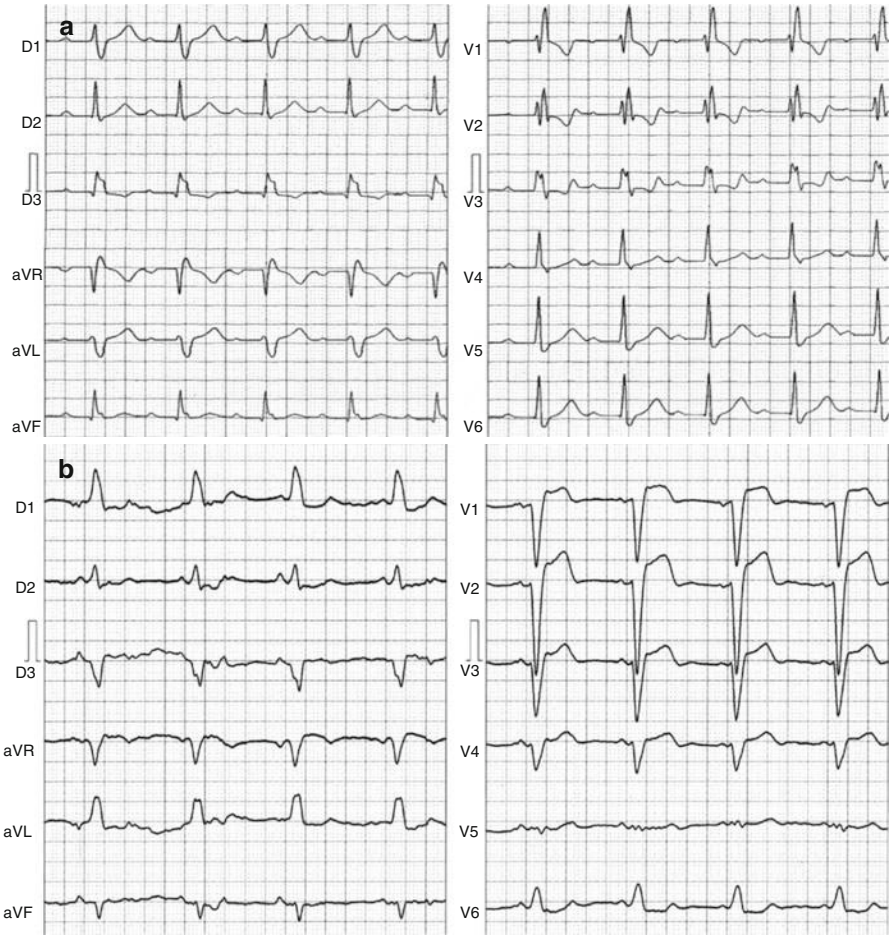

Fig. 1.15 12 lead ECG's showing RBBB (**a**), LBBB (**b**), Left Anterior Fascicular Block (**c**) and Left Posterior Fascicular Block (**d**). The ECG in panel **a** shows RBBB with first degree AV block (PR Interval 280 ms). The QRS duration is 120 ms with an rsR pattern in leads V1 and V2. (**b**) This ECG shows a LBBB with a QRS duration of 165 ms. An rS is seen in leads V1 and V2 and a dominant R wave in leads I, aVL and V6. (**c**) This ECG shows a left anterior fasicular block. The QRS duration is within normal range with a leftward axis. There is poor R wave progression V1–V3. The QRS is negative in leads II, III and aVF and positive in lead I. There is also a tall R wave in lead aVL. (**d**) This shows left posterior fasicular block. The QRS axis is in a rightward direction. There is an rS in lead aVL. There is a small q wave in lead III and a dominant R in leads II, III and aVF with the R wave being greater in amplitude in lead III than lead II

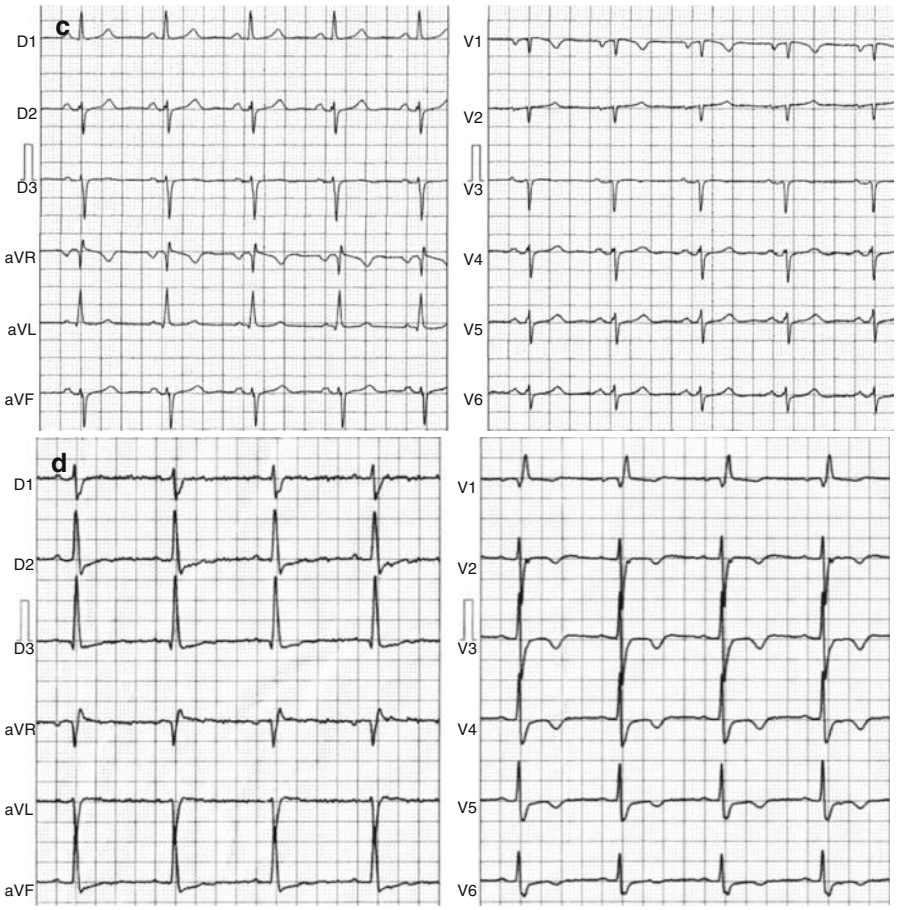

Fig. 1.15 (continued)

musculature of the ventricular septum toward the midseptum where it becomes subendocardial running along the posterior margin of the septal band. Continuing toward the apex, it divides into several branches one of which courses through the moderator band to the base of the anterior papillary muscle, and then the right ventricular free wall. It gives off septal branches which activate the septum almost immediately after left ventricular activation. Septal activation is generally complete within 35 ms and terminates in Purkinje fibres at the apex.

Right bundle branch block (**RBBB**) is more common than LBBB and as shown in Fig. 1.15 the initial septal activation is followed by depolarization of the left ventricle, resulting in R waves in I, aVL and V6. Following this, right ventricular free wall and septal depolarization results in S waves in these leads. Overall, the QRS is ≥120 ms in adults with an rsr, rsR, or rSR in leads V1 or V2. The R or r deflection is usually wider than the initial R wave. ST segment deviation is generally discordant to the QRS vector.

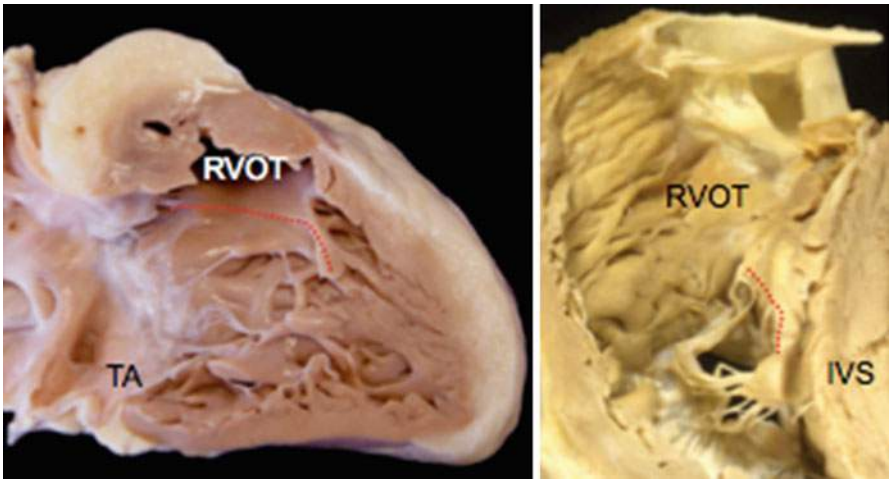

Fig. 1.16 Anatomical image of the Right Ventricle in Right Anterior Oblique (RAO seen on the *left*) and Left Anterior Oblique (LAO seen on the *right*) showing the walls of the chamber, interventricular septum (*IVS*), Tricuspid annulus (*TA*) right ventricular outflow tract (*RVOT*)

Aberrant Ventricular Conduction

This occurs when a supraventricular beat conducts rapidly to the His Purkinje system while one of the bundle branches is refractory and then depolarizes the other bundle branch, resulting in a wide QRS complex.

There are four types of aberrancy:

1. **Phase III dependent** (**Ashman Phenomenon**)
   This occurs when a short RR interval follows a longer RR interval. The longer RR interval results in a prolonged action potential in the His and bundle branches. The right bundle usually has a longer action potential duration than the left bundle and therefore the following beat with the shorter RR interval is blocked in the right bundle, which is still refractory and conducts down the left bundle with a RBBB morphology (Fig. 1.17). This may be seen in AF, where there is a variable cycle length and may be misinterpreted as a PVC.
2. **Acceleration dependent**
   This occurs with very slight acceleration of the heart rate (less than 5 ms) at a critical cycle length which is often within normal heart rate ranges. This tends to occur more commonly in the left bundle resulting in a LBBB morphology (Fig. 1.18). Of note as the rate increases further, the aberrancy often resolves as the action potential duration of the bundles reduces more than that of the AV node. Additionally the action potential duration of the bundle branches often reduces in a time dependent manner known as restitution.
3. **Deceleration dependent**
   This occurs following a long pause during which a premature atrial beat conducts to the ventricle with a resultant bundle branch block pattern (Fig. 1.19). This

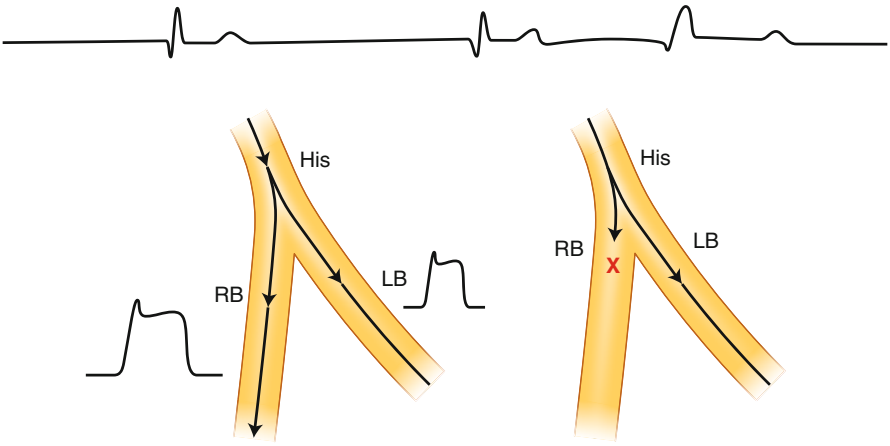

Fig. 1.17 Diagrammatic representation of Phase III dependent aberrant conduction. During AF the longer RR interval on the left results in a prolongation of the action potential in the Right Bundle (*RB*) and to a lesser extent the Left Bundle (*LB*). An early activation occurs during phase III of the action potential in the RB resulting in conduction down the LB with a RBBB morphology

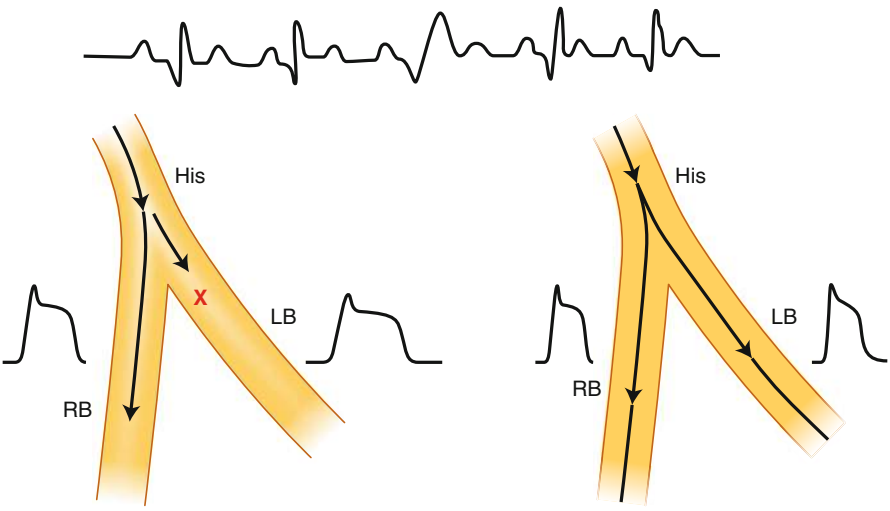

Fig. 1.18 A very slight acceleration in the RR interval results in antegrade block in the left bundle (*LB*). An increase in the rate after this results in a narrowing of the action potential duration with normalization of the surface QRS

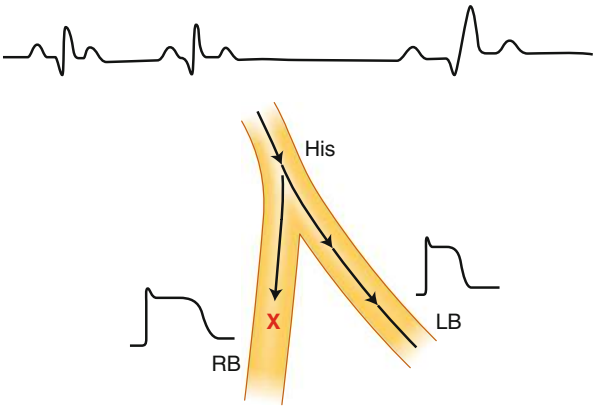

Fig. 1.19 A slow rate with a long pause results in prolongation of the action potential duration in both the right bundle (*RB*) and left bundle. A premature atrial complex (*PAC*) conducts through the His and conducts along the LB with block in the RB

occurs as a result of slow phase IV depolarization of the bundle branches resulting in refractoriness of one of the bundles as the atrial beat results in depolarization. This can be either a RBBB or LBBB pattern,

An example of deceleration dependent right bundle aberrancy is shown in Fig. 1.20. The His catheter is positioned so that the proximal electrogram is recording a His deflection and the distal recording is recording a right bundle potential.. The first beat shows a His potential on the proximal electrogram and a right bundle potential on the distal electrogram followed by ventricular activation. Following this a PAC is introduced by pacing the high RA (arrow). The following beat shows a His potential on the proximal electrogram with no right bundle potential on the distal electrogram and a characteristic RBBB pattern on the surface ECG.

4. **Concealed retrograde conduction**
   This occurs when retrograde conduction in one of the bundle branches from a PVC results in refractoriness for the next antegrade beat. As the bundle recovers the next beat which conducts down the contralateral bundle conducts retrogradely up the bundle again (Fig. 1.21). This continues until a different PVC alters the activation retrograde activation of the bundle. This is a relatively common cause of aberrancy during SVT.

ECG Signal Acquisition

The ECG is used to record the alterations in electrical potentials during the cardiac action potential. Any number of leads can be recorded in order to electrically visualize the heart from different angles.

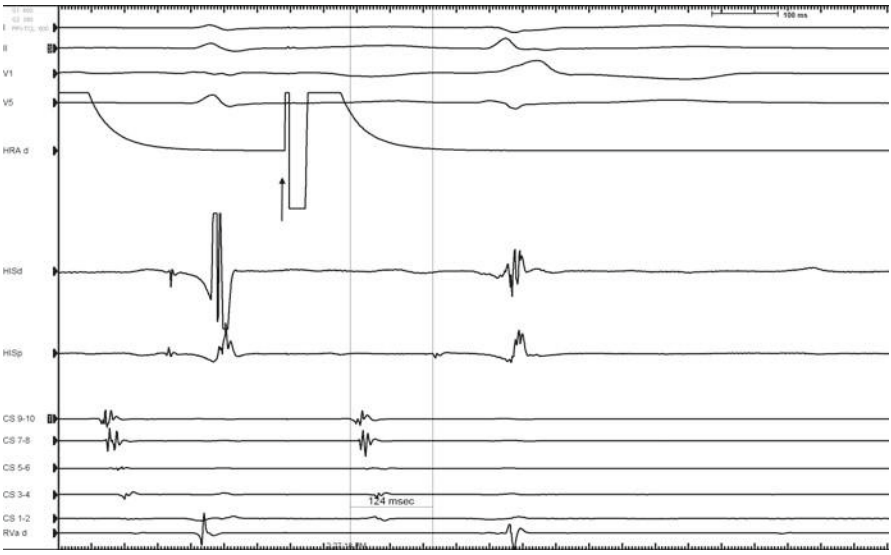

Fig. 1.20 Electrograms showing right bundle abberancy from a PAC (from HRA pacing labeled with an *arrow*). The HIS d is positioned along the proximal right bundle while the HIS p is positioned along the His. The PAC conducts along the His but does not conduct down the right bundle (no RB potential on HIS d on the second beat) with a RBBB morphology QRS. (CS 9–10 is positioned in the proximal CS with CS 1–2 in the distal CS. RV a is positioned in the RV apex)

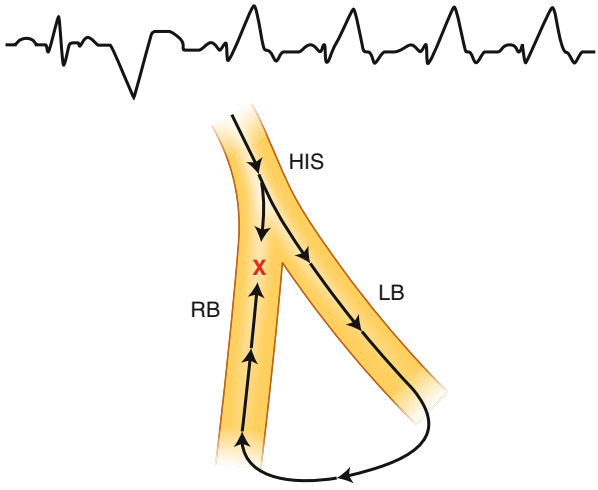

Fig. 1.21 Following the first sinus beat a PVC conducts retrogradely up the right bundle (RB) resulting in antegrade block in the RB with conduction down the left bundle (LB) (from third beat onwards). These beats then conduct retrogradely up the RB which is no longer refractory

The standard 12 lead ECG is composed of six unipolar precordial leads positioned as follows across the anterior chest wall:

V1 4th Intercostal Space Right Parasternal
V2 4th Intercostal Space Left Parasternal

V3 Midway between V2 and V4
V4 5thIntercostal Space Mid Clavicular Line
V5 5th Intercostal Space Anterior Axillary Line
V6 5th Intercostal Space Mid axillary line

The locations of these leads relative to the cardiac chambers can be seen on Fig. 1.22.

Each lead records electrical activation between the precordial electrode and **Wilsons Central Terminal** (WCT). This is a theoretical point close to zero potential created from the electrodes between the right arm, left arm and left leg (Fig. 1.23). These vectors create three bipolar leads I (right arm to left arm), II (right arm to left leg) and III (left arm to left leg) through three large resistors. The electrical activation between these three leads therefore cancels out to come close to a zero potential (WCT). The remaining three leads aVR, aVL and aVF are augmented unipolar leads created from the limb electrodes and referenced to **Goldberger's Central Terminal** (GCT) rather than WCT. GCT is created from two of the three

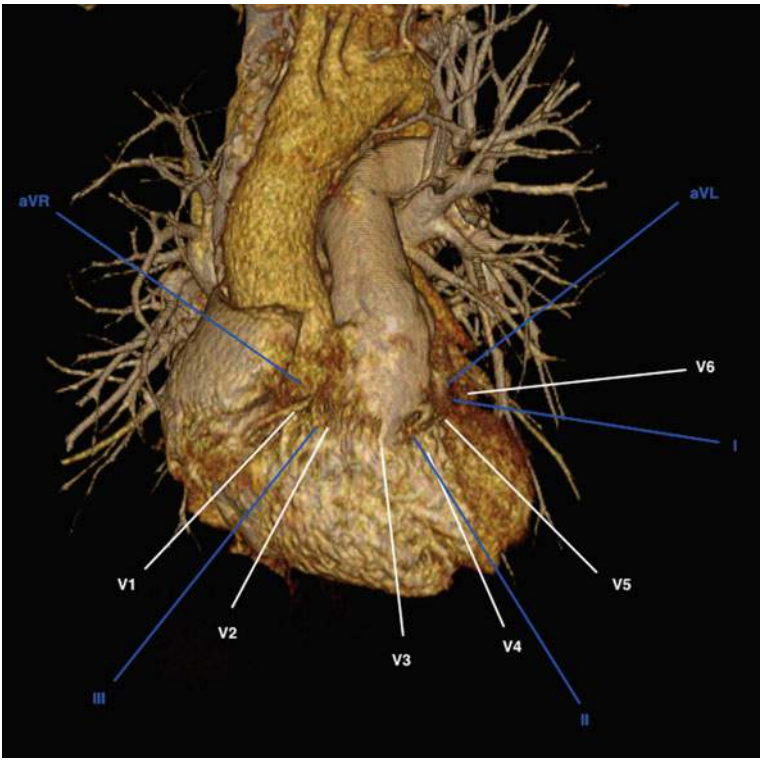

Fig. 1.22 CT Image of the Thorax showing the positions of the surface ECG leads relative to the cardiac chambers. The precordial leads V1–V6 are seen as well as the augmented leads aVR, aVL, II, III and aVF

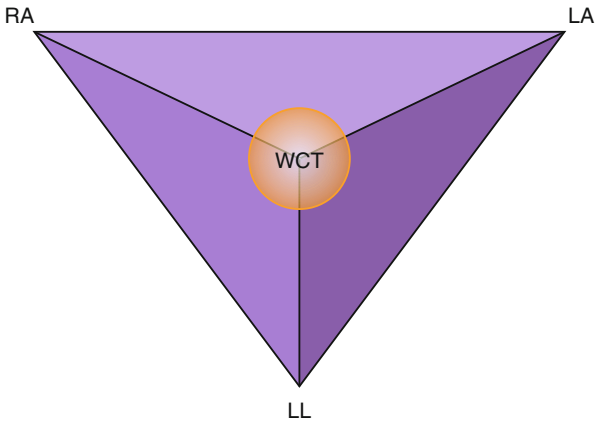

Fig. 1.23 Diagrammatic Representation of an ECG Vector created from the ECG leads from the Right Arm (*RA*), Left Arm (*LA*), Left Leg (*LL*) and Wilsons Central Terminal (*WCT*)

limb leads. When aVR is being recorded the GCT is composed of left arm and left leg, for aVL this is formed by right arm and left leg and for aVF is the right arm and left arm.

The right leg lead is used to introduce a current to the patient in order to maintain a voltage equivalent to that of the amplifier. This feeds back an inverse of potential low frequency interference and which increases if this lead is disconnected.

The QRS axis refers to the mean direction of ventricular activation in the frontal plane. In order to calculate the QRS axis the first step is to identify a limb lead where the QRS complex is isoelectric. In theory, the overall direction of electrical activation should be perpendicular to this. As there are two potential perpendicular directions, the leads either side of the isoelectric lead need to be examined and the axis is in the direction of the more positive lead. For example, if the QRS complex is isoelectric in lead I and positive in lead II, the QRS frontal axis is +90. In general principles the QRS axis shifts for several reasons. If there is chamber hypertrophy the QRS axis will shift in the direction of the hypertrophied ventricle as there is a greater component of electrical activation in that direction. In bundle branch block, activation moves from the opposite side to the side with the bundle branch block and therefore the axis will be in the same direction. In cases of myocardial infarction, the axis tends to move in the opposite direction away from the infarcted tissue.

Autonomic Innervation of the Heart

There is a continual balance between the two main components of the autonomic nervous system; the **sympathetic** (**adrenergic**) and **parasympathetic** (**vagal**) **innervation**.

The sympathetic efferent neurons innervate the SN as well as the atria, AV node and ventricles acting principally on the beta-adrenoceptors. Increased sympathetic

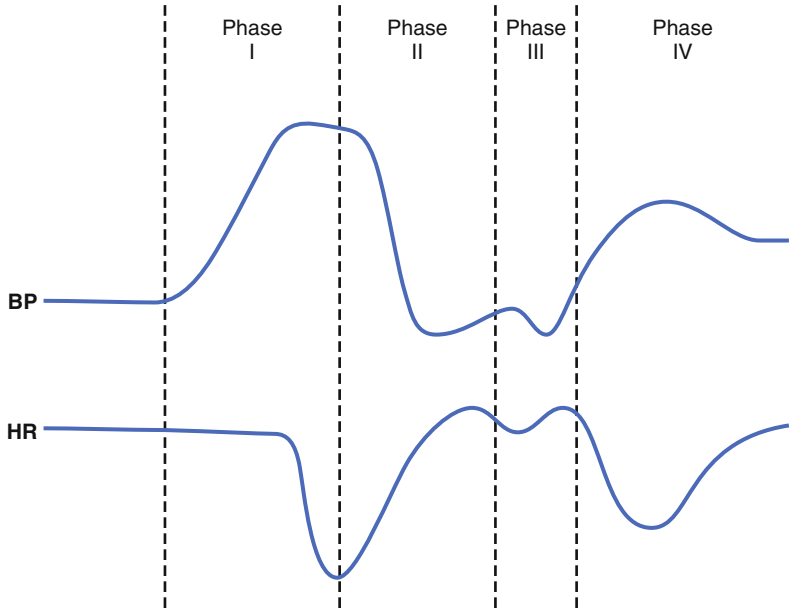

Fig. 1.24 Phases of the valsalva maneuver. The initial rise in intrathoracic pressure results in a elevation in blood pressure (*Phase I*) with a stable and then compensatory drop in heart rate. As well as an elevation in aortic pressure there is a reduction in preload which results in a drop in blood pressure with a rise in heart rate (*Phase II*). As the actual maneuver ends pressure on the aorta is reduced and the blood pressure transiently decreases with a resulting increase in the heart rate (*Phase III*). As the cardiac output increases to normal the blood pressure then increases with a compensatory drop in heart rate (*Phase IV*)

activity results in positive inotropy, positive chronotropy and an increased conduction velocity.

The parasympathetic (vagus) nervous system synapses with ganglia acting on muscarinic receptors in the heart. In general the right vagus innervates the SA node while the left vagus innervates the AV node. The vagus nerve innervates the atria to a lesser extent. There is minimal innervation of the ventricles. Increased vagal stimulation results in negative chronotopy and reduced conduction velocity. Given the lack of vagal innervation in the ventricles there is minimal inotropy.

There are several methods of assessing autonomic activity of the heart including the **valsalva maneuver** and the **tilt table test**.

The valsalva maneuver is performed by exhaling with a closed glottis for a period of 10 s therefore increasing intrathoracic pressure. There are four phases as depicted in Fig. 1.24.

Phase I: Transient increase in blood pressure with no change in heart rate as a result of compression of the ventricles and aorta.

Phase II: A significant reduction or plateau in blood pressure as a result of compression of the intrathoracic vena cava reducing venous return. As a result of this

there is a baroreflex mediated increase in heart rate via the sympathetic nervous system.

Phase III: As the maneuver has now stopped the intrathoracic pressure returns to normal reversing phase I and resulting in a reduction in left ventricular output and an increase in right ventricular output as a result of an increase in venous return.

Phase IV: As the venous return increases further there is an increase in the cardiac output and blood pressure. This results in stimulation of baroreflex which increases parasympathetic activity resulting in a reduction in heart rate.

A tilt table test may be useful in patients with a history of pre-syncope, syncope or postural symptoms such as palpitations when structural heart disease has been excluded. During this test the patient is attached to a specialized table and positioned at a 60–70 degree angle. The ECG and non-invasive blood pressure are continually monitored. Although some laboratories do not gain an intravenous (IV) due to the potential effects on vagal tone, it is reasonable to insert an IV for the administration of pharmacological agents and wait for 15 min prior to commencing the test.

The patient is monitored in the supine position for five minutes and then placed in an upright position at a 60–70 degree angle. The heart rate and blood pressure are monitored and recorded every five minutes for 45 min. If there is an acute drop in blood pressure or loss of consciousness, the table is returned to the supine position. Some centers administer 300–400 microgrammes of sublingual nitrate within the last five minutes of the study while others repeat a negative tilt table test with the administration of isoprenolol at a rate of 1–3 microgrammes per minute in order to increase the heart rate by 25 % above the baseline. It is not uncommon to get a slight drop in blood pressure with isoprenolol and therefore this test is generally only considered positive if syncope occurs. Carotid sinus massage can often be performed either in the supine or erect position, the latter having a slightly higher yield.

Carotid sinus hypersensitivity is defined as a ventricular pause greater than or equal to three seconds with or without a drop in systolic blood pressure by $\geq$50 mmHg. If there is associated syncope then this is defined as carotid sinus syndrome. Carotid sinus hypersensitivity is more common in the elderly and in males, and is extremely uncommon in individuals under the age of 40 years. Carotid sinus massage should not be performed in patients with a prior transient ischemic attack or stroke within the prior three months, or in patients with a carotid artery bruit unless significant carotid artery disease has been excluded on carotid dopplers. Both nitrates and isoprenolol increase the sensitivity but reduce the specificity of the tilt table test.

If syncope occurs in association with bradycardia or reflex hypotension the diagnosis is **neurocardiogenic syncope**. If the major precipitant is bradycardia this is **cardio-inhibitory**, and if the major precipitant is hypotension it is **vasodepressor**.

Postural Orthostatic Tachycardia syndrome (**POTS**) is defined as an increase of heart rate of greater than or equal to 30 bpm or a rate of greater than or equal to 120 bpm within the first 10 min of moving from a supine to erect position with

associated symptoms [29]. Other potential causes such as medications or prolonged bed rest which may alter vascular tone should be excluded prior to making this diagnosis.

POTS can be divided into either partial dysautonomic or hyperadrenergic types.

In **partial dysautonomic POTS** the increase in heart rate is partially due to increased blood pooling in the lower limbs as a result of an alteration in the control of vascular tone.

In **hyperadrenergic POTS** there is often an associated increase in blood pressure associated with the increase in heart rate.

The tilt table results depend on the age of the patient, with younger patients more likely to have cardioinhibitory neuro- cardiogenic syncope, and older patients more likely to have vasodepressor neurocardiogenic syncope.

Important Points to Remember

1. The cardiac action potential is composed of 4 phases.

   Phase IV (resting membrane potential) occurs with a membrane potential of −80 to −95 mV in atrial, purkinje and ventricular cells, −50 to −60 mV in the SN and −60 to −70 mV in the AV node. In both the SN and AV nodes there is a slow spontaneous diastolic depolarization which merges with Phase 0 resulting in spontaneous automaticity while Phase IV in other cells is generally more flat.

   Phase 0 (rapid depolarization) occurs when the membrane potential becomes positive.

   Phase I (rapid repolarization) occurs in the atrium and ventricle but not in the SN and AV node. It is much more prominent in the purkinje and epicardial cells.

   Phase II (plateau phase) occurs when the action potential becomes relatively flat and does not occur in the SN or AV node.

   Phase III (rapid repolarization) occurs when there is restoration of the membrane potential to the resting phase.

2. Refractoriness describes the period during which a stimulus does not result in a new depolarization after phase 0 of the cardiac action potential. There are three different types of refractory periods (RP): relative, absolute and effective.

   The relative RP is the longest coupling interval resulting in local capture therefore marking the end of refractoriness.

   The absolute RP is the longest coupling interval which does not result in local capture.

   The effective RP is the longest coupling interval delivered which fails to propagate through the distal tissue.

3. Re-Entry occurs when a wave of excitation moves around a circuit which is determined anatomically, functionally or a combination of the two. For re-entry to occur the following conditions have to be fulfilled:

   There must be two or more pathways for conduction
   Unidirectional block in one pathway
   Alternative conduction over the other pathway with sufficient delay as to retrogradely invade the formerly blocked pathway

4. Automaticity results from spontaneous depolarization during phase IV of the action potential.
5. Afterdepolarizations are defined as depolarizations which occur after Phase 0 of the cardiac action potential and may result in a spontaneous action potential known as a triggered response. These are divided into early afterdepolarization (EAD) or delayed afterdepolarization (DAD).

   EAD occurs during phase II and phase III while DAD occur after the cardiac action potential is complete. EADs tend to occur when there is an increase in the inward movement of positive ions during the plateau phase of the action potential.

   DADs occur as a result of an increase in the inward movement of calcium. This can occur in the setting of digoxin toxicity or in conditions such as catecholamine induced polymorphic ventricular tachycardia (CPVT).
6. The RAO projection helps to demonstrate the postero-anterior (PA) location of a catheter within the cardiac chambers and shows the AV groove more clearly than the PA view. In this view the spine is on the left.
7. In the LAO view the AV rings are viewed parallel to the image. The left cardiac border is formed by the LA superiorly and the lateral wall of the LV inferiorly.
8. Following discharge from the SN conduction occurs through the RA predominantly utilizing aligned myocytes. Conduction occurs preferentially from the RA to the LA using the Bachmann's bundle.
9. AV conduction occurs through the AV junctional region, the atrial component of which is termed the AV node. This is located between the coronary sinus os and the septal leaflet of the tricuspid valve.
10. The His bundle is a continuation of the compact AV node. Although it has similar cellular components it is better insulated than the AV node and therefore is not as easily damaged with RF. The proximal bundle runs from the distal AV node to the fibrous tissue of the central body where it is termed the penetrating portion. Following this it bifurcates into the right bundle (RB) and left bundle (LB) branches at the level of the septal TV leaflet. The RB tends to have a more anterior origin than the LB.
11. The LB branch originates below the right and non-coronary cusps and then courses along the LV septal surface. It divides into two or three

fascicles. The anterior fascicle which is superior runs towards the base of the anterosuperior papillary muscle, the posterior fascicle which is inferior runs towards the posteroinferior papillary muscle and in 60% of cases a central or septal fascicle which runs to the mid septum. In the remaining 40% of cases this area is supplied by the anterosuperior and posteroinferior fascicles.

12. In LBBB the initial activation is rightward and anterior resulting in small q waves in I, avL, and V6 with an rS in V2. Following this depolarisation spreads from the apex to the base and to the RV free wall and apex. During this process, septal activation is the pre- dominant force and therefore the vector is anterior and to the left, resulting in a wide slurred QRS in I, aVL and V6. Depolarization then occurs in a leftward and posterior direction through the LV. Finally, the anterior wall of the LV is depolarized.
13. Anterior fascicular block results in a leftward QRS axis deviation poor R wave progression in V1-V3, with a negative QRS in II, III and aVF, positive in lead I. There is also a tall R wave in aVL and aVR. The QRS is not broad.
14. Posterior fascicular block results in a QRS axis greater than 100° with an rS morphology in leads I and aVL; and a qR pattern in leads II, III, and aVF. The QRS is not broad.
15. Septal fascicular block has a variable ECG appearances. In general the changes noted are Q waves in V1 and V2 as a result of anteriorly directly right ventricular depolarization. This may also cause a qrS in V1 and V2. There is also loss of q waves in leads V5, V6 and I due to loss or reversal of left to right ventricular septal activation. The QRS is not significantly broad because activation of the left ventricular free wall and apex occurs via the anterosuperior and posteroinferior fascicles.
16. The RB branch is an insulated bundle of fibers as a direct continuation of the penetrating atrioventricular bundle. It runs along the RV septum to the apex where it becomes subendocardial in the mid septum running along the posterior margin of the septal band, courses through the moderator band to the base of the anterior papillary muscle, and then the right ventricular free wall. It gives off septal branches which activate the septum almost immediately after left ventricular activation. Septal activation is generally complete within 35 ms and terminates in Purkinje fibres at the apex.
17. In RBBB the initial septal activation is followed by depolarization of the left ventricle, resulting in R waves in I, aVL and V6. Following this, right ventricular free wall and septal depolarization results in S waves in these leads. Overall, the QRS is ≥120 ms in adults with an rsr, rsR, or rSR in leads V1 or V2. The R or r deflection is usually wider than the initial R wave. ST segment deviation is generally discordant to the QRS vector.

18. Phase III dependent aberrancy also known as Ashman Phenomenon occurs when a short RR interval follows a longer RR interval. The longer RR interval results in a prolonged AP in the His and bundle branches. The right bundle has a longer AP duration than the left bundle and therefore the following beat with the shorter RR interval is blocked in the right bundle which is still refractory and conducts down the left bundle with a RBBB morphology.
19. Acceleration dependent aberrancy occurs with very slight acceleration of the heart rate (less than 5 ms) at a critical cycle length which is often within normal heart rate ranges. This tends to occur more commonly in the left bundle resulting in LBBB.
20. Deceleration dependent aberrancy occurs following a long pause during which a premature atrial beat conducts to the ventricle with a resultant bundle branch block.
21. Aberrancy due to concealed retrograde conduction occurs when retrograde conduction in one of the bundle branches from a PVC results in refractoriness for the next antegrade beat. As the bundle recovers the next beat which conducts down the contralateral bundle conducts retrogradely up the bundle again.

Chapter 2
Cardiac Electrophysiology Study, Diagnostic Maneuvers and Ablation

Benedict M. Glover, Orla Buckley, Siew Yen Ho, Damian Sanchez-Quintana, and Pedro Brugada

Abstract The overall aim of an invasive electrophysiological (EP) evaluation is to accurately diagnose the mechanism and substrate responsible for a documented or suspected arrhythmia to treat the patient's symptoms or improve his/her prognosis. Significant developments in the understanding of arrhythmias as well as technological advances have allowed electrophysiology studies to be considered as a diagnostic first line option. This chapter discusses the fundamental principles of invasive electrophysiology and provides an essential guide in terms of establishing the correct diagnosis and ablation strategy.

Indications for an EP Study and Ablation

The overall decision on whether to perform an EP study and ablation depends on the balance between the potential benefits, alternative treatment options, risks as well as the individual patient preference. In general for symptomatic supraventricular

arrhythmias an EP study and ablation should be considered early as the success rates are high and the results of pharmacological treatment are often suboptimal. The decision for the invasive management of AF and VT is often more complex and requires very careful examination of the patients symptoms and potential complications which must be balanced against alternative treatment options. As techniques and technology improve for more complex ablations the threshold for an invasive strategy is already clearly changing.

Supraventricular Arrhythmias (SVT)

Ablation can be considered as first line therapy for the treatment of symptomatic SVT due to AV nodal re-entry tachycardia (AVNRT), atrioventricular re-entry tachycardia (AVRT) or atrial tachycardia (AT) (Class I Indication, Level of Evidence B) [1]. Although it is ideal to have inducible tachycardia at the start of the EP study this is not critical and it is entirely reasonable to perform an ablation if either dual AV nodal anatomy or accessory pathway conduction is present in the setting of electrocardiographic evidence of an SVT.

The issue of ablation in the setting of asymptomatic ventricular pre-excitation is somewhat more complex. Ablation is indicated in patients with high-risk occupations such as pilots, scuba divers and school bus drivers [1]. Inducibility of AVRT in the absence of symptoms may be considered as an indication for ablation although this is not a clear cut decision and may also depend on patient and physician preference as well as the conduction properties of the pathway. Accessory pathways that can lead to rapid ventricular rates during atrial fibrillation should be ablated.

Atrial pacing may be used to calculate the antegrade refractory period of the AP with a measurement greater than 250 ms being considered lower risk. The **Shortest Pre-Excited R-R Interval** (**SPERRI**) may be a more useful measurement with an RR interval greater than 250 ms probably being associated with a lower risk. These measurements may help to guide the decision regarding ablation of an AP.

Typical Atrial Flutter

Typical atrial flutter involving the cavo-tricuspid isthmus (CTI) can be successfully ablated in the majority of cases. An ablation may be considered after a single episode of typical atrial flutter (Class IIa Indication; Level of Evidence B) or following a recurrent episode (Class I Indication; Level of Evidence B) [1]. Ablation can also be considered for atypical atrial flutter (Class IIa Indication; Level of Evidence B) although the overall success may not be as high as for typical atrial flutter [1] (Fig. 2.1).

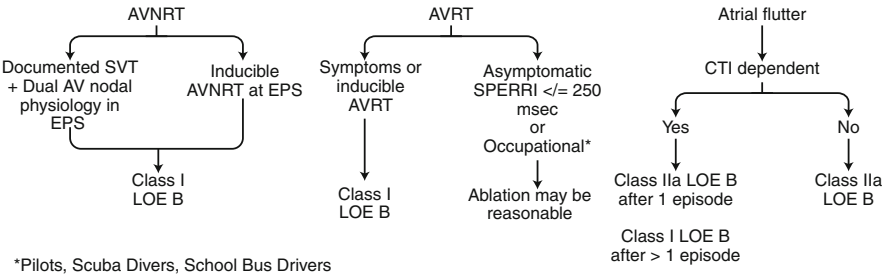

Fig. 2.1 Decision tree for ablation for AV Nodal Re-entry Tachycardia (*AVNRT*), AV Re-entry Tachycardia (*AVRT*) and Atrial Flutter regarding consideration for Catheter Ablation. *SPERRI* shortest pre-excited R-R interval)

Atrial Fibrillation (AF)

In order to consider a catheter ablation for a patient with AF the patient must have symptoms attributed to the arrhythmia. This is extremely important as symptoms may be non-specific and therefore it is often useful to consider an electrical cardioversion and reassess after sinus rhythm has been established. Additionally all patients who are being considered for a catheter ablation must be able to tolerate anticoagulation therapy at least during and after their ablation [2]. There is insufficient data to support routine withdrawal of oral anticoagulation following an AF ablation even if it appears successful and the longer term decision regarding oral anticoagulation should be based on the CHADS2VASC score [2]. This is because patients may continue to have asymptomatic episodes of AF which continue to pose a thrombo-embolic risk.

For patients with symptomatic paroxysmal AF catheter ablation can be considered if at least one Class I/III anti-arrhythmic drug has been tried and is ineffective or poorly tolerated. (Class I Indication, Level of Evidence A) [2]. Catheter ablation may also be considered prior to commencing a Class I/III antiarrhythmic drug in some patients with symptomatic paroxysmal AF. (Class IIa Indication, Level of Evidence B) [2].

Catheter ablation may also be considered in patients with symptomatic persistent AF not controlled effectively with at least one Class I/III antiarrhythmic drug. (Class IIa Indication, Level of Evidence A)

The recommendations and evidence for performing catheter ablation for symptomatic persistent AF prior to commencement of a Class I/III antiarrhythmic drug are not as strong. (Class IIb Indication, Level of Evidence C) [2]. Catheter ablation can also be considered for the management of longstanding persistent symptomatic AF (Class IIb Indication, Level of Evidence B) although the overall success for such a procedure may not be high. If available in the center, a hybrid ablation with thoracoscopic approach and closure of the left atrial appendage offers a better future in these patients [3] (Fig. 2.2).

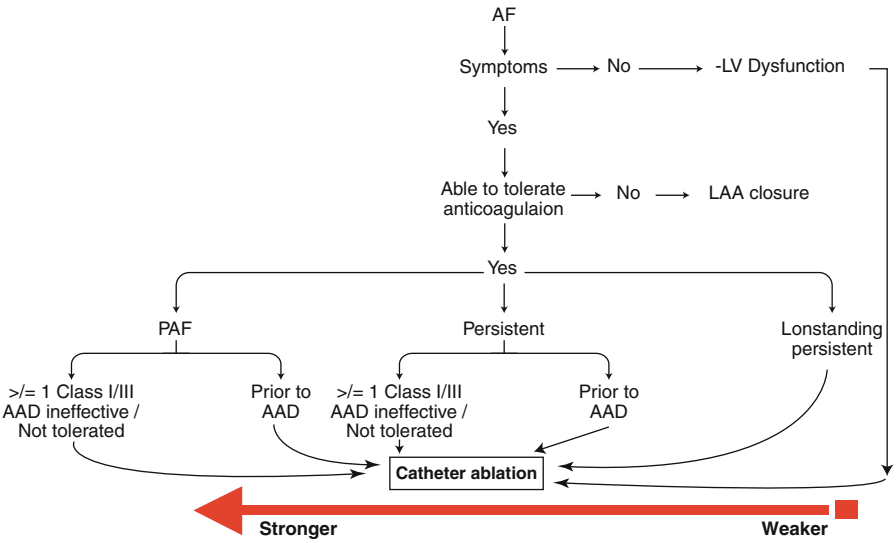

Fig. 2.2 Decision tree for consideration for catheter ablation for atrial fibrillation. *AAD* anti-arrhythmic drug therapy

Ventricular Arrhythmias

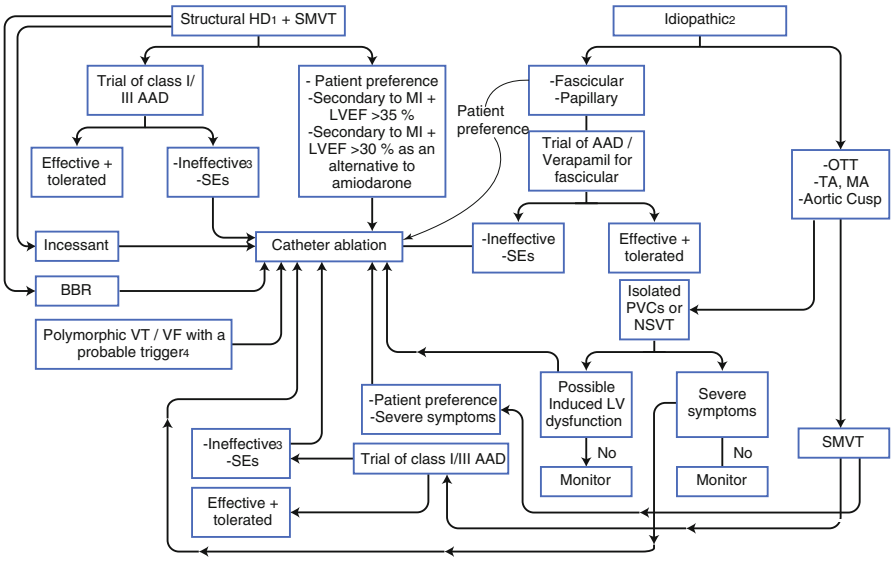
Catheter ablation is recommended for patients with sustained monomorphic VT including VT terminated by an ICD where anti arrhythmic drug therapy is either ineffective or not tolerated as well as the control of incessant VT [4].

It may also be considered when anti-arrhythmic drug therapy has not failed and in particular may be a suitable alternative to amiodarone therapy. Catheter ablation is also recommended for bundle branch re-entry VT and interfascicular VT and for patients with frequent PVC's or non sustained VT resulting in left ventricular dysfunction. It is not recommended for the treatment of asymptomatic PVC's or non-sustained VT not resulting in left ventricular dysfunction (Fig. 2.3).

EP Study and Ablation: Patient Preparation

The most useful test for any patient prior to an EP Study is an ECG or rhythm strip of the arrhythmia as this may guide the entire approach, chamber of access and threshold for potential ablation.

A baseline ECG should be performed as well as electrolytes and urea, full blood count and an international normalized ratio for patients taking warfarin [5].



1 Previous Myocardial Infarction; Dilated cardiomyopathy; ARVC; Congenital Heart Disease

2 Outflow Tract Tachycardia; Annular Tachycardia, Aortic Cusp Tachycardia; Fascicular VT; Papillary Muscle VT

3 ≥ 1 episode of MSVT despite the use of ≥ 1 antiarrhythmic drug

4 For either structural or idiopathic VT

Fig. 2.3 Decision tree for the ablation of ventricular arrhythmias. *HD* heart disease, *SMVT* sustained monomorphic VT, *SE* side effects, *BBR* bundle branch re-entry, *OTT* outflow tract tachycardia, *TA* tricuspid annulus, *MA* mitral annulus

Additionally a pregnancy test in any female of childbearing age should be checked within the 2 weeks prior to the procedure [5].

For potentially high risk procedures a group and crossmatch should be considered.

In general for most diagnostic studies anti-arrhythmic drugs should be stopped for at least 5 half lives. This is not required in patients undergoing catheter ablation unless an EP study or rotor mapping is also being performed.

EP Study and Ablation: Potential Risks

The risks associated with EP studies and ablation vary greatly depending on the procedure being performed. General complications include groin hematoma, vascular injury and pericardial effusion. More specific complications may occur in AF and VT ablations. In general many of these risks can be significantly minimized if care is taken and appropriate action taken. These risks, as well as preventative measures are summarized on Table 2.1.

Table 2.1 Reported incidence, features, prevention and management of potential complications associated with EP procedures

Complication	Features	Prevention and management	Reported incidence (%)	
Groin hematoma Pseudoaneurym AV Fistula	Swelling Tenderness Bruit	Careful palpation of femoral artery Medial approach to the vein Careful post procedure groin management	SVT	0.3 [6] – 0.4 [7]
			AF	1.8 – 2.7 [8]
			VTs	2.0 – 3.6 [9]
			VTsn	0.7 – 0.8 [10]
AV Block	PR prolongation Loss of AV conduction	Map His prior to ablation If close to compact AV node consider lower energy RF or cryoablation Monitor for Accelerated Junctional rhythm, loss of VA conduction, prolongation of AH or PR interval	SVT	0 [7] – 1 [11]
			AF	0.1 [8] – 0.2 [12]
			VTs	0 [6] – 1.6 [13]
			VTsn	0 [6] –0.4 [10]
Coronary Artery Injury	ST elevation Chest pain	Careful use of RF in certain locations of the coronary sinus, LVOT, epicardium. Do not deliver RF if closer than 5 mm	SVT	0 [7] – 0.1 [14]
			AF	0 [7] –0.1 [15]
			VTs	0.6 (epi) [16]
			VTsn	<0.1 [17]
Pericardial Effusion	Hypotension Tachycardia Change in left heart border motion in LAO view Accumulation of pericardial effusion on ICE/TEE	Caution when manipulating catheter, sheaths and wires Cautious use of RF in certain areas considered higher risk such as RVOT, RV apex, RV free wall, LAA, LA roof and LA posterior wall Monitor closely during trans–septal access	SVT	0.4 [18] – 1.0 [7]
			AF	1.8 [7] – 2.5 [8]
			VTs	1.4 [7] – 2.7 [19]
			VTsn	1.3 [20] – 1.7 [7]
Thrombo-embolism	TIA/stroke Systemic embolism	Maintain ACT greater than 350 s for left sided ablations Use of heparinized saline through sheaths on left side Careful use of equipment to ensure no air embolism	SVT	0 [7] – 0.2 [11]
			AF	0.3 [7]–1.0 [5]
			VTs	0.8 [7]–2.7 [18]
			VTsn	0.8 [7]
Phrenic Nerve Injury	Loss of movement of hemidiaphragm, post procedure dyspnea, pleural effusion, consolidation on CXR	Monitor movement of hemidiaphragm Pacing from ablation catheter to monitor for phrenic nerve capture	SVT	<0.1
			AF	0.2 [9]
			VTs	<0.1
			VTsn	<0.1

VTs VT ablation in the setting of structural heart disease; *VTns* VT ablation in structurally normal ventricle; *Epi* Epicardial

Collateral Damage During Ablation

Pericardial Effusion

Pericardial effusion may occur as a direct result of catheter, sheath or wire manipulation as well as during or after trans-septal access or as a direct result of catheter ablation. It is therefore important to be gentle with all of the equipment being used. Some regions within the heart are particularly thin and extra caution should be taken. As demonstrated in Fig. 2.4 these regions include the RV apex, RV free wall, RVOT, LAA, LA posterior wall and LA roof. A pop and/or sudden rise in impedance during ablation may be associated with perforation. The incidence of perforation resulting in either a pericardial effusion or tamponade is 1.3 % for all EP procedures [7]. For SVT ablations this is 0.2 %, 1.8 % for patients undergoing catheter ablation for AF, 1.7 % for VT in a structurally normal heart (predominantly outflow tract tachycardia) and 1.4 % in patients with structural heart disease undergoing VT ablation [7].

Although the pericardial space may accommodate up to 500 cc of fluid accumulated over a long period of time decompensation may occur with 50–100 cc when

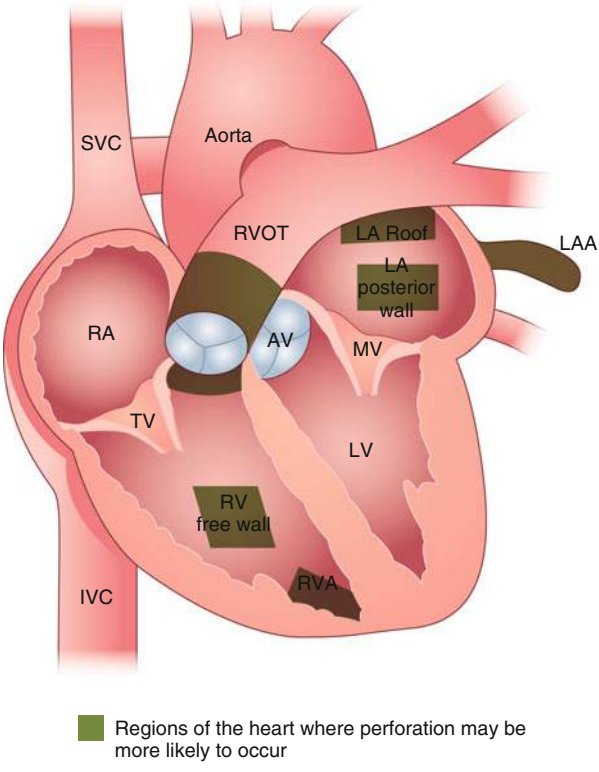


Fig. 2.4 Diagrammatic representation of regions of the heart which are at an increased risk of perforation during instrumentation with catheters and wires; *SVC* superior vena cava, *IVC* inferior vena cava, *RA* right atrium, *TV* tricuspid valve, *RV* right ventricle, *RVOT* right ventricular outflow tract, *LA* left atrium, *LV* left ventricle, *LAA* left atrial appendage

fluid accumulation occurs quickly. This tends to be most evident around chambers with the lowest pressures first; the RA followed by the RV, LA and finally the LV. Accumulation may also be localized and therefore may occur on the left side prior to the right side.

The accumulation of a significant pericardial effusion may be associated with an increase in heart rate with or preceding a drop in blood pressure. It must also be noted, however, that an increase in sympathetic drive may initially result in an increase in the blood pressure. Pericardial stretch may occasionally result in an increase in parasympathetic tone with a transient bradycardia and hypotension. A drop in blood pressure is a relatively late sign of acute pericardial effusion and it is therefore important to monitor for earlier signs.

A reduction in the left lateral wall excursion in the LAO fluoroscopic view has been shown to be associated with pericardial effusion [21]. This occurs as the pericardium is relatively fixed to the spine and the sternum and therefore fluid in the pericardial space is more likely to accumulate posterolaterally followed by anterolaterally. The accumulation of pericardial fluid during ablation can easily be observed using Intracardiac Echo (ICE) or Trans-esophageal echo (TEE). The accumulation of a small pericardial effusion detected on ICE during an AF ablation may indicate an increase in the risk of a late post procedure pericardial effusion while no evidence of effusion on ICE indicates a very low post procedural risk.

All EP laboratories should have equipment for emergency pericardiocentesis including rapid access to echocardiography. In order to keep this as simple as possible the needle used to access the femoral vein and a 0.35 wire can be kept on the table for rapid access. After confirmation that the wire is within the pericardial space by pushing it as far as possible and ensuring that it is not within one or more cardiac chambers a short sheath and a pigtail catheter can be used to rapidly drain the effusion.

Phrenic Nerve Injury

The right phrenic nerve runs alongside the SVC and passes laterally along the RA running anteriorly to the right pulmonary veins passing more closely to the superior than the inferior right pulmonary vein (Fig. 2.5). The left phrenic nerve runs over the fibrous pericardium with a variable course over the LA and LV and terminates in the left hemidiaphragm. The incidence of phrenic nerve palsy following an AF ablation is approximately 0.2% [8] and more commonly affects the right than the left side. This generally occurs with isolation of the right superior pulmonary vein or the superior vena cava. Left phrenic nerve palsy is less common but may occur in left atrial appendage ablation. The incidence of phrenic nerve palsy is much higher with cryoablation and has been reported to occur in approximately 6% of cases although it is usually transient [22].

Various techniques may be used to help map the location of the phrenic nerve before or during catheter ablation. Pacing at high output may be performed in order to assess for phrenic nerve capture. This should be discussed with the anesthesiologist

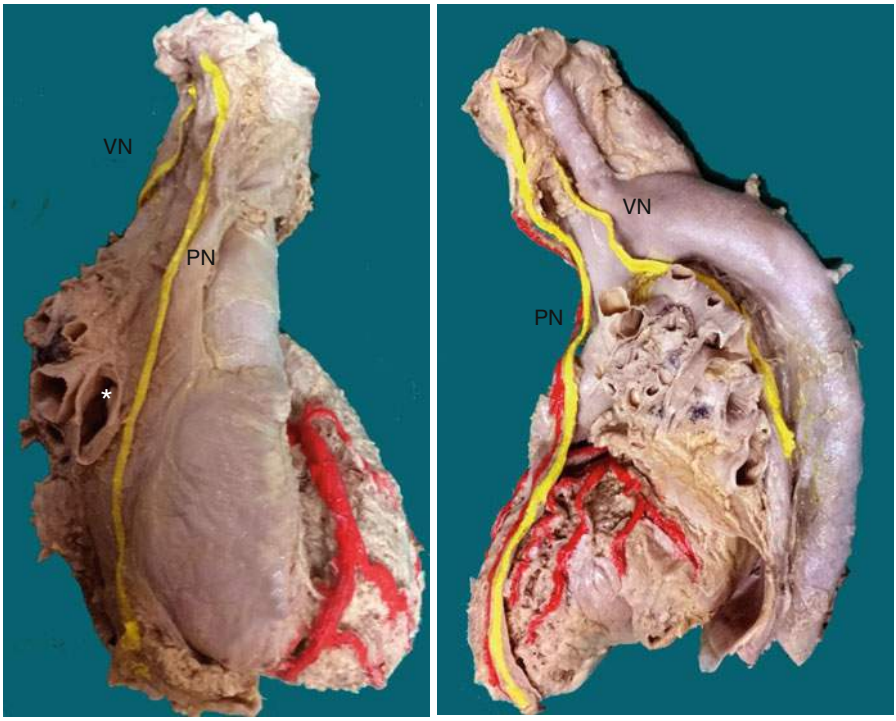

Fig. 2.5 Anatomical images showing the course of the right phrenic nerve (PN) on the *left image* and the left phrenic nerve (PN) on the *right image*. The right lareral view on the *left* shows the close relationship of the right PN to the right inferior pulmonary vein (*). The vagus nerve is also seen in both images

prior to performing this maneuver as muscle relaxants are often administered which will inhibit the effects of pacing on the phrenic nerve. Additionally the diaphragm can be monitored using fluoroscopy during ablation in the absence of nerve paralytic agents. More novel techniques such as recording electromyograms from the diaphragm have been described in which either a catheter is positioned in the hepatic vein or modified surface electrodes are positioned over the diaphragm with pacing performed from either subclavian vein.

Phrenic nerve palsy is generally noted on CXR as an elevated hemidiaphragm and may be associated with dyspnea, a cough or hiccups. The majority of phrenic nerve palsy recovery within 9 months.

Esophageal Injury

As shown on the CT scan in Fig. 2.6 the esophagus is immediately posterior to the LA separated by a thin layer of fibrous pericardium and a layer of fibrofatty tissue containing esophageal arteries as well as the vagus plexus. The distance between the

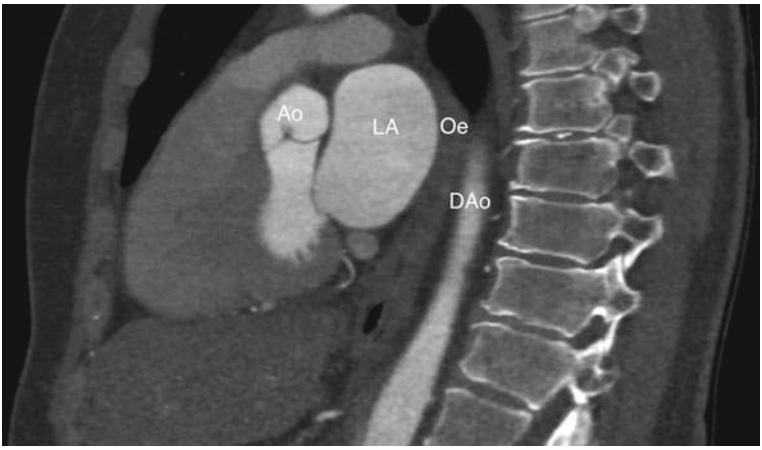

Fig. 2.6 CT showing proximity of esophagus to the posterior wall of the left atrium. In this lateral image the ascending aorta (*Ao*) is anterior to the left atrium (*LA*). The oesophagus (*Oe*) is posterior to the left atrial wall. Also seen in this image is the descending aorta (*DAo*)

posterior wall of the LA and the anterior portion of the esophagus is variable but may be as little as 5 mm [23]. The location of the esophagus may run either central to the posterior wall of the left atrium, towards the left pulmonary veins or towards the right pulmonary veins as is generally closer at the atrial pulmonary vein junction and in more inferior locations. Although the esophagus can be clearly visualized on a pre-ablation CT scan the esophagus is a mobile structure and therefore the location may change during the procedure.

Esophageal injury occurs predominantly as a result of direct thermal injury from catheter ablation along the posterior wall of the LA. Other contributing factors may include damage to the arterial flow to the esophagus as well as to the vagus nerve and plexus. This may result in mucosal erythema, esophagitis or atrioesophageal fistula. Discrete mucosal changes have been noted to be present in approximately half of all patients who undergo catheter ablation for AF with almost one fifth developing esophageal ulceration [24].

The incidence of fistula formation between the left atrium and the esophagus as a result of catheter ablation for AF ranges from 0.03 [25] to 0.2 % [26].

Symptoms relating to atrio-esophageal fistula may occur from 3 days to 6 weeks post ablation and are often non specific. The most common is a pyrexia followed by neurological symptoms relating to thrombo-embolism. Other symptoms include chest pain and dysphagia. The white cell count is generally elevated. Management depends on acute recognition of the condition followed by surgical repair.

Although the esophagus can be visualized pre-procedure this is generally unreliable due to intra-procedural movement. The esophagus can be visualized during ablation using fluoroscopy with a marker such as a naso-gastric tube, a temperature probe or barium paste. This requires fluoroscopy being performed during ablation

along the posterior wall of the left atrium and although it marks the lumen of the esophagus it does not provide an accurate distance from the ablation catheter to the most anterior aspect of the esophagus.

Esophageal temperature monitoring is performed by some operators using a temperature probe. Evidence for the efficacy in preventing esophageal injury is limited and conflicting and overall there is no general consensus as to whether luminal esophageal temperature is a good predictor of mucosal injury.

It is generally considered reasonable to limit maximum power to 25–30 W and to spend no longer than 30 s on one region when ablating along the posterior wall of the left atrium. It is also common to prescrive proton pump inhibitors post ablation in order to reduce the effects of acid reflux on the esophagus.

Coronary Artery Injury

This may occur if ablation is performed in close proximity to a coronary artery such as the aortic cusps. Other regions where ablation may be in close proximity to a coronary artery or one of its branches include the coronary sinus (as shown in Fig. 2.7), great cardiac vein, CTI, mitral annulus, base of the LAA or in the epicardium.

Endocardial ablation of accessory pathways along the mitral and tricuspid annulus carries a low risk of coronary artery stenosis. The risk is increased when ablation is performed in the proximal CS which may be the optimal location for posteroseptal AP's as well as occasionally the slow pathway and focal atrial tachycardia's. The posterolateral branch of the RCA or the circumflex coronary artery often run closely to this location and this may be a closer to the anterior and inferior walls of the

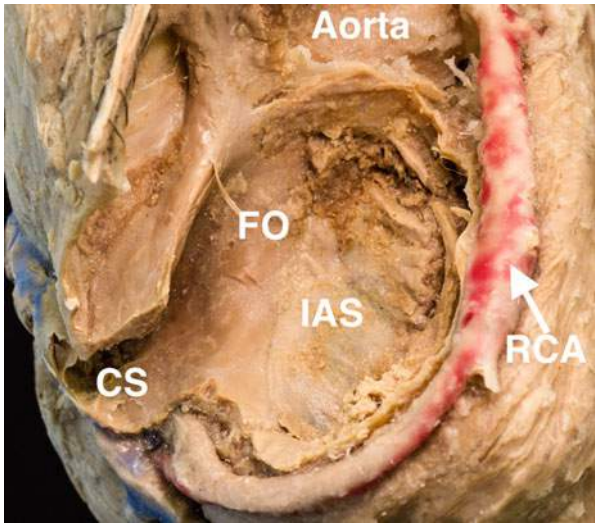

Fig. 2.7 Anatomical images showing proximity of the right coronary artery (*RCA*) to the coronary sinus (*CS*). The RCA originates in the right coronary cusp of the aortic root and courses along the right atrioventricular grove anteriorly and inferiorly where it eventually courses towards the proximal coronary sinus (*CS*). In this region there is close proximity to the CS. Also shown in this image is the right ventricular outflow tract (*RVOT*) and the fossa ovalis (*FO*)

CS. If ablation is being performed in this location a coronary angiogram should be considered and a minimum distance of 5 mm should be maintained between the site of ablation and the coronary artery.

Ablation in the distal cardiac vein for PVC's along the epicardial annulus may also result in coronary artery damage and similar precautions have to be taken in terms of distance.

Epicardial ablation is now increasingly performed particularly for non-ischemic VT and to a lesser degree ischemic VT. Coronary CT or angiography should be performed in these cases prior to ablation.

Important Note on Ionizing Radiation

Ionizing radiation may result in molecular injury to the DNA. In the EP laboratory this is measured in Grays (Gy) or Sieverts (Sv). One gray is defined as the absorption of 1 J of ionizing radiation by 1 Kg of matter. The equivalent dose Sievert is the absorbed dose in Gy multiplied by the radiation weighting factor which varies according to the source of radiation and is 1 for X-rays. This can be further modified in order to calculate the effective dose when the radiation is predominantly exposed to certain regions of the body. It is important to achieve as low as reasonably achievable (ALARA) radiation doses. This can be achieved by reducing the frame rate to as low as possible, minimizing the duration of time performing fluoroscopy and not taking cine images. The development of 3 D mapping systems has had a significant impact on reducing the need for fluoroscopy particularly in complex ablations.

Administration of Sedation and Anesthesia

The requirements for sedation and anesthesia vary according to the precise procedure being performed. For EP studies minimal doses of sedation are given for anxiolytic effects as larger doses may reduce the inducibility of the arrhythmia particularly in adrenaline sensitive focal atrial tachycardia and outflow tract tachycardia. Moderate doses of sedation are often required for ablation and in particular for performing anatomical lesions such as a cavotricuspid isthmus ablation. Ablation for AF and complex VT may be performed with moderate to deep sedation or general anesthesia. There are several potential advantages to the use of general anesthesia in such procedures such as minimizing patient discomfort and movement thus facilitating 3D mapping as well as allowing the use of TEE visualization. Care must be taken in order to minimize the doses of paralytic agents when assessing for phrenic nerve capture.

Benzodiazepines and opioids are used in the EP laboratory for their anxiolytic and partial amnesic effects. If these agents are used it is ideal to administer low

doses before the procedure is performed in order to assess the effect on the individual patient. All patients undergoing any procedure involving the administration of intravenous sedation should have a history and rapid airway assessment prior to starting the procedure. Ideally there should be involvement of an anesthesiologist. It is also advisable to have an individual whose sole purpose is to monitor the patient's respiratory rate, oxygen saturations as well as heart rate and blood pressure throughout the procedure. All patients should be closely monitored post procedure until their vital parameters have returned to normal limits.

The most common benzodiazepines used in the EP laboratory are midazolam and diazepam. Although either of these agents can be used midazolam tends to have a shorter duration of action particularly in the elderly or in those with reduced cardiac output, respiratory depression, hepatic and renal impairment.

Midazolam can be administered at a dose of 0.03–0.07 mg/kg over 2 min for most adults adult with additional doses given after 3 min, if required, at 25 % of the initial dose. Generally no more than 10 mg is needed for the entire procedure.

Midazolam tends to have less effect on suppression of induction of supraventricular tachycardia compared to diazepam. Routine administration of the benzodiazepine antagonist flumazenil should not be performed and this should be reserved only for cases of significant over sedation. A dose of 0.2 mg over 15 s with another dose of 0.2 mg after 45 s and then every 1 min up to a maximum dose of 1 mg should be used. The patient should be monitored closely for 2 h in order to ensure that there are no further sedative effects as the drug effects wear off.

Fentanyl is a useful opioid which can be administered at the start of the case at a dose of 0.5 microgrammes/kg if used with a benzodiazepine or 2 microgrammes/kg if used alone. The effects can be re-assessed after 15 min and a further 25 % of the initial dose administered if required. The overall duration of action is approximately 30–60 min. If used in conjunction with a benzodiazepine fentanyl may result in respiratory depression and therefore monitoring is required. The effects of fentanyl can be partially reversed by naloxone at a dose of 0.1–0.2 mg over 2 min.

Propofol is frequently used in the EP laboratory. The individual responsibility for this depends on the country where the procedure is performed. Propofol is generally administered at a dose of 0.5 mg/kg over a period of 3–5 min. Further doses may be administered in 5 mg boluses if required. It has no significant electrophysiological effects on arrhythmia induction.

Very occasionally propofol infusion syndrome may occur particularly at higher doses and for longer periods of time. This may occur as a result of mitochondrial respiratory chain inhibition or impaired fatty acid metabolism and results in acute refractory bradycardia leading to asystole with either metabolic acidosis, rhabdomyolysis, hyperlipidaemia, and or fatty liver. Coved type ST elevtaion with RBBB occurs in the precordial leads. The only effective treatment for this condition is haemodialysis or haemoperfusion with cardiorespiratory support.

Peri-procedural Anticoagulation

For the majority of right sided ablations anticoagulation is not required although some operators choose to give low dose heparin in order to try to lower the potential risk of deep venous thrombosis and pulmonary embolism. For left sided ablations intravenous heparin is administered aiming for an Activated Clotting Time (ACT) of greater than 350 s. In patients who are already taking oral anticoagulation the decision to continue, discontinue or bridge with heparin depends on the risks of thrombo-embolism compared to the risk of bleeding.

Patients undergoing ablation for AF are at an increased risk of thrombo-embolism due to a combination of pre-existing factors involved in Virchow's triad as well as potential for embolic formation during ablation in the left atrium and possible reversion from AF to normal sinus rhythm. The need for pre-procedural anticoagulation depends on the patients CHADS2VASC score. If this is 0 then anticoagulation is generally not required pre-ablation however in all other cases therapeutic anticoagulation is recommended for a minimum period of 4 weeks [2] (Table 2.2).

Even in patients considered to have a low baseline CHADS2VASC score there is an increased risk of thrombo-embolism post ablation. This occurs as a result of endothelial injury as well as potential mechanical dysfunction of the left atrium post ablation. As shown in Fig. 2.8 manipulation of ablation and mapping catheters and guidewires results in endothelial injury and activation of factor XII which results in intrinsic pathway activation and tissue factor which activates the extrinsic pathway. It is therefore necessary to administer heparin for left sided ablations aiming for an activated clotting time (ACT) of 350 s [2] even in patients who are receiving warfarin. In patients who are allergic to heparin bivalirudin may be considered.

It is recommended that oral anticoagulation is continued for at least 8 weeks post ablation in these patients and long-term in patients with a higher risk of thromboembolism [2].

The choice of whether to continue with oral anticoagulation compared with heparin bridging is largely dependent on individual operator and center experience. Continuation of warfarin during catheter ablation for AF is likely superior to bridging with heparin with reported lower rates of thrombo-embolism, pericardial effusion and major bleeding [27]. Although there is limited data regarding the use of uninterrupted direct oral anticoagulants in AF catheter ablation given the shorter half life of the direct oral anticoagulants minimal interruption can be performed pre-ablation and appears to be effective particularly if a pre-procedure

Table 2.2 Pharmacological properties of Warfarin and direct oral anticoagulants

Drug	Mechanism of action	Time to peak (h)	T1/2 (h)	Renal excretion (%)
Warfarin	Vitamin K antagonist	96–120	40	0
Dabigatran	DTI	1–2	12–17	80
Rivoroxaban	Xa inhibitor	2–3	7–11	33
Apixaban	Xa inhibitor	1–2	12	25

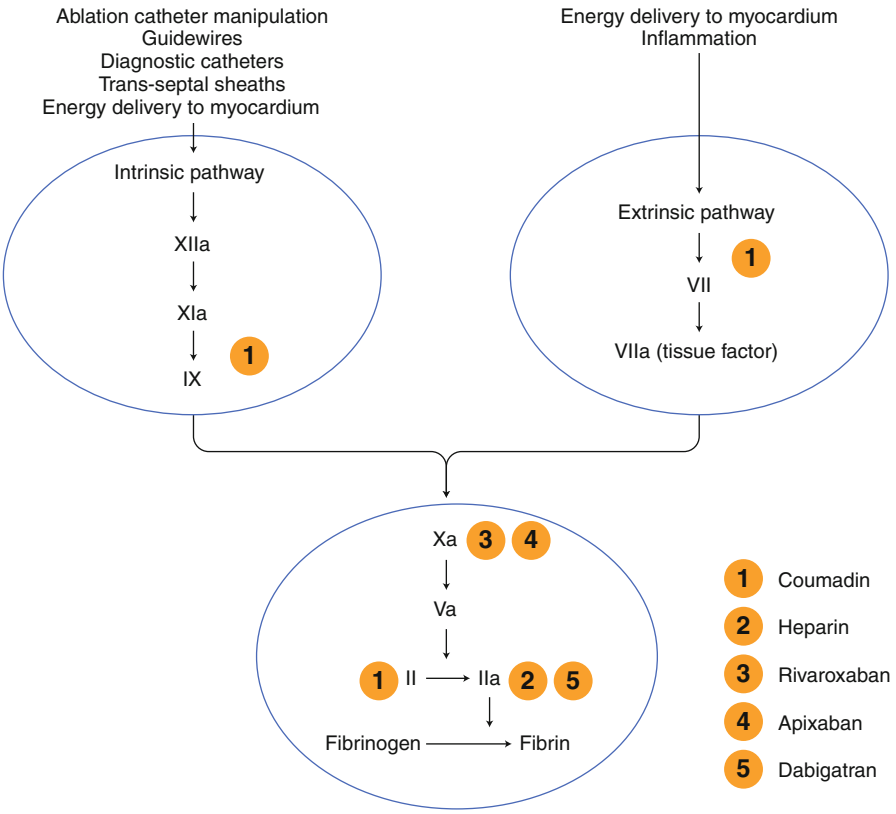

Fig. 2.8 Effect of catheter ablation, sheath and wire manipulation on the coagulation cascade and pharmacological intervention

transesophageal echocardiogram (TEE) is performed. In general provided the patient has normal renal function the last dose of oral anticoagulant can be administered 24 h pre ablation with the first dose post procedure administered 4 h after sheath removal.

EP Laboratory Set-Up

The EP lab is composed of an EP recording system, a stimulator, a RF generator with the potential for irrigation and an electroanatomic mapping (EAM) system as well as a cryoablation system and the cables and interfaces which connect these systems. Additional to this is resuscitation (at least one defibrillator with rapid access to a second and ventilation equipment) and fluoroscopic equipment for image acquisition (Fig. 2.9).

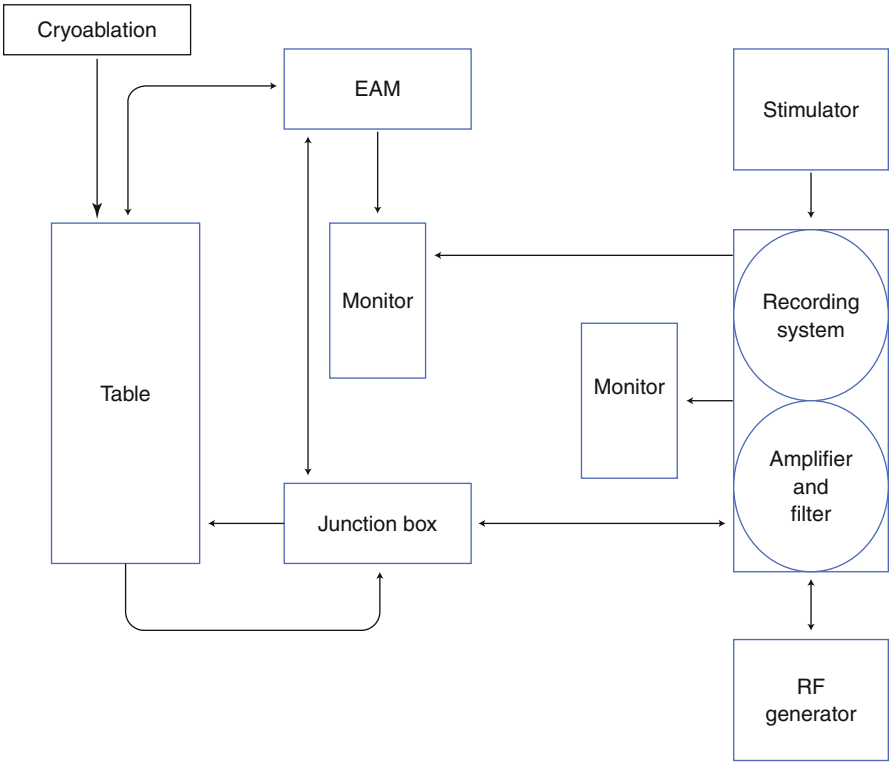

Fig. 2.9 Diagrammatic representation of a typical setup for an EP laboratory. *EAM* electroanatomic mapping system

How Electrograms Are Derived: Amplification and Filtering

Electrograms recorded in the heart are generally less than 5 mV in amplitude and often as small as 0.01 mV in scarred tissue. In order to display these signals they must be amplified and filtered. Signals may be amplified up to 10,000 times prior to being filtered.

The amplified signal then passes through a **high pass filter**. This allows higher frequency signals to pass through while removing signals below a designated frequency. On the **surface ECG** this is set very low at **0.05 Hz** therefore allowing a larger range of low frequencies to pass through. For **bipolar intracardiac signals** this is set higher at **30 Hz** which therefore filters out a larger range of low frequencies that may occur as a result of catheter movement, electrical farfield or respiratory variability.

For **unipolar intracardiac signals** where the morphology of the signal is more relevant the setting is similar to the surface ECG at **0.05 Hz** or else switched off.

This signal then passes through an isolation amplifier which isolates the current from the patient and is subsequently transmitted through a **low pass filter**. This

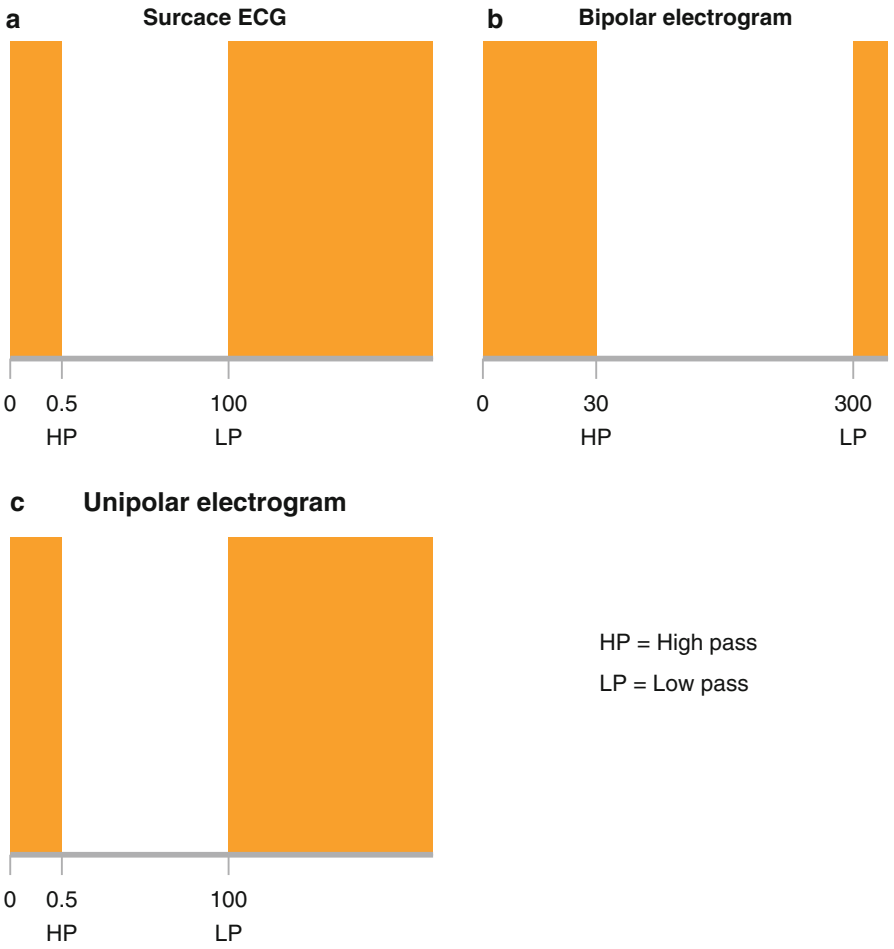

Fig. 2.10 High Pass (*HP*) and Low Pass (*LP*) settings for the surface ECG (**a**), Bipolar intracardiac electrograms (**b**) and Unipolar intracardiac electrograms (**c**)

allows lower frequency signals to be transmitted while filtering out higher frequencies. This is generally set at **300 Hz for bipolar intracardiac electrograms and filtered and unfiltered unipolar electrograms and 100 Hz for surface ECG signals** (Fig. 2.10).

Additionally most EP systems have a **notch filter**, which removes signals at a specific frequency range generally in the range of electrical frequency. This is often set at **50 Hz in Europe and 60 Hz in North America** and is designed to reject interference outside of the range around this. This also has several potential disadvantages including a reduction in the amplitude of certain electrograms such as pulmonary vein potentials as well as the potential to add interference.

Electroanatomic mapping systems have their own high pass and low pass filters programmed and can also be adjusted and are generally set with the range of

30–500 Hz for intracardiac electrograms. For unipolar electrograms the low pass is either minimized or switched off in order to reduce artifact on the signal. If the standard settings are kept on for unipolar signals often an artefactual R wave may appear on the signal.

Despite filtering of signals the best policy is to minimize noise in the first place. This can be due to direct electrical interference from other devices in the lab, leakage current from other devices as well as electrical cables which may be closely coupled with cables transmitting electrograms. It is therefore important when designing the EP laboratory in the first place that electrical cables are not positioned beside cables used for transmitted electrocardiograms. **Leakage current** is the total current from patient connections through the patient to earth and is required to be less than **10 μA** [28]. This cumulative current also may result in considerable electrical interference which must be filtered.

Noise which occurs specifically during ablation may often be due to the fact that the pacing function is enabled at the distal electrode at the same time as the ablation function. This is the result of a slight difference in the current between the distal and proximal poles which exists even when pacing is not being performed.

Other potential causes include problems with the ablation catheter or cable, issues with the grounding pad and inadequate gel on the back patch.

Electrogram Signals: Unipolar and Bipolar

Electrogram signals occur as a result of voltage gradients which occur between myocytes at different phases of the cardiac AP. **Unipolar electrograms** are amplified signals which are recorded between the distal pole of the catheter (+) and Wilsons Central Terminal (−) and are in essence bipolar signals between two regions spaced far apart. This therefore records both near and farfield, the latter of which may distort the local signal.

Bipolar signals are amplified signals recorded from two closely spaced unipoles. In general the distal pole is negative while the proximal pole is positive. Bipolar recordings are affected by the direction of the wave front with respect to the electrode orientation, electrode spacing and configuration and are generally considered more useful in clinical practice.

Both types of signal can be used in cardiac mapping for example in exit site and accessory pathway localization where a deep Q wave with no R wave may indicate proximity to the activation site in unipolar electrograms [29]. This is not perfect for localization of the focus. As shown in Fig. 2.11 during a PVC originating from the LV inferior wall there is a deep Q wave with no R wave in the ABL WCT electrogram. Despite this the electrogram is not significantly earlier than the surface QRS. Although this was the earliest unipolar and bipolar electrogram on the endocardium this focus was found to be located on the epicardial surface.

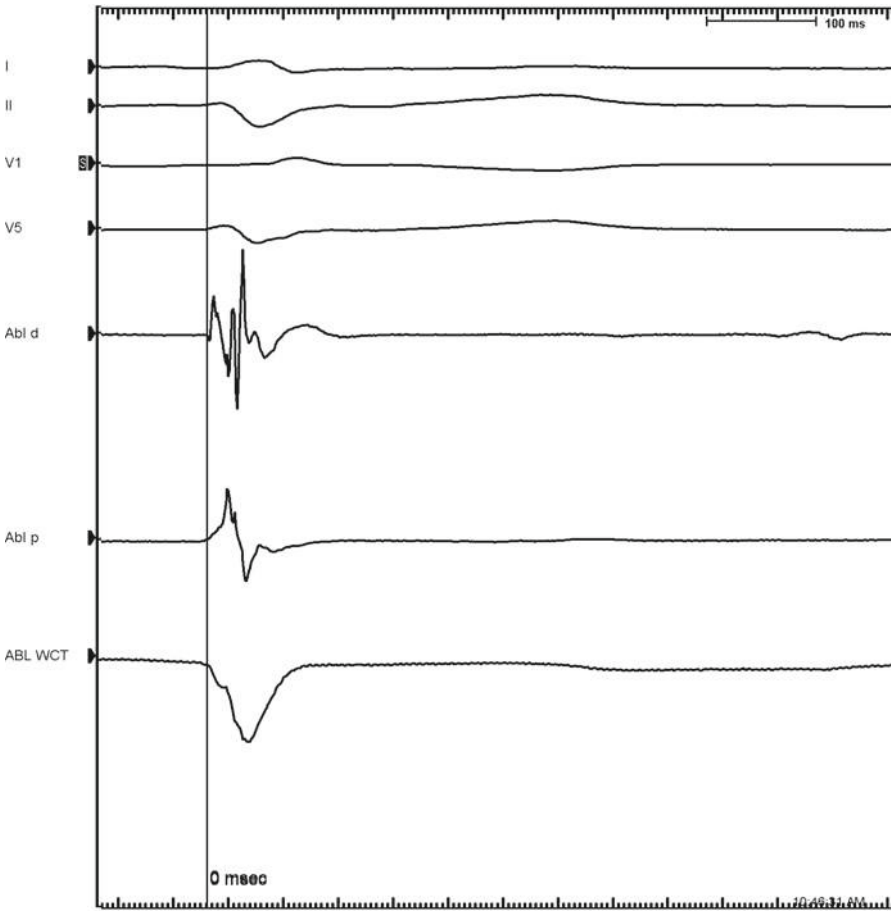

Fig. 2.11 A PVC originating from the inferior LV wall. The bipolar and unipolar electrograms are on time with the onset of the surface QRS. The unipolar electrogram has no R wave and a deep Q wave. Although this indicated activating moving away from the catheter the fact that the signal is not early indicated that this was not the focal site of the PVC. This was mapped to the epicardial surface of the inferior wall of the LV where the local signal was 20 ms ahead. (Abl d is recorded as a bipolar electrogram recorded from the distal electrode on the ablation catheter, Abl p is the bipolar electrogram recorded from the proximal electrode on the ablation catheter, ABL WCT is the unipolar electrogram recorded from the distal electrode on the ablation catheter to Wilson's Central Terminal)

RF Generation and Ablation

Radiofrequency (RF) energy is the most commonly used energy source using for creating an ablation lesion. The generator produces a continuous sinusoidal waveform at a frequency between **500** and **1000 KHz** which is then delivered between

the catheter tip and a patch electrode placed on the skin. As a result of the difference in the surface area between the tip of the ablation catheter and the dispersive electrode pad the maximum zone of resistive heating, which is directly related to current density is generally within 2 mm of the catheter tip. The majority of this is lost in the blood flow as blood has a lower resistance than myocardium.

The rest of the lesion, which is in fact the majority, is formed by conductive heat. This diminishes as a function of $1/r^4$ where r is the distance from the point of maximum resistive heating. The size of the lesion increases as the temperature increases. In general an irreversible lesion occurs at or above 50 °C. If the temperature at the electrode-tissue interface rises to greater than 100 °C the tissue immediately adjacent to the electrode forms a coagulum and a steam pop is heard.

The actual impedance during RF ablation is dependent on the tissue in contact with the catheter, the temperature, body characteristics, catheter properties, cables and reference patch. During the delivery of RF in order to create a lesion there is generally a reduction in the impedance of greater than 10 Ω. A sudden rise in the impedance as shown in Fig. 2.12 is often associated with a steam stop and potential perforation.

A thermocouple incorporated into the tip of the ablation catheter measures the temperature. In temperature guided ablation the temperature of the ablation electrode is set at the start of the ablation and automatically adjusts power output to

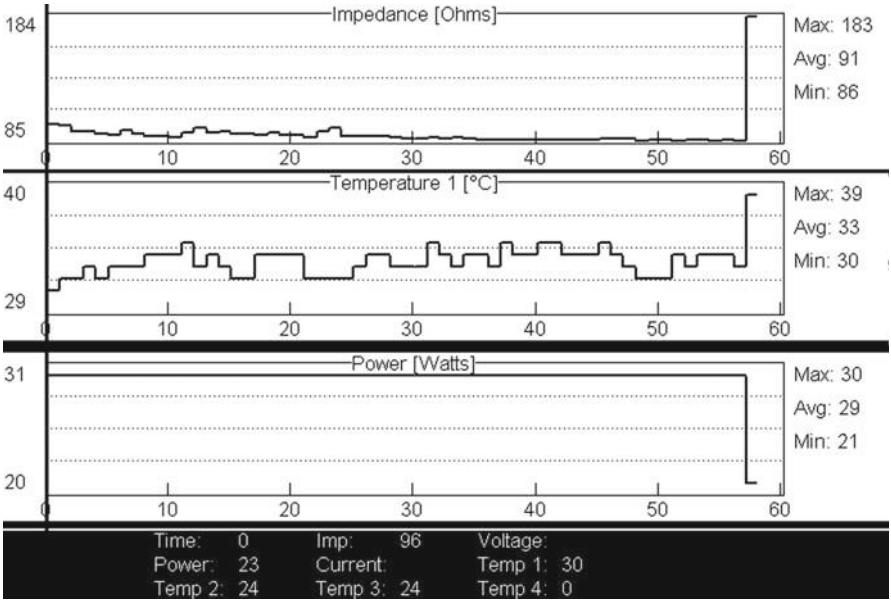

Fig. 2.12 RF ablation in the left atrium using a 4 mm irrigated catheter. There is a sudden rise in impedance and temperature at the interface between the catheter and the endocardium. This results in a steam pop

achieve a targeted electrode temperature of between **55** and **70 °C**. Ablation can also be set at a power limit so that RF is delivered until a certain power is achieved.

Lesion sizes are usually 5 mm in diameter but can be increased by the use of a larger diameter ablation catheter or with the addition of irrigation, which flushes the tip of the catheter.

Cryoablation

Cryoablation has been used in the ablation of slow and accessory pathways anatomically close to the compact AV node as well as in pulmonary vein isolation (PVI). There are several potential benefits in the use of this modality. Following the application of cryoablation there is an initial degree of reversibility in lesion formation, particularly between −10 and −25 C. This confers the potential advantage in the case of ablation of a nodal or accessory pathway that is close to the compact AV node where the risk of AV block is considered to be significant. Permanent tissue damage occurs at temperatures less than −50 C.

During the application of cryoablation the catheter tends to remain stuck to the tissue which results in increased catheter stability.

The concept relies on localised hypothermia at the catheter endocardial surface. There are three biophysical phases to this process.

1. Freezing – thawing phase
   This occurs acutely during delivery of cryoablation. During the first few minutes this may be reversible. Microscopic extracellular ice formation occurs as the temperature drops below −15 °C. Intracellular ice formation then occurs as the temperature drops to less than −40 °C. As a result of this there is an increase in ion concentrations in the extracellular space which becomes hypertonic resulting in a shift of fluid from the intracellular space to the extracellular space. This results in a reduction in intracellular pH causing mitochondrial damage. There is progressive microcirculatory vasoconstriction resulting in further localised damage to the local tissue. Following the completion of localised freezing passive rewarming occurs knowing as thawing. This results in fusion of the ice crystals with further cellular damage as well as resulting in microvascular occlusion as a result of platelet aggregation and microthrombi formation.
2. Hemorrhagic – inflammatory phase
   As thawing continues the changes in the microvasculature result in regional hyperemia and tissue edema with microscopic hemorrhagic changes and inflammation. This tends to occur within 48 h of the thawing process and may continue for up to 1 week.
3. Replacement – fibrosis phase
   Replacement fibrosis and apoptosis of cells near the periphery of the lesion occurs within the first week and up to 3 months after the delivery of the lesion. Neovascularisation and collagen remodelling occurs until finally a fibrotic scar forms.

Ablation Catheters

Ablation catheters in their simplest form delivery energy to the myocardium while providing feedback in terms of tissue temperature and impedance. They vary in the size of the tip electrode as well as ability to delivery irrigation. Some catheters also provide feedback in terms of contact force data. The majority of available catheters tend to have a platinum tip. Other materials such as gold have also been studied and also appear to be efficacious.

Ablation Catheter Size

Larger electrode sizes have a larger percentage of surface area exposed to blood rather than endocardium. As shown in Fig. 2.13 as a result of the cooling effect of the blood flow a smaller lesion is delivered using similar power with a larger diameter catheter [30]. A higher power is therefore required in order to achieve the target temperature which results in a larger lesion. Smaller electrodes have a better electrogram resolution.

Larger tip catheters have been shown to be more effective with a reduced number of RF applications and reduced fluoroscopy time in atrial flutter ablation [31].

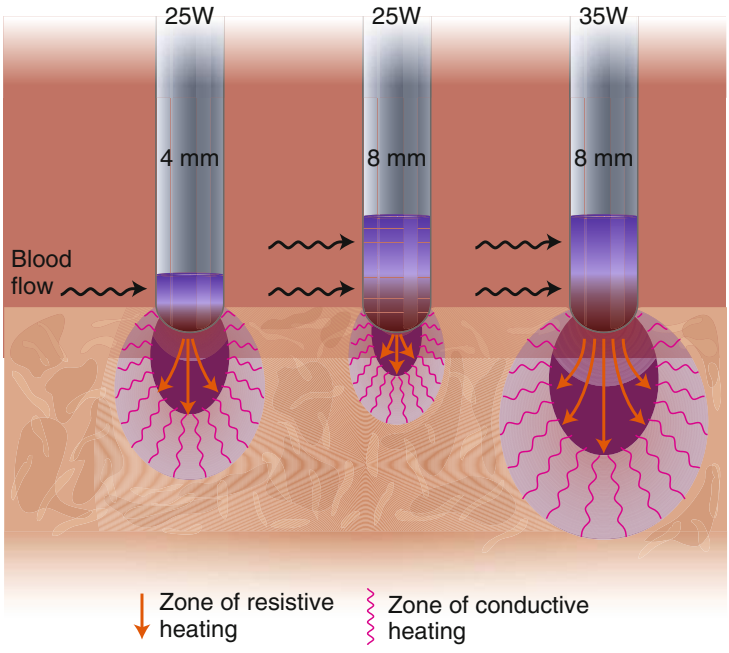

Fig. 2.13 Effect of ablation catheter tip size on the ablation lesion consisting of the zone of resistive heating and the zone of conductive heating. A higher power is required for a lesion to be created by a larger tip electrode due to an increase in loss of energy through an increase in flow across the larger surface area of the catheter

There is a better electrogram resolution with smaller tip catheters and overall smaller tip irrigated catheters have been shown to be very effective in atrial flutter ablation. The temperature measured at the tip of the catheter is not a good estimate of the tissue temperature.

Irrigation

In open loop irrigation saline is flushed through the ablation catheter resulting in cooling of the catheter tip with lowering of the catheter tip temperature resulting in the ability to create deeper lesions, with less focal hot spots and a reduced risk of thrombus formation. As shown in Fig. 2.14 a larger lesion is created over a shorter time period using a catheter with irrigation when compared with no irrigation. Using the same power and electrode size a catheter with irrigation tends to result in a larger lesion (Fig. 2.15). Temperature feedback is not reliable and therefore ablation is limited by power.

Although lesion sizes are larger using irrigation they tend to grow beyond 60 s and therefore a longer application should be considered.

The rate of irrigation should be altered according to the power delivered.

The general recommendations are **2 ml/min during mapping**, **17 ml/min during ablation at a power of less than 30 W** and **30 ml/min at a power of greater than or equal to 30 W**.

Contact Force Catheters

The contact force and orientation between the catheter tip and the endocardial surface provides valuable information regarding whether delivery of RF energy is having a significant impact on the tissue rather than the blood pool. It has been shown

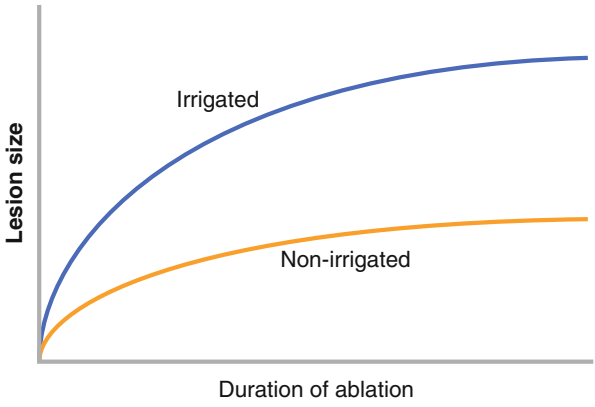

Fig. 2.14 Diagrammatic representation of lesion size developed over time for irrigated and non-irrigated ablation showing a larger lesion created over a shorter time for an irrigated catheter when compared with a non irrigated catheter

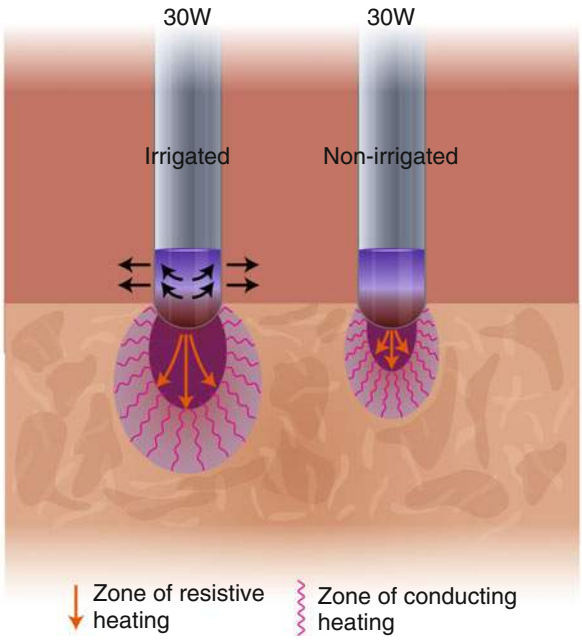

Fig. 2.15 Representation of the effects of irrigation on lesion size using a catheter with the same electrode size and at the same power

that poor tissue contact results in a higher recurrence of AF in patients who underwent a PVI [32, 33]. Excessive contact force may result in perforation. There are two commercially available contact force catheters which employ different technologies.

The SmartTouch catheter (© Biosense Webster, Inc) is shown in Fig. 2.15. This is an irrigated 7.5 Fr catheter with an 3.5 mm electrode in which a magnetic transmitter connected to the main body of the catheter with a spring. This is able to transmit data regarding directionality of the electrode tip relative to the shaft of the catheter to the processing unit. In order to measure the force applied there are an additional 3 sensors within the shaft. Although this records a minimum change of 1 g every 50 ms the mean force is displayed every 1 s [34].

Minimum contact force, duration of force as well as catheter stability, power, impedance and temperature changes can all be programmed on in order to set a minimum criteria for display of a lesion using Visitag software on Carto 3. Given the sensitivity of the electrode tip an introducing tool should be used when advancing the catheter through a sheath. A zero baseline reference should also be obtained after the catheter has been in the blood pool for a minimum of 15 min while the catheter is not in contact with any cardiac structure (Fig. 2.16).

The Tacticath catheter (St. Jude Medical, Cardiology Division, Inc., Plymouth, Minnesota) is an irrigated unidirectional 7 Fr catheter with a 3.5 mm tip electrode with a triaxial fibreoptic sensor shown in Fig. 2.17. Contact force is measured

Fig. 2.16 Image showing the distal component of the SmartTouch Catheter (© Biosense Webster, Inc)

every 100 ms and continually displayed. The force time interval (FTI) can also be displayed and may help to guide ablation. Using the Tacticath a contact force greater than 20 g appears to result in durable pulmonary vein isolation while a contact force less than 10 g tended to be associated with recurrences [32]. A target of 20 g with a minimum greater than 10 g and a minimum force time index greater than 400 g appears to result in a higher likelihood of transmural lesions in the left atrium [33].

Vascular Access

Electrophysiology catheters are positioned in the heart by gaining access via the central veins; generally the femoral veins for most catheters and occasionally the internal jugular or subclavian veins for coronary sinus catheter placement.

Femoral Cannulation

Femoral vein access is the most commonly used for most EP procedures. The femoral artery is palpated and cannulation is performed medial to the femoral artery while maintaining a position inferior to the inguinal ligament. Superior to the

Fig. 2.17 Image showing the TactiCath Catheter and Connector (St. Jude Medical, Cardiology Division, Inc., Plymouth, Minnesota)

inguinal ligament may result in a difficultly with compression and potential bleeding into the retroperitoneal space. In generally up to three standard EP catheters can be positioned into a femoral vein provided separate cannulations are performed although this depends on the overall size of the patient. If there is any concerns regarding the potential for vein occlusion then the left femoral vein can also be cannulated.

The femoral artery may be used to access the left ventricle and in particular LVOT focal tachycardias. It may also be used for LV VT's and left sided accessory pathway ablations. It is important to maximize the distance between the femoral venous and arterial access points in order to minimize the risk of arteriovenous fistula. The relationship of the right femoral vein to the femoral artery is shown on the anatomical images in Fig. 2.18.

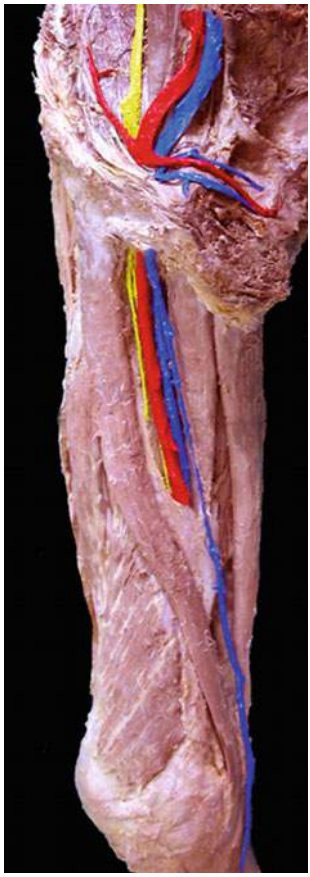

Fig. 2.18 Anatomical images showing the relationship of the femoral vein (*blue*), the femoral artery (*red*) and the femoral nerve (*yellow*)

Subclavian/Axillary Vein

The axillary vein combines with the cephalic vein to become the subclavian vein as it passes superficial to and medial to the anterior portion of the first rib. The course of the left axillary and subclavian vein are shown on the CT scan in Fig. 2.19. Following infiltration with local anesthesia the needle is directed towards and very slightly deep to the junction of the medial one third of the clavicle with the remainder of the clavicle. This should be superficial to the first rib. If fluoroscopy is used this can be achieved. If venous flow is not obtained a slightly deeper approach can be made. Provided the needle does not pass medial to the first rib or deep to the first rib via the second intercostal space then a pneumothorax should not occur. Alternatively a venogram can be performed. The advantage of subclavian access over internal jugular is that the vein does not appear to collapse and remains patent due to soft tissue attachments with the costoclavicular ligament and the clavicular periostium. The Trendelenberg position is therefore not required to

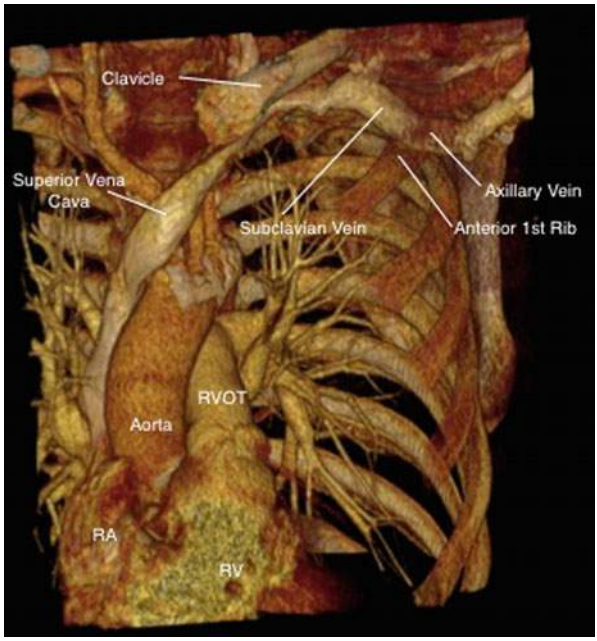

Fig. 2.19 Anatomic course of the left axillary and subclavian vein on a CT scan. The axillary vein runs anterior to the first rib towards the clavicle. Medial to this it becomes the subclavian vein which joins the superior vena cava. Also seen in this image is the ascending aorta. the right ventricular outflow tract (*RVOT*), the right atrium (*RA*) and the right ventricle (*RV*)

increase vein patency although it may reduce the incidence of air embolism. At the subclavian axillary junction the subclavian artery is significantly posterior and slightly superior to the vein. These two structures are separated by the anterior scalene muscle which is 1–1.5 cm thick and reduces the risk of accidental arterial puncture. This muscle is not present laterally however and the risk of arterial puncture increases in more lateral positions. More medial to the juncture of the subclavian and axillary juncture the apical pleura of the lung is posterior to the vein. It is therefore important to keep the needle as horizontal as possible with only slight increases in depth if a more medial approach is being made. More inferior locations are also more likely to puncture the pleura and lung due to the conical shape of the chest.

Internal Jugular Vein

Cannulation of the internal jugular vein may occasionally facilitate positioning of the coronary sinus catheter. Infiltration of local anaesthesia following by Seldinger cannulation should be performed at the apex of the triangle of Sedillot. This triangle is formed medially by the sternal head of the sternocleidomastoid, laterally by the clavicular head of the sternocleidomastoid and inferiorly by the medial one third of the clavicle. Transient flexion of the neck should help to accentuate these landmarks in most patients if they are not clear. If the patient is under general anesthesia

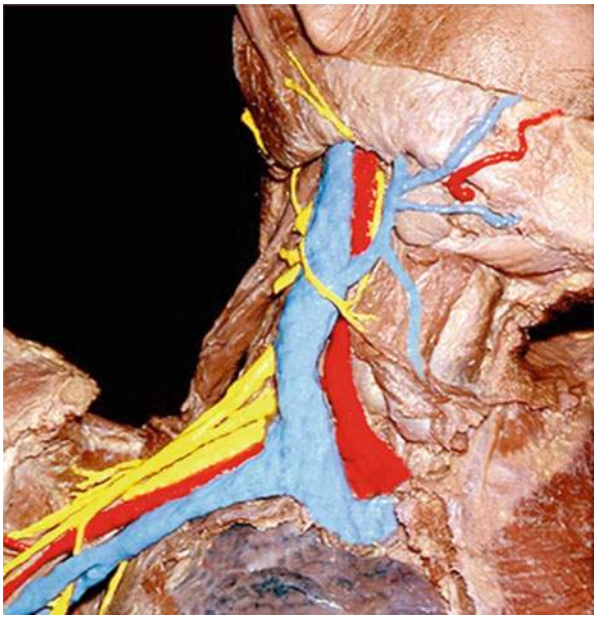

Fig. 2.20 Anatomical image showing the relationship of the right internal jugular vein (*blue*) which lateral to the right common carotid artery (*red*). The right internal jugular passes anterior to the right subclavian artery and joins the right subclavian vein where the two become in innominate vein. The right brachial plexus is shown in *yellow*

palpation of the trachea can be performed while palpating laterally over the sternal head of the sternocleidomastoid into the recess of the triangle. The carotid pulse can also be palpated prior to but not at the same time as cannulation as this often compresses the internal jugular vein. The carotid artery runs medial and posterior to the internal jugular although on occasions may only be posterior. Excessive contralateral rotation of the head beyond a 45 degree angle pushes the carotid artery more lateral and posterior to the internal jugular vein.

The internal jugular vein generally lies 1–2 cm deep in the skin at the apex of the triangle. The needle should be advanced at a 45 degree angle. Advancing the needle greater than 2 cm increases the risk of a pneumothorax. The use of an ultrasound may be helpful to differentiate between vein and artery. The artery is in general more medial, deeper, non compressible and has a visible pulsation. The anatomy of the right internal jugular vein is shown on Fig. 2.20.

Electrophysiology Catheters and Positioning

Electrophysiology catheters are generally made of platinum coated electrodes with polyurethane coated shafts. They are categorized according to the diameter of the shaft, the number of poles used to record and pace through, the spacing between electrodes and the ability to deflect. Ablation catheters are also categorized according to the curve, length of the tip of the catheter, ability for irrigation and ability to measure contact force.

The external diameter of an EP catheter in measured in **French** (**Fr**) where **1 Fr is 1/3 mm**. Therefore to convert the French size to mm it is simply divided by 3. The majority of diagnostic EP catheters are either 5 Fr or 6 Fr. The number of poles recording and pacing can range from 2 up to 20. Commonly quadripolar catheters are positioned in the right atrium, His bundle and right ventricle while a decapolar is positioned in the coronary sinus. A duodecapolar catheter may be used to map right atrial activation during a cavotricuspid isthmus ablation although this is generally not required.

Catheters that are deflectable are easier to position.

The high right atrium (RA) catheter in an EP study is generally positioned in the high posterolateral wall at the junction of the RA with the superior vena cava close to the sinus node. The catheter can also be positioned in the RA appendage. A non deflectable quadripolar catheter is sufficient for this. This can generally be positioned in either the RAO or LAO views.

The RV catheter is generally best placed along the base or septum. It may be positioned close to the His and used to record the His and ventricular signals. This position is achieved in the RAO or LAO projection while withdrawing the catheter from the RV with a clockwise rotation towards the septum.

The coronary sinus catheter is initially positioned in the RA and advanced with a clockwise rotation towards the more posterior CS Os in the LAO projection. Alternatively it can be positioned in the RV and withdrawn with clockwise rotation in the same view. The general locations of EP catheters are shown in Fig. 2.21.

Baseline Measurements

Sinus Node Recovery Time (SNRT)

SNRT is measured using the principle of overdrive suppression in which pacing is performed close to the sinus node at a rate faster than the sinus rate and the time taken from the last paced beat to the first intrinsic sinus beat is measured. This is performed at a cycle length of 600/500/400/300/200 ms for a period of 30 s during each drive train. As shown in Fig. 2.22 the interval from the last paced beat to the first intrinsic beat is then measured. This is longer than the baseline sinus rate and generally takes 5 to 6 beats to return to normal after this maneuver is performed. A prolonged sinus node recovery time **greater than 1500 ms** is abnormal. This may not always occur at faster cycle lengths as entry block may intermittently occur in the perinodal cells and therefore not every beat may depolarize the sinus node. The SNRT is also dependent on the baseline sinus cycle length and is longer for longer baseline cycle lengths and shorter for shorter cycle lengths. In order to correct for this the corrected SNRT can be calculated as:

$$\text{cSNRT} = \text{SNRT} - \text{BCL}$$

A cSNRT of 525 ms or more is considered abnormal.

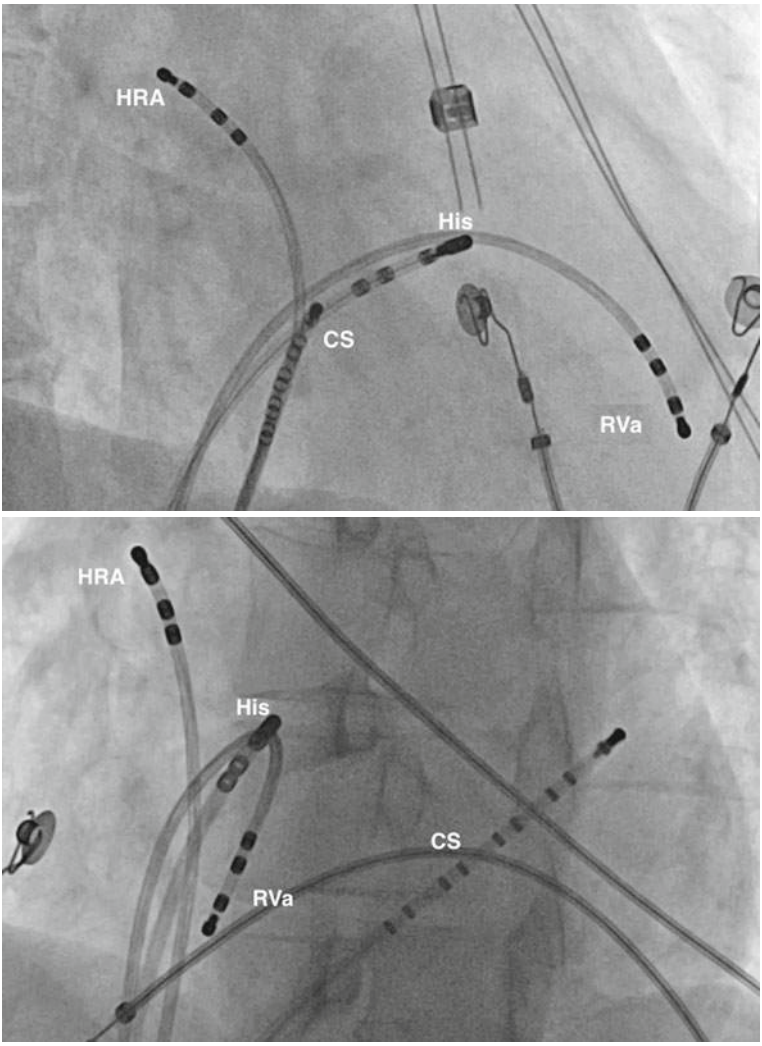

Fig. 2.21 Fluoroscopic image in RAO 30 (*top*) and LAO 30 (*bottom*) showing the locations of EP catheters in the high right atrium (*HRA*), coronary sinus (*CS*), His and right ventricle apex (*RVa*)

Sinoatrial Conduction Time (SACT)

This is the conduction time from the SN to the RA tissue. This is measured by positioning a catheter close to the sinus node and pacing at a rate slightly faster than the baseline cycle length for a single beat only in order to avoid overdrive suppression. As shown in Fig. 2.23 the interval from the last paced beat to the next intrinsic sinus beat is measured and is known as the return cycle length. If the basic cycle length is subtracted from the return cycle the remaining interval is equivalent to the time

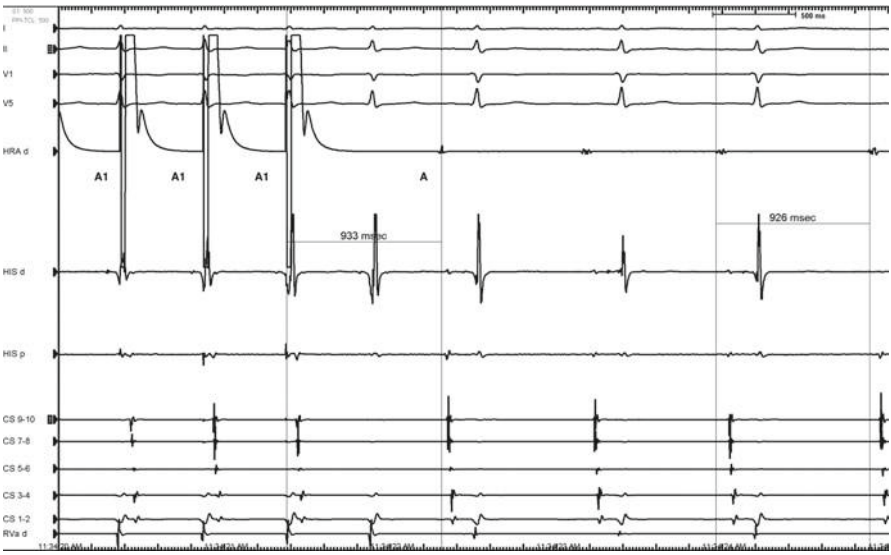

Fig. 2.22 Showing calculation of the sinus node recovery Time (HRA d is positioned in the high right atrium, HIS d in the distal His, HIS p at the proximal component of the His, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex) *A1* = paced atrial complexes. *A* = spontaneous sinus beat post pacing

Fig. 2.23 Calculation of sino atrial conduction time (HRA d is positioned in the high right atrium, HIS d in the distal His, HIS p at the proximal component of the His, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

taken to conduct into and out of the sinus node. This is therefore divided by two in order to calculate the SACT. **A normal SACT** is considered to be to be **50–125 ms**.

AV Conduction Times (AH and HV Intervals)

The **AH interval** is recorded from the onset of the local atrial electrogram recorded in the His catheter to the onset of the His signal and is considered to represent conduction through the AV node (Fig. 2.24). The normal range is **50–120 ms**. A prolonged AH interval may occur as a result of intrinsic AV nodal dysfunction, as a result of increased vagal tone or a result of antiarrhythmic drugs. A short AH interval can occur spontaneously or under the effect of sympathetic stimulation.

The **HV interval** is measured from the onset of the local His signal to the earliest ventricular signal on the surface ECG (Fig. 2.24). This generally reflects the

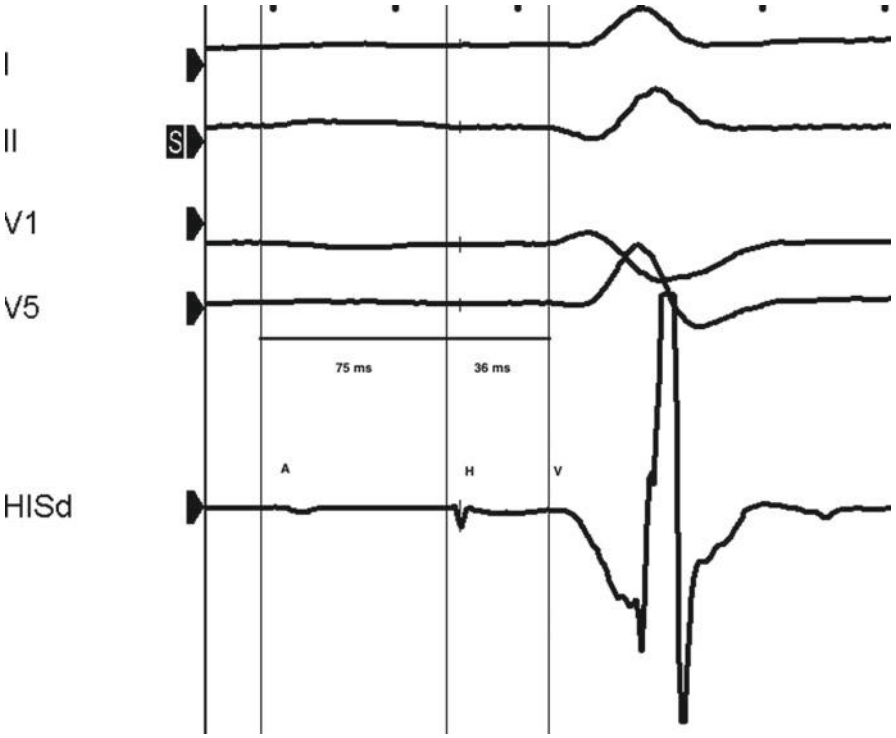

Fig. 2.24 Calculation of the AH interval (75 ms) from the onset of the atrial electrogram on the His recording to the start of the His electrogram and the HV Interval (36 ms) measured from the onset of the His signal to the onset of the ventricular activation on the surface ECG (HIS d is positioned in the distal His)

conduction time through the proximal His, bundle branches and the Purkinje system. The normal range is considered to be between **30** and **55 ms**. Intrinsic His dysfunction or antiarrhythmic drugs may prolong the HV interval. A short HV interval may be seen with accessory pathway conduction which may even be negative. In the presence of accessory pathway conduction the HV does not reflect His-Purkinje conduction but is the result of accessory pathway conduction the true HV interval.

Care must be taken not to confuse the right bundle electrogram as the His electrogram as this may artificially lead to what may seem like a short HV interval.

Refractory Periods (AERP, AVNERP, VERP, VANERP)

During an EP study the **effective refractory period** (**ERP**) is recorded. This is the longest coupling interval in which the stimulus **fails** to stimulate the myocardium at twice the diastolic threshold.

As shown in Fig. 2.25 to calculate the ERP a drive train of eight beats followed by a progressively shorter extrastimulus is performed. The **normal atrial ERP is 170–300 ms while the ventricular ERP is 170–290 ms** [35]. In order to evaluate the AVNERP the atrium is paced in the same way as when calculating the AERP. During decremental atrial extrastimuli the AH interval gradually prolongs while the HV interval remains the same. The **normal AVNERP is 230–425 ms** [35].

AV Wenckebach Point

As shown in Fig. 2.26 decremental atrial pacing can be performed at progressively shorter cycle lengths until AV block occurs. The AV Wenckeback point is defined as the **longest cycle length which results in AV block**. This provides some data on the functional conduction through the AV node.

Fig. 2.25 Calculation of the atrial RP (**a**), AV node RP (**b**), and ventricular ERP (**c**). In each case a drive train is performed at a cycle length of 600 ms for 8 beats in order to achieve a steady state. This is followed by a progressively shorter extrastimulus until capture fails to occur. In the case of the atrium and ventricle this is seen as lack of local capture. In the case of the AV node local capture of either the atrium or ventricle occurs with failure of the impulse to propagate through the AV node either antegradely (AV Node ERP) or retrogradely (VA ERP). (HRA d is positioned in the high right atrium, HIS d in the distal His, HIS p at the proximal component of the His, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

Basic EP Study

There is a considerable variability in the number of catheters and positioning of these. In most diagnostic EP studies a quadripolar catheter is positioned in the HRA as well as the RV septum and a decapolar catheter is positioned in the coronary sinus. The RV quadripolar catheter can sometimes be used to record the AH and HV intervals.

Pacing is performed from the RV septal catheter at a constant rate faster than the sinus rate. This is to look for the presence of VA conduction, and if present the atrial activation sequence. As shown in Fig. 2.27 decremental VA conduction is initially anterior and septal. This generally indicates VA nodal conduction. This is not always the case and it is important not to miss an anteroseptal accessory pathway with decremental retrograde conduction. On the converse lack of decrement does not always exclude VA conduction as rapid ventricular pacing from the RV may result in infrahisian block.

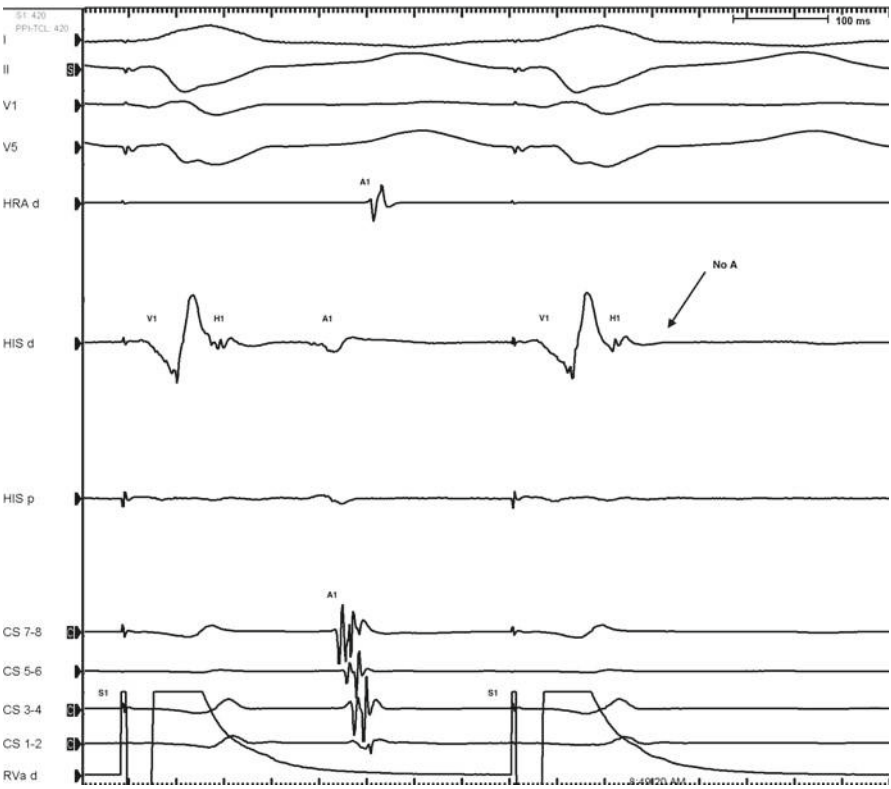

Fig. 2.27 Decremental ventricular pacing (*S1*) from the RV apex (*RVAd*). The first paced beat on the left propagates from the RV apex retrogradely up the right bundle and activates the His. A small His deflection (*H1*) is seen after the ventricular activation (*V1*) on the distal his (*HIS d*) channel. Following this there is atrial activation (*A1*) recorded on the HIS d channel followed shortly thereafter by the proximal his recording (*HIS p*). Atrial activation (*A1*) then occurs from the proximal CS (in this case CS 7–8) and spreads distally. The high RA (*HRAd*) is activated (*A1*) after the proximal CS. This activation is concentric with the His first followed by proximal to distal CS activation and then the HRAd last). In the following beat there is no conduction from the RV activation followed by His activation and no atrial activation

As shown in Fig. 2.28 pacing from the RV does not always result in VA conduction. Although this may infer that AVRT is not possible it is generally better to repeat pacing during infusion of isoprenaline where VA conduction may become evident.

A **ventricular extrastimulus test** is performed by pacing at a contant cycle length and adding in an extrastimulus at a progressively shorter cycle length. This pacing mode is used to calculate the VERP and the retrograde conduction properties.

Pacing from the HRA is performed in order to calculate sinus node function. Atrial extrastimulus testing is then performed looking at the AERP and AVNERP as well as the antegrade conduction properties.

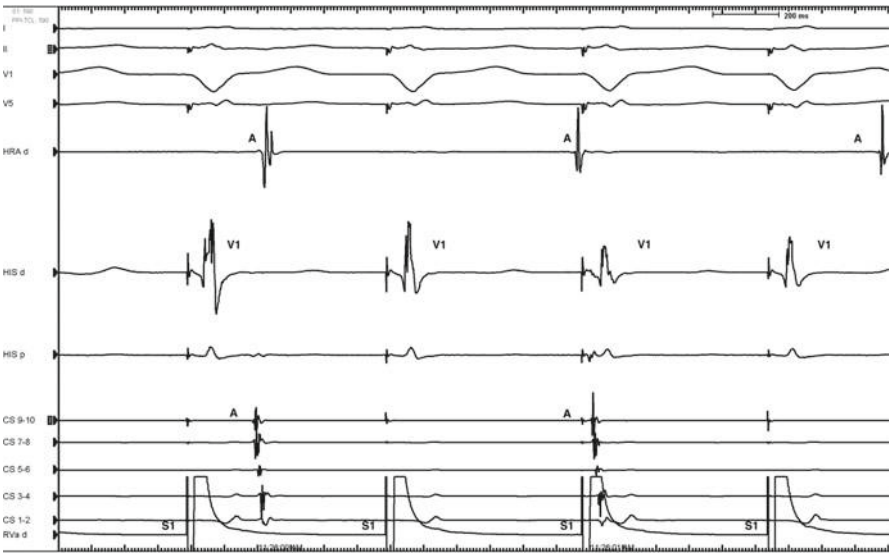

Fig. 2.28 Pacing from the RV (S1) does not penetrate the His and there is no evidence of VA Conduction. (HRA d is positioned in the high right atrium, HIS d in the distal His, HIS p at the proximal component of the His, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

An example of an AH jump caused by dual AV nodal pathways is shown in Fig. 2.29. In panel A conduction occurs antegradely over the fast pathway. In panel B a sudden reduction in the atrial extrastimulus by 20 ms results in an increase in the AH interval by more than 50 ms. Antegrade conduction has suddenly shifted from the fast to a slow pathway.

The AV nodal conduction curve in dual AV nodal physiology is shown in Fig. 2.30. A1A2 refers to the interval from the last paced beat of the drive train to the onset of the atrial extrastimulus. A2H2 refers to the interval from the extratimulus (A2) to the his activation A2H2. As the atrial extrastimulus becomes earlier the interval to the His prolongs until there is a sudden increase from 300 to 350 ms which is most likely indicative of a change in antegrade activation from the fast pathway to the slow pathway.

An example of a AH jump and echo beat are shown in Fig. 2.31. In this example there is a jump as antegrade conduction occurs along the slow pathway with ventricular activation and retrograde activation up the fast pathway.

Decremental atrial pacing is used to calculate the AV Wenckebach Point.

Further decremental atrial and sometimes ventricular pacing may be used to initiate tachycardia. If this is ineffective the addition of one or more atrial extrastimuli and the use of incremental doses of atropine or isoprenaline may be required.

In Fig. 2.32 an atrial extrastimulus results in an AH jump in which conduction occurs antegradely along the slow pathway followed by tachycardia in which retrograde conduction occurs along the fast pathway resulted in a short VA interval. This is most likely in keeping with a typical AVNRT

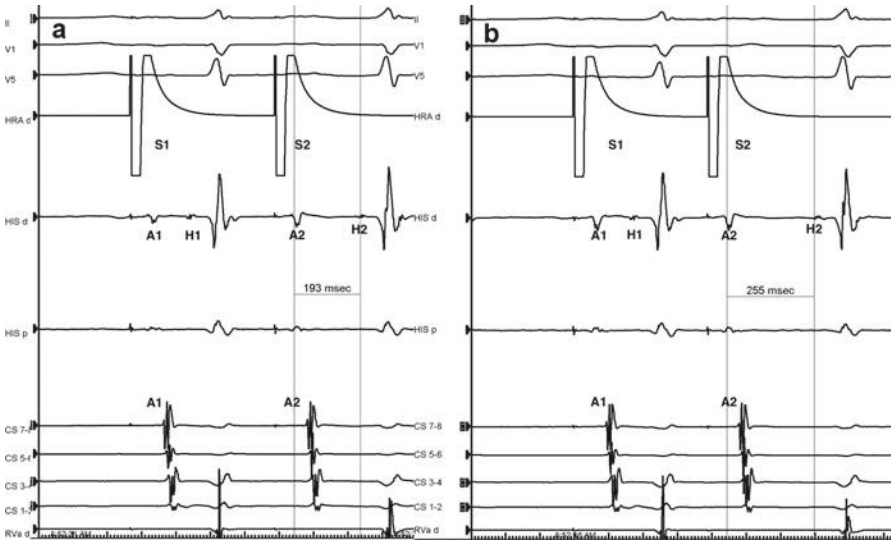

Fig. 2.29 Panel **a**: Atrial extrastimulus testing showing conduction antegradely over the fast pathway. Panel **b**: Antegrade conduction over the slow pathway. Continuous pacing is performed at a cycle length of 600 ms (*S1*). Following this an extrastimulus (*S2*) is given after 400 ms on panel **a** with conduction over the fast pathway. In panel **b** the S2 is shortened to 380 ms. The fast pathway is refractory and conduction shifts to the slow pathway. This is evidenced by a sudden prolongation in the AH interval by more than 50 ms. (HRA d is positioned in the high right atrium, HIS d in the distal His, HIS p at the proximal component of the His, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

VT Stimulation Protocol

The general principle of a VT EP study is to assess the potential future risk of VT in a susceptible patient by performing a basic drive train followed by the introduction of extrastimuli at shorter cycle lengths. In general this should be performed at the RV apex and the RV outflow tract with a single quadripolar catheter and another catheter in the right atrial appendage. A basic drive train (S1) of eight beats is introduced at a cycle length of 600 ms followed by an extrastimulus (S2) which is reduced in 10 ms intervals until the ventricular myocardium is refractory. Following this, S2 pacing rate is brought to 20 ms greater than refractoriness and an S3 introduced in the same manner. S3 is then set 20 ms higher than refractoriness and S1 is reduced to 400 ms and the same protocol repeated. If VT is not induced then S1 is brought back to 600 ms and S2 and S3 set at 20 ms above refractoriness and then an S4 is introduced in a similar manner to that describes above.

Following this, S1 is reduced to 400 ms. If no VT is induced then the protocol can be reintroduced with an isoprotenolol infusion. Induction of a monomorphic VT using this protocol is considered a significant finding and if possible this can be compared with the clinical VT. An example of a VT stimulation using a drive train at a cycle length of 400 ms with 3 extrastimuli is shown in Fig. 2.33.

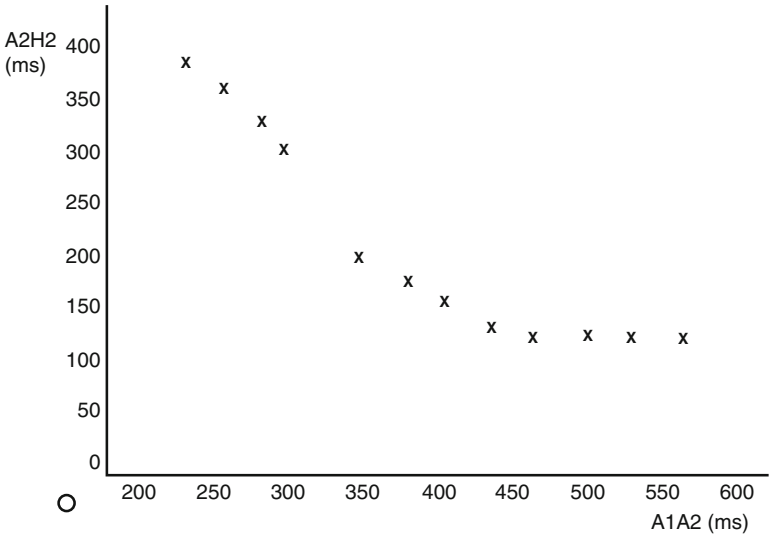

Fig. 2.30 Pacing is performed with a drive train (*A1*) followed by a gradually decmrental atrial extrastmulus (*A2*). As this interval shortens the interval from the atrial extrastimulus (*A2*) to the His (*H2*) prolongs. There is then a sudden increase in this interval by 50 ms which is generally suggestive of antegrade conduction shifting from the fast pathway to the slow pathway

Fig. 2.31 Antegrade conduction occurs along the slow pathway with ventricular activation and retrograde activation up the fast pathway. This is an example of an atrial echo beat

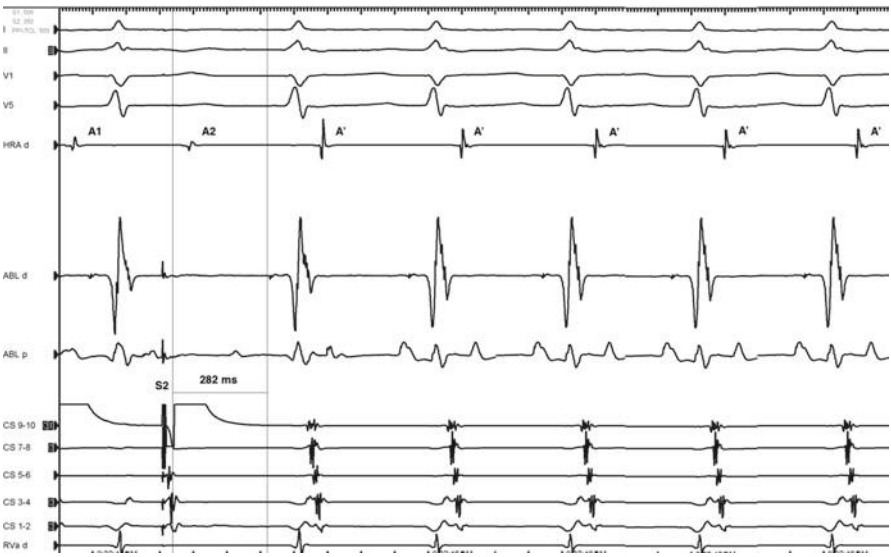

Fig. 2.32 Induction of typical AVNRT. Following a drive train at 500 ms (not shown) an extrastimulus is given after 350 ms from the proximal CS (*S2*). This results in an AH interval of 282 ms (200 ms on prior S2 indicating an AH jump of 82 ms). This is indicative of antegrade conduction shifting from the fast to the slow pathway followed by tachycardia. The ablation distal (*ABL d*) is positioned in the location of the His. Activation is earliest in the proximal CS with a short VA interval. Overall the inititiation and activation sequence is suggestive of a typical AVNRT. (HRA d is positioned in the high right atrium, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

Initiation of polymorphic VT or VF may be non-specific, although this depends on the clinical context. Torsades de pointes in the setting of long QT syndrome is not inducible by ventricular pacing. On the contrary, a polymorphic VT in Brugada syndrome is highly significant.

VT induced during the study can often be terminated by pacing at a rate 20 ms faster than the VT. If this is unsuccessful or the patient is hemodynamically unstable, a DC cardioversion should be performed.

SVT Diagnostic Maneuvers

Although specific maneuvers will be discussed in each chapter this section provides an overview on this topic. Although the diagnosis can frequently be made during basic pacing occasionally it may be difficult to differentiate between AVNRT, AVRT in particular utilizing paraseptal AP's and atrial tachycardia's. In order to help, certain baseline observations can be made which may help followed by pacing maneuvers. In cases where tachycardia cannot be easily initiated parahisian pacing can be

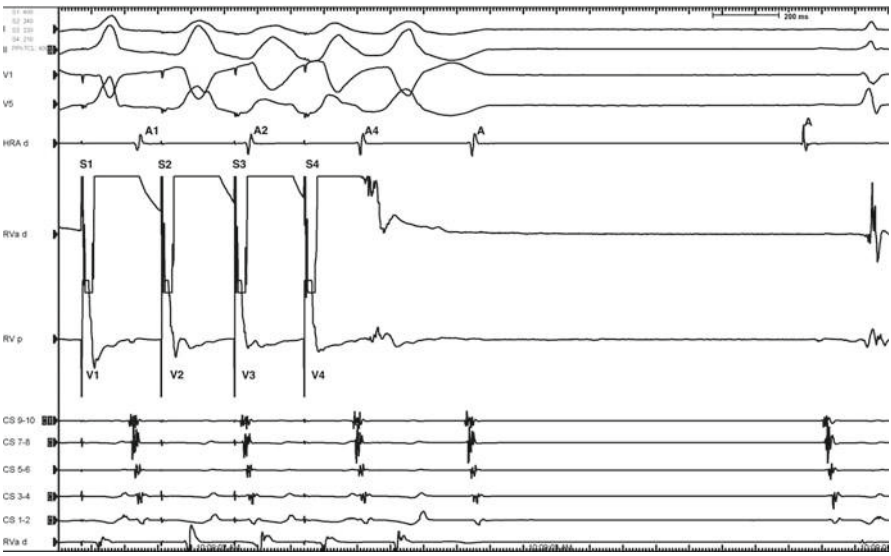

Fig. 2.33 VT stimulation protocol in which a drive train is performed at 400 ms with an S2 of 240, S3 220 and an S4 of 210 from the RV apex. Ventricular activation (*V*) and atrial activation (*A*) can be seen corresponding to each extrastimulus. (HRA d is positioned in the high right atrium, HIS d in the distal His, HIS p at the proximal component of the His, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

performed. In those cases where tachycardia can be initiated entrainment, His synchronous PVC's and overdrive pacing can be performed. The choice of maneuver is therefore dependent on the individual case.

Baseline Observations

During baseline testing the presence of dual AV nodal physiology, the onset and termination of tachycardia, presence and effect of tachycardia variability, VA relationship and atrial activation sequence and effect of bundle branch block can all be used to establish the diagnosis.

The presence of functional dual AV nodal physiology may increase the suspicion of AVNRT. This can be demonstrated as an **AH jump** of greater than or equal to **50 ms** in the case of a typical AVNRT or a HA jump of greater than or equal to 50 ms in the case of an atypical AVNRT. The presence of dual AV nodal physiology is reasonably predictive that the mechanism of the tachycardia is AVNRT in a patient with a prior documented SVT and no evident of AP conduction.

Initiation and Termination

Both AVNRT and AVRT can be initiated by a PAC. In the case of a typical AVNRT there is a sudden prolongation of the duration between the PAC and the initial QRS complex as antegrade conduction occurs down the slow pathway (AH jump) (Fig. 2.34).

In orthodromic AVRT the time from the PAC to the initial QRS is shorter as antegrade conduction occurs along the fast pathway. As seen in Fig. 2.35 pacing is performed at a drive train (S1) of 400 ms with an extrastimulus (S2) at 280 ms. This atrial beat conducts antegradely along the fast pathway which shows decrement but no jump. Conduction then occurs retrogradely with a VA interval of 94 ms. This could be in keeping with a paraseptal AP, atypical AVNRT or less likely an AT. In this case the diagnosis was a posteroseptal AP.

Atrial tachycardias tend to warm up and cool down with a gradual shortening of the tachycardia cycle length at the onset. The initial P wave in an atrial tachycardia has a different morphology in general to the preceding sinus beats although occasionally this may be subtle if the focus is close to the sinus node.

PVC's rarely initiate an AVNRT as the His is generally refractory during the timing of retrograde activation. On the other hand PVC's can commonly initiate an AVRT (Fig. 2.36).

Termination of tachycardia with AV block occurring either spontaneously, following a vagal maneuver or following the administration of IV adenosine occurs in arrhythmias in which the AV node plays a vital role in the circuit i.e., AVNRT and AVRT and does not occur in atrial tachycardia. AT's generally but not exclusively terminate with a ventricular complex (Fig. 2.37).

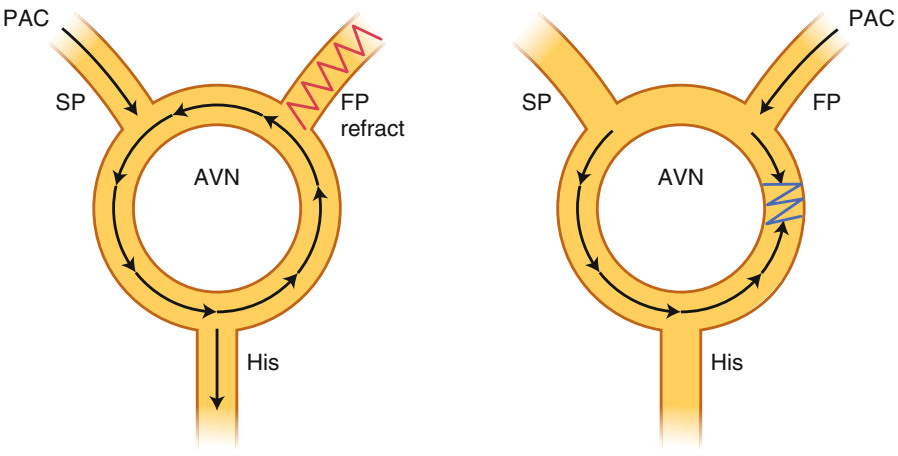

Fig. 2.34 Initiation of a Typical (Slow Fast) AVNRT with a PAC (1) and termination with another PAC (2)

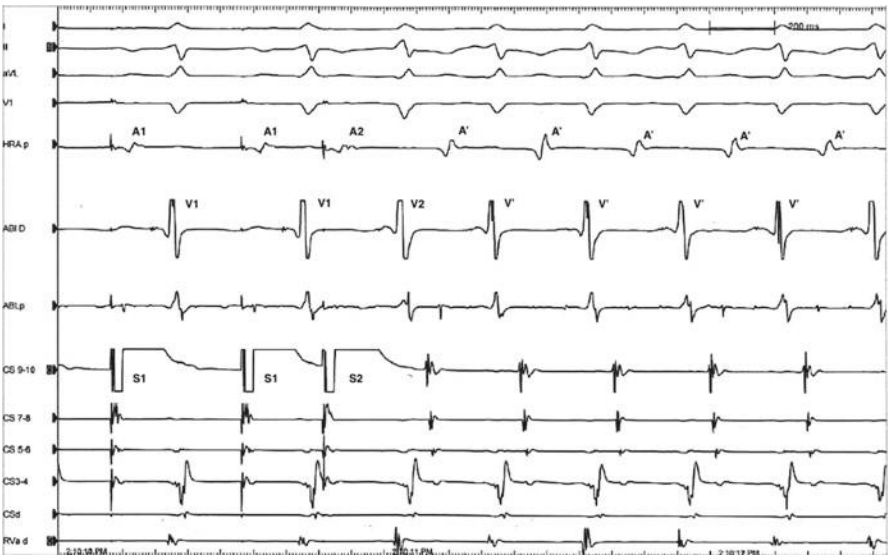

Fig. 2.35 Initiation of an ORT utilizing a retrograde posteroseptal AP. Following a drive train at 400 ms (*S1*) an atrial extrastimulus is given after 280 ms (*S2*). This conducts antegradely over the fast pathway and retrogradely over the AP with a VA interval of 94 ms. The corresponding atrial (*A*) and ventricular (*V*) activations are shown. (HRA p is positioned in the high right atrium, HIS d in the distal His, HIS p at the proximal component of the His, CS 9–10 is in the proximal CS while CS d is in the distal CS and RVa d is located in the RV apex)

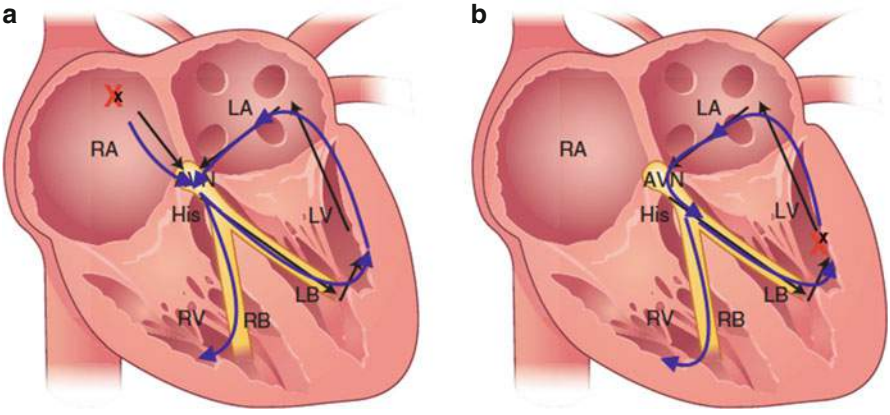

Fig. 2.36 Initiation of AV Re-entry Tachycardia with either a Premature Atrial Complex (PAC) (**a**) or Premature Ventricular Complex (PVC) (**b**)

The continuation of tachycardia despite the presence of AV block however only rules out the possibility of AVRT, but AVNRT and AT may continue to occur in the presence of AV block.

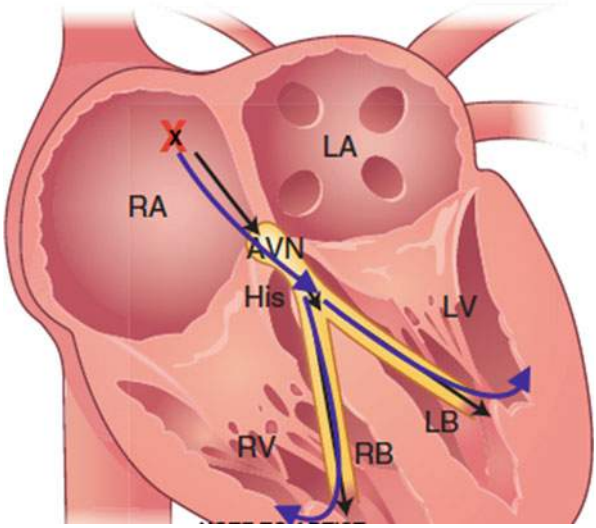

Fig. 2.37 Initiation and termination of Atrial Tachycardia with a long RP Interval

All SVT's can be terminated by varying degrees with either atrial or ventricular premature complexes. In the case of AVNRT the number of atrial beats required depends on the location of the circuit. Generally at least 2 premature ventricular complexes are required to terminate AVNRT. For AVRT termination may occur with either premature atrial complexes or ventricular premature complexes. The number of beats required depends on the distance from the circuit as well as the rate of the tachycardia. In atrial tachycardia the mechanism of the arrhythmia determines the ability for premature atrial complexes to terminate the tachycardia. In general at least 3 PVC's are required for termination of an AT.

VA Relationship and Atrial Activation

The P wave should always be identified in SVT in order to help ascertain the diagnosis. The VA interval corresponds with the RP interval in the surface ECG and is useful in helping to discriminate between various SVT mechanisms. If the septal VA interval is less than 70 ms, this is highly predictive for a typical AVNRT. The VA time is generally longer than 70 ms in cases of orthodromic AVRT, atrial tachycardia and atypical AVNRT. Coumel's tachycardia also known as permanent junctional reciprocating tachycardia (PJRT) results in a long VA time with negative P waves in leads II, III and aVF during tachycardia. This is caused by an orthodromic reciprocating tachycardia using the Av node as the antegrade limb and a slowly conducting accessory pathway as the retrograde limb. The accessory pathway is generally a right sided posteroseptal pathway with an atrial insertion point close to the coronary sinus.

It is useful to compare the P wave morphology during tachycardia with sinus rhythm. This is particular helpful in helping to localize the focus of an atrial tachycardia with narrower P waves more indicative of septal origins.

The atrial activation sequence is very useful in discriminating between the potential causes of SVT. However, central atrial activation may occur with any SVT while eccentric activation more commonly but not exclusively occurs with AVRT or an atrial tachycardia. Eccentric activation may also be seen with AVNRT depending on the atrial insertion point of the retrograde slow pathway. For this reason pacing maneuvers are required to help further differentiation.

Effect of Bundle Branch Block

If the tachycardia cycle length (TCL) prolongs with induction of BBB then this implies that the arrhythmia is AVRT with a VA connection on the same side as the BBB. This principle is known as **Coumel's sign** and is represented on Fig. 2.38 and on the electrogram in Fig. 2.39. As BBB does not affect the AV nodal common pathway this does not affect AVNRT. It also has no effect on AT. Due to the rapid ventricular conduction ventricular aberration is relatively common in the setting of SVT. Bundle branch block on the contralateral bundle has no impact on tachycardia cycle length.

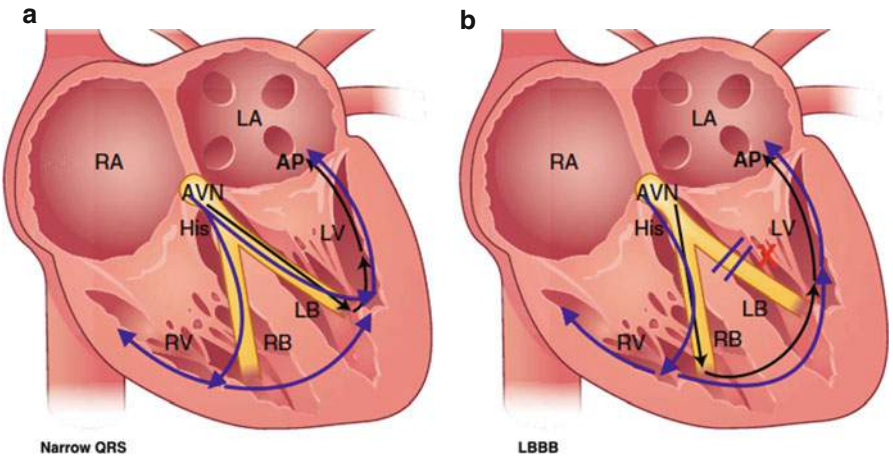

Fig. 2.38 Schematic demonstrating the effect of bundle branch block on the same side as a retrograde accessory pathway. In both images a orthodromic reciprocating tachycardia (ORT) using the AV node as the antegrade pathway is seen. Conduction then occurs through the His and bundle branches. The accessory pathway is located in the left lateral position. In image (**a**) conduction occurs through both the right and the left bundle. Given that this is a left lateral accessory pathway activation along the left bundle will activate the accessory pathway rapidly. In image (**b**) a LBBB occurs thus delaying activation which occurs through the right bundle and then across the interventricular septum. This results in an increase in the VA interval and prolongation of the tachycardia cycle length (TCL)

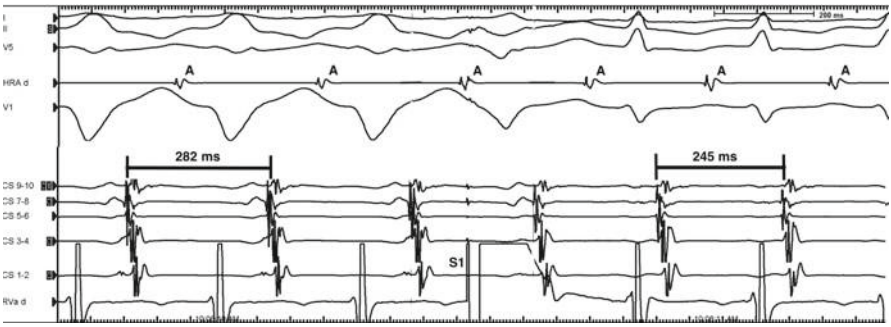

Fig. 2.39 Electrogram showing the effect of bundle branch block on the tachycardia cycle length in a orthodromic reciprocating tachycardia using a left sided accessory pathway as the retrograde limb. On the left of the electrogram the patient is in tachycardia with a wide complex left bundle pattern and a tachycardia cycle length of 282 ms. The atrial activation sequence is earliest in CS 7/8 which is located in the mid coronary sinus and indicates left sided activation. The introduction of a PVC during His refractroriness retrogradely penetrates the left bundle and retrogradely activates the accessory pathway with shortening of the tachycardia cycle length. Following resolution of the left bundle branch block the QRS is narrow and the tachycardia cycle length is shorter. This is indicative of a left sided AP playing a fundamental role in the tachycardia. This electrogram not only demonstrates the effect of a bundle branch block on the tachycardia cycle length but also the effect of a His refractory PVC advancing the next atrial activation. (HRA d is positioned in the high right atrium, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

RV Entrainment

Entrainment is the continual resetting of a re-entry tachycardia by pacing at a site close to or within the circuit at a cycle length slightly shorter that the tachycardia cycle length. The pacing stimulus travels both orthodromically in the same direction as the preceding tachycardia beat and antidromically resulting in a fused beat which is morphologically different to the tachycardia and the paced beats. This continues for all beats during entrainment apart from the final entrained beat where there is no collision of an antidromic beat with the orthodromic waveform.

As the RV apex is closer to the ventricular insertion point of an accessory pathway and further from the AV node entrainment from the RV apex will result in a shorter post pacing interval (PPI) minus tachycardia cycle length for AVRT versus AVNRT. This concept is demonstrated in Fig. 2.40.

This pacing is performed at the RV apex cycle length 20–30 ms shorter than the TCL. This is then examined in order to ensure that capture during pacing has occurred.

If this is confirmed then the PPI – TCL is measured, and the post pacing activation sequence is examined.

As shown in Fig. 2.41 in patients with **AVNRT** (**typical or atypical**) **the PPI – TCL is generally greater than 115 ms** [36]. Figure 2.39 demonstrates a short PPI-TCL of less than 115 ms which is indicative of AVRT.

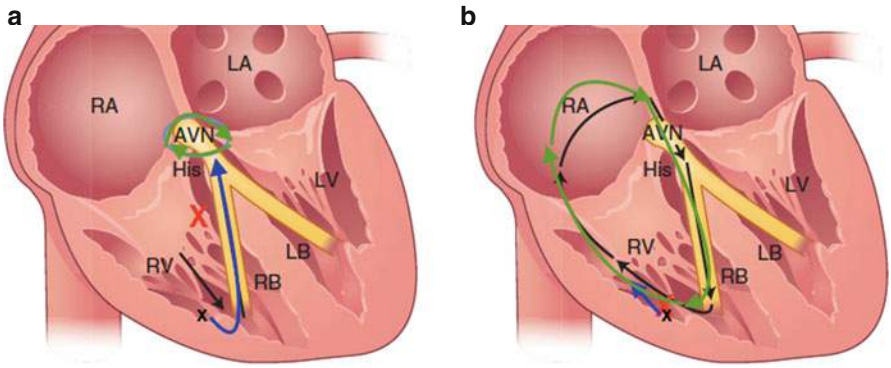

Fig. 2.40 Diagrammatic representation of entrainment from the RV apex. (**a**) On the *left image* the AVNRT circuit is located in the slow and fast pathways in the AV node and pacing from the RV apex is anatomically and electrically distant from the critical circuit resulting in a long PPI – TCL. (**b**) In the image on the *right* the ORT is utilizing the ventricle as part of the circuit and therefore pacing in the RV apex results in a PPI – TCL of less than 115 ms

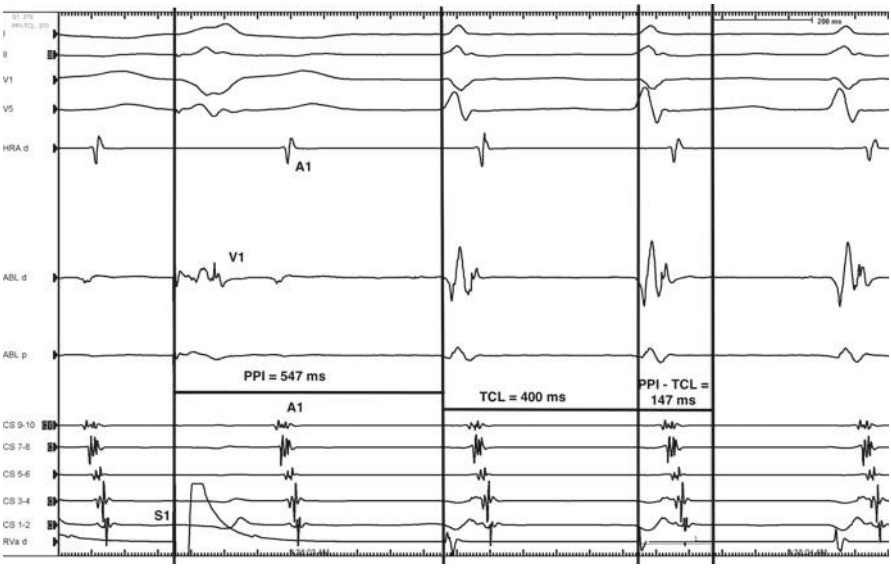

Fig. 2.41 Right ventricular entrainment during SVT. The tachycardia cycle length (*TCL*) of the tachycardia is 400 ms. Pacing is performed at a cycle length of 370 ms from the RV apex. Following confirmation of entrainment (not shown on this tracing) the post pacing interval (*PPI*) is calculated as 547 ms. The post pacing interval (PPI) minus the tachycardia cycle length (*TCL*) is 147 ms which is more indicative of an AVNRT (A refers to atrial activation while *V* is ventricular activation and S is stimulus. The ablation catheter (*ABL d*) is positioned close to the His, HRA d is positioned in the high right atrium, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

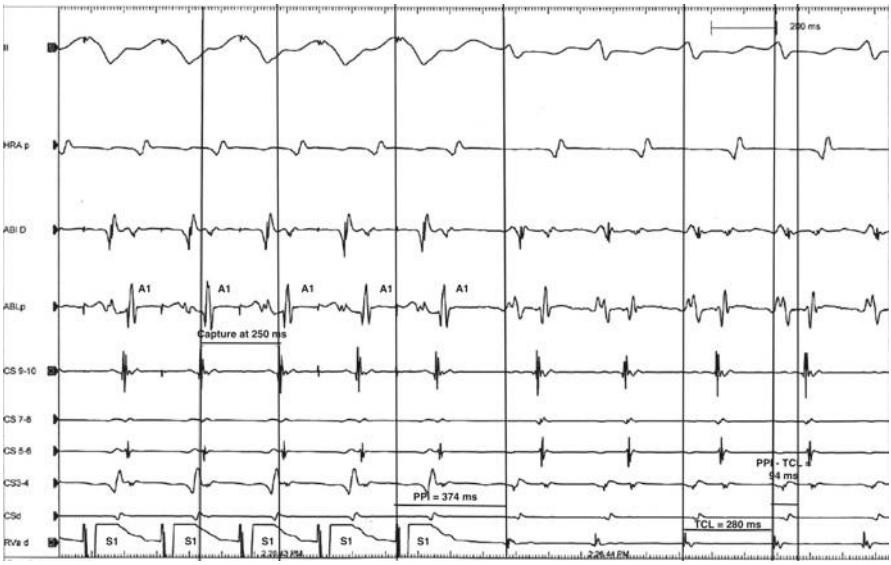

Fig. 2.42 RV entrainment during SVT. The tachycardia cycle length (*TCL*) is 280 ms. Pacing is performed at the RV apex at 250 ms with confirmation of atrial capture at that rate. The PPI – TCL is 94 ms which is suggestive of an ORT. The atrial activation sequence is suggestive of a left sided paraseptal pathway with the earliest retrograde atrial activation at CS 7/8. (The ablation catheter is positioned on the His, HRA d is positioned in the high right atrium, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

It should be noted that rapid ventricular pacing may result in AH prolongation which could artificially prolong the PPI. Therefore this should be corrected by subtracting the baseline AH interval from the PPI. The corrected PPI-TCL should be less than 110 ms for AVRT and greater than 110 ms for an AVNRT.

Examination of the post pacing activation sequence is also important. If the final entrained ventricular beat is followed by an atrial and then ventricular beat this is more likely to be due to an underlying AVNRT or AVRT. If the post pacing sequence is AAV then this is more likely to represent an underlying atrial tachycardia.

An alternative maneuver is to pace from the RV apex and compare the PPI-TCL with pacing from the RV base. A difference of greater than 30 ms between these two locations is suggestive of an AVNRT. This implies that there is a longer PPI-TCL moving further from the septum [37]. A difference less than 30 ms is more indicative of an AP (Fig. 2.42).

PVC During Tachycardia

This is performed in order to differentiate an SVT in which the critical component of the circuit is not dependent on the His such as an AVNRT versus a mechanism which is dependent on the His such as an ORT.

In order to perform this maneuver a PVC is delivered from the RV base earlier and earlier during tachycardia until the His is refractory. The subsequent atrial activation sequence and timing is then compared with that during the tachycardia. If it has no impact on the VA timing then there either is no accessory pathway or it was not penetrated by the PVC. This may occur if the accessory pathway is anatomically distant from the site of pacing such as a left lateral accessory pathway or if it has decremental retrograde conduction properties in which the activation is blocked.

If the next atrial activation is advanced then this implies the presence of an accessory pathway which conducts retrogradely. This does not mean that the accessory pathway is part of the tachycardia circuit. If the atrial activation sequence for this beat is different to that during tachycardia then this is a bystander. If the atrial activation sequence is then the following AH, AA and AV intervals have to be examined in order to assess if the tachycardia has been reset. If the subsequent AH, AA and AV intervals are increased then this implies that the PVC has reset the tachycardia and therefore that the accessory pathway is part of the circuit.

If a PVC delivered during His refractoriness post excites the next atrial activation or terminates the tachycardia then the accessory pathway is part of the circuit. The concept of delivering a PVC during tachycardia is demonstrated in Fig. 2.43.

Para-Hisian Pacing

This can be performed if the tachycardia cannot be induced and is used to differentiate retrograde conduction over the fast or slow pathway in the AV node from that over an accessory pathway. Although it is most commonly used for differentiating septal accessory pathway's from AVNRT it may also be used for left lateral (posterior) and right lateral (anterior) accessory pathway's.

There are two ways to perform this maneuver. The first is to position the mapping catheter towards the RV outflow tract slightly superior to the His recording and pace at 5 mA and 2 ms pulse duration [38]. The catheter is then slowly withdrawn with slight clockwise rotation along the RV anteroseptum until a His signal is recorded on the distal electrodes. The signal is then monitored for evidence of His capture and loss of capture with variability in respiration. With both capture of the His and the local anteroseptum the QRS is less broad than with loss of His capture.

Another method is to position the catheter along the RV basal anteroseptum so that a His signal is recorded on the distal electrodes and pacing is performed during normal sinus rhythm at a high output starting at 10 mA with a pulse width of 2 ms and reducing the output. At high pacing output there is capture of both the His and the local ventricle. As the output is lowered there is loss of His capture with widening of the QRS complex indicating activation of ventricular myocardium further away from the pacing site at the RV basal anteroseptum.

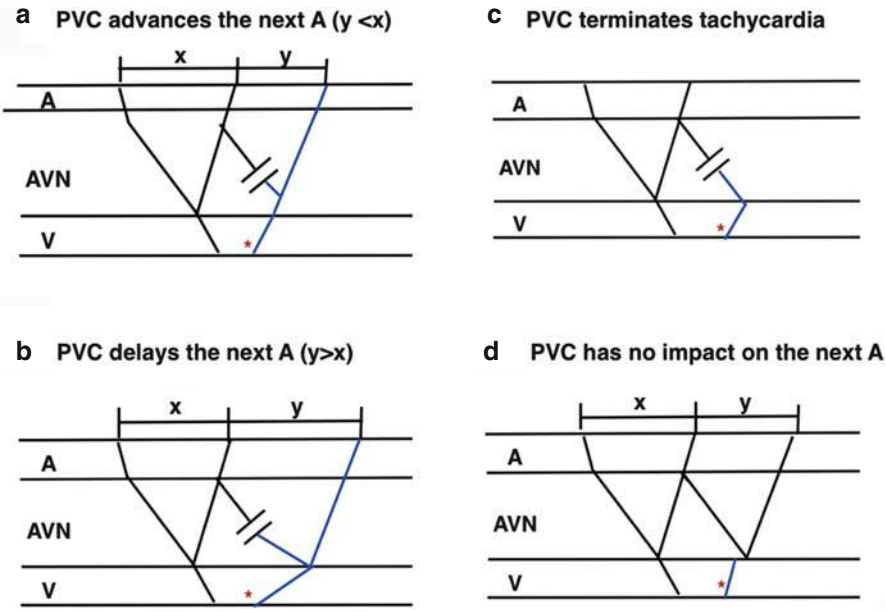

Fig. 2.43 Diagrammatic representation showing the effect of a PVC delivered during His refractoriness during tachycardia. The PVC (*) is delivered in the RV base. In (**a**) the PVC advances the next atrial activation. This indicates the presence of an accessory pathway however does not prove that this is a critical part of the circuit. In image (**b**) the PVC delays the next atrial signal. This indicates the presence of an accessory pathway which is a critical part of the circuit. In image (**c**) the PVC terminates the tachycardia. This also indicates the presence of an accessory pathway which is a critical component of the tachycardia circuit. In image (**d**) the PVC has no effect on the next atrial signal. This may indicate the absence of an accessory pathway. However an accessory pathway may be present but may be anatomically distant from the site of the PVC or may be a decremental pathway which is refractory to the PVC

The following measurements are then compared between a single beat with His and local ventricular capture compared with a single beat with loss of direct His capture:

Stimulus: Atrial Interval (SA)

His: Atrial Interval (HA)

Atrial Activation Sequence (AAS)

The basic principle relies on the anatomic fact that the His is subendocardial and encapsulated in annular tissue meaning that direct capture can only occur when a catheter is positioned along the RV anteroseptum at high pacing outputs. Lowering

the output therefore results in local ventricular capture which activates the RV apex with retrograde conduction up the right bundle to the His resulting in a significant delay to His activation. Although any pacing catheter can be used to perform this maneuver the use of a deflectable catheter with 1 mm spaced electrodes allows easier visualization of the His signal by reducing the width of the recorded local ventricular signal. This principle is demonstrated in Fig. 2.44.

The usual responses to this are shown in Table 2.3. In VA conduction using only the AV node loss of direct His capture results in a prolongation of stimulation to

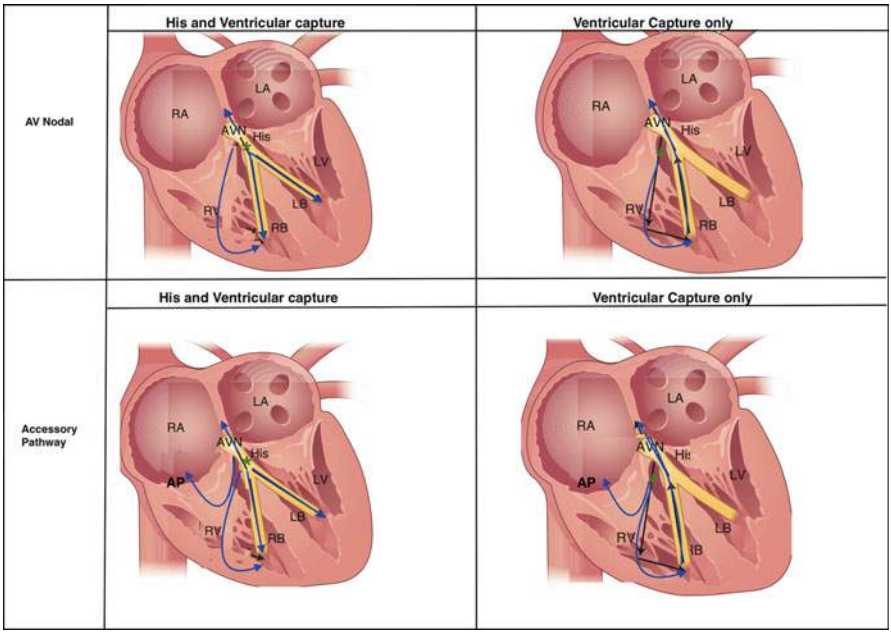

Fig. 2.44 Diagrammatic representation of Parahisian Pacing. In the *top left image* there is capture of both the His and the Ventricle resulting in a relatively short VA time and stimulation to RV apical time. In the *top right* image ventricular capture only conducts via the distal bundle branches via the His and to the atrium resulting in a prolonged VA time. This is indicative of AV nodal conduction. In the bottom left image conduction through the His and ventricle results in the most rapid conduction through an accessory pathway (AP). Conduction through the ventricle only (*bottom left*) results in a similar short VA conduction time through the AP

Table 2.3 Responses to ParaHisian pacing in AV nodal and AP conduction

VA conduction	SA	HA	AAS
AVN	Prolongs	Generally no change but may shorten with dual AVN physiology	Generally no change but may change with dual AVN physiology depending on the atrial insertion point of the slow pathway
AP conduction only	Unchanged or shorter	Shorter	May or may not change

atrial activation interval. In general there is no change in the HA interval although this may shorten in cases of dual AV nodal physiology. This is shown on the electrogram in Fig. 2.45 in which the His and ventricle and the His are both captured at a higher pacing output resulting in a stimulus to atrial interval of 76 ms. When the pacing output is reduced there is only ventricular capture with a prolongation of the stimulus to atrial activation of 136 ms. There is no change in the AAS. This is suggestive of AV nodal conduction only. Generally in AV nodal conduction the atrial activation sequence is generally unchanged, however in certain cases it may change. The slow pathway may have a left atrial insertion point, the CS to atrial connections could be distal or there may be functional block along the Eustachian ridge resulting in activation in the left atrium preceding septal and right atrial activation. Therefore the retrograde AAS is not sufficient to rule out AV nodal conduction only.

In VA conduction using an accessory pathway loss of direct His capture does not prolong the stimulation to atrial activation as the accessory pathway conduction is not dependent on conduction through the His. The HA interval often shortens. The AAS may or may not change depending on the atrial insertion point of the AP and occurs as a result of fusion of retrograde VA nodal and AP conduction.

This maneuver cannot be performed in patients with retrogradely conducting fasciculoventricular accessory pathways as direct His capture will occur at the site

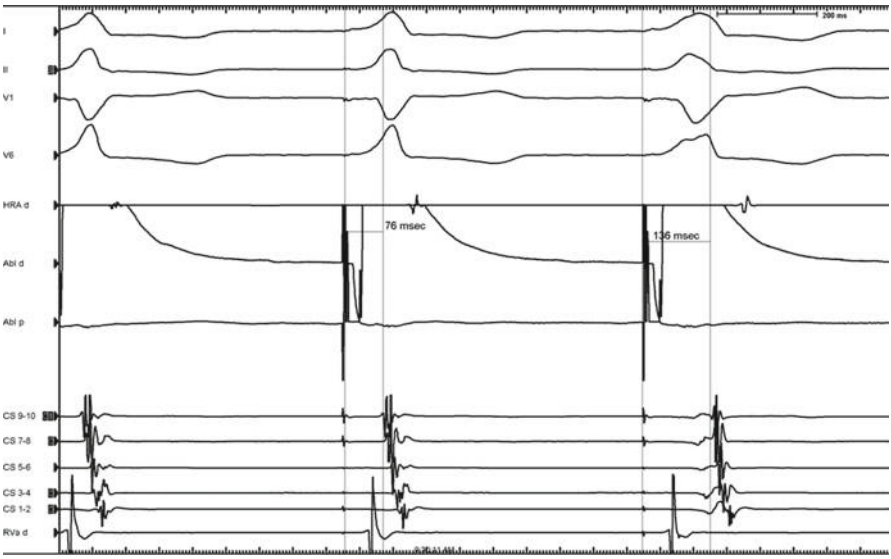

Fig. 2.45 Parahisian pacing in a patient with AV nodal conduction only. Pacing is performed from the ablation catheter which is positioned on the His. The narrower beat indicates capture of both the ventricle and the His with a stimulus to atrial time of 76 ms. When the pacing output is reduced there is only ventricular pacing with loss of His capture. The stimulus to atrial time is longer at 136 ms. This is indicative of AV nodal conduction. (HRA d is positioned in the high right atrium, HIS d in the distal His, HIS p at the proximal component of the His, CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS and RVa d is located in the RV apex)

of the accessory pathway insertion point during both high and low output pacing with no widening of the QRS at lower pacing output. In the reverse situation proximal RBBB may mean that direct pacing of the His via the proximal right bundle is not possible resulting in a wide QRS at high and low pacing output.

High output pacing may result in capture of other closely related structures resulting in an incorrect interpretation. Direct atrial capture at high output may reveal an apparent short stimulus to atrial activation time. High output pacing may also result in capture of the left bundle branch which may result in shortening of VA conduction for left sided pathways with an apparent increase in VA conduction time as the pacing output is reduced.

Transseptal Access

Transseptal access is used in order to gain access to the left atrium and left ventricle for AP mapping and ablation, left sided AT's, AF ablation, VT ablation and left atrial appendage occlusion. This procedure is performed using a combination of fluoroscopic images, pressure monitoring, contrast and often with the assistance of echocardiographic information.

Equipment

Trans-septal Needles

A number of transseptal needles are available for use which vary both in length and angulation. The most commonly used is the Brockenbrough (BRK) which is an 18 Guage needle with an arrow at the proximal end which indicates the direction of the tip of the needle. The BRK needle has a shaft to needle tip angle of 19° while the BRK 1 needle shown in Fig. 2.46 has a shaft to needle tip angle of 55°.

Additionally BRK needles vary in length. For the majority of standard non deflectable sheaths the needle is 71 cm while for a long deflectable sheath this is 98 cm.

The NRG RF transseptal needle shown in Fig. 2.47 (Baylis Medical, Montreal, Canada) is a 21 Guage device which allows delivery of RF at the tip of the needle. This comes in similar lengths to the BRK needle with similar curve option. This needle is useful for aneurysmal septums and has been shown to have a lower incidence of sheering from the inside of a transseptal sheath [39]. The needle is positioned against the fossa ovalis and RF is applied to the tip at 10 W for 2 s. On TEE and ICE entry into the left atrium is seen as bubbles in this chamber.

Fig. 2.46 Showing the main types of BRK Transseptal Needles (St Jude Medical, St Paul, MN, USA). The image on the top shows the 71 cm BRK needle at the top with a shaft to tip angle of 19°, below this is the 71 cm BRK1 needle which has a shaft to tip angle of 55°. Below this is the 56sm BRK needle. On the *bottom right image* the tips of the three needles are shown in closer detail. The image on the *bottom left* shows the *pointer arrow* which in general should be directed at 4–5 o'clock

Fig. 2.47 Showing the Baylis NRG ® Needle (Baylis, Montreal, Canada)

Transseptal Sheaths

There are various sheaths available for trans-septal access. These are either fixed or deflectable. The Swartz Left (SL) range of sheaths (St Jude Medical, St Paul, MN, USA Medical) is most commonly used. These sheaths were principally designed to deflect towards the mitral annulus for accessory pathway mapping and ablation. All of these sheaths have a primary curve of 50° with a secondary curve of 0° in the SLO, 45° in the SL1, 90° in the SL2 and 135° in the SL3. The SL4 has a 35° primary curve and has an angulation of 180°. Other non-deflectable transseptal sheaths include the Channel FX (Boston Scientific Way Marlborough, MA, USA) and the Convoy Advanced (Boston Scientific Way Marlborough, MA, USA).

Several deflectable sheaths also exist. The Agilis sheath (St Jude Medical, St Paul, MN, USA Medical, St Paul, MN, USA) is 91 cm long and requires the 98 cm transeptal needle. This sheath is available in medium and long reach options. Other deflectable sheaths include the Channel steerable (Boston Scientific Way Marlborough, MA, USA), the Direx (Boston Scientific Way Marlborough, MA, USA) and the Mobicath (© Biosense Webster, Inc).

Guidewires

These are generally 0.032 in. in diameter with a J shaped distal end of approximately 3 mm in length at the tip. These wires are placed into the superior vena cava and are used to advance the sheath and dilator over. They may also be advanced through the sheath and dilator into the left superior pulmonary vein in order to confirm position and allow dilatation of the transseptal access point while minimizing the potential risk of the dilator advancing through the lateral left atrial wall. If unsure whether the transseptal needle is in the left atrium an angioplasty wire can also be advanced through the needle prior to advancement of the sheath and dilator.

Fluoroscopic Approach

In order to help with fluoroscopic access a catheter can be positioned in the coronary sinus and the His. The His catheter is at the same level but anterior to the fossa ovalis. The electrode recording the proximal His acts as a surrogate for the aortic root. The coronary sinus catheter shows the direction in which the transseptal needle should pass in an LAO projection. This is parallel and inferior to the direction of the transseptal needle. The distal end of the coronary sinus also marks the lateral wall of the left atrium. The relevant anatomy is demonstrated on the CT in Fig. 2.48.

Fig. 2.48 Relevant anatomy in a trans septal approach. In the top image the fossa ovalis (*FO*) is posterior to the aorta (*Ao*). Also seen in this image is the right atrial appendage (RAA) anteriorly, the coronary sinus (*CS*) posteriorly and the left atrium (*LA*). The mid image shows a trans-septal sheath engaging the fossa ovalis (*FO*) posterior to the aorta). The image at the bottom is a CT showing the right atrium (*RA*) and left atrium (*LA*). The fossa ovalis (*arrow*) is posterior to the ascending aorta (*AAo*). Also seen in this image is the right superior pulmonary vein (*RSPV*), right inferior pulmonary vein (*RIPV*), left superior pulmonary vein (*LSPV*), left inferior pulmonary vein (LIPV), left atrial appendage (*LAA*) as well as the right ventricle (*RV*), left ventricle (*LV* and descending aorta (*DAo*)

Although various fluorosocopic views may be used the most useful are the LAO 30, RAO 30 and the left lateral. The sheath and dilator are flushed with heparinized saline in order to eliminate all air. The trans-setpal needle is flushed and in the case of a BRK the stylet is placed back inside the needle and locked in

place. The needle can be placed inside the sheath and dilator in order to ensure that these are compatible in terms of length. The needle is then removed and the sheath and dilator are introduced over a 0.032 J shaped wire into the superior vena cava. The wire is then removed and the dilator is aspirated and flushed with heparinized saline. The transseptal needle is then introduced into the dilator and sheath with the tip of the needle kept inside the dilator. In the case of a BRK needle it is important that the stylet is kept inside the needle while introducing this into the dilator in order to prevent sheering of plastic from the dilator. This is not required for the NRG RF which has a less sharp tip. Once the needle is close to and still inside the dilator tip the stylet is removed and the needle is aspirated and flushed with heparinized saline. This can then be connected to a three way tap and connected to pressure monitoring and contrast if required. Systemic heparin is then administered to the patient prior to transseptal access being achieved.

The sheath with dilator and needle are positioned between 4 and 6 o clock and withdrawn from the superior vena into the right atrium using an LAO 30 projection. As the apparatus is withdrawn along the superior vena cava the sheath and

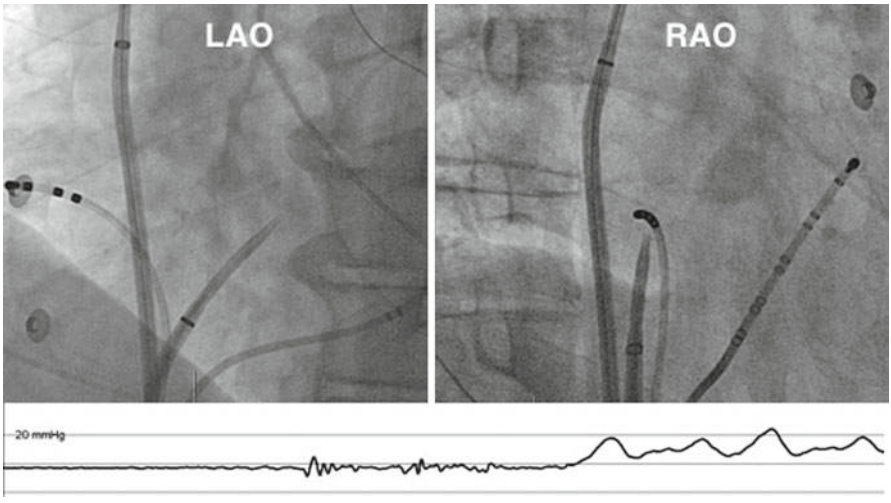

Fig. 2.49 Fluoroscopic guidance of trans-septal access in the *LAO* view (*top left*) and *RAO* view (*top right*). In the LAO projection the tip of the dilator should be superior to and parallel to the coronary sinus which demonstrates the AV groove parallel and posterior to the mitral annulus. The proximal poles of the quadripolar catheter are positioned along the His which acts as an approximate marker of the aortic root. In the RAO image on the *top right* the needle and sheath is clearly posterior to the His catheter. The pressure tracing on the bottom is recorded through the trans septal needle and shows a damped pressure tracing as it is against the septum followed by a left atrial pressure as access is achieved

dilator jumps to the left as it deflects from the descending aorta into the right atrium, Further withdrawal results in a second jump as the apparatus engages the fossa ovalis. In the LAO projection the tip of the dilator should be superior to and parallel to the coronary sinus which demonstrates the AV groove parallel and posterior to the mitral annulus, thus helping to demonstrate the widest portion of the LA. The relevant anatomy for trans septal access is shown in Fig. 2.49. In the RAO projection the anterior and posterior projections can be checked relative to the His catheter. This can also be demonstrated in the left lateral position with the His catheter pointing anterior and the CS posterior. The needle is pointed at 1 o'clock in this view for engagement of the fossa ovalis. The proximal His recording identifies the central fibrous body at the most inferior aspect of the noncoronary aortic cusp. Prior to transseptal access a bolus of heparin should be administered.

The apparatus is then withdrawn very slightly and then advanced with the needle outside of the sheath and dilator with pressure measured from the tip of the needle. There is usually a jump as the needle crosses the septum. Confirmation should be performed by checking the pressure and injecting contrast. As soon as this is confirmed, the dilator and sheath can be advanced over the needle, and the needle and dilator removed so that a long J wire can be gently advanced into the left superior pulmonary vein. Care must be taken at all times to ensure that the sheath and dilator are not advanced too far resulting in a perforation, or that the wire is not advanced into the left atrial appendage. For the second transseptal sheath, some operators withdraw the sheath and leave the J wire in place and then advance the ablation catheter through the puncture site, while others perform a second transseptal puncture using the same puncture.

Echocardiographic Visualization

Although fluoroscopic guidance is fundamental in achieving transseptal access variations in anatomy may result in difficulties crossing the foramen ovale. These include an aneurysmal atrial septum defined as a deviation during the cardiorespiratory cycle of at least 10 mm, prior cardiac surgery, congenital heart disease, dilated atria, multiple prior trans-septal procedures and a dilated aortic root. The interatrial septum cannot be reliably differentiated from the aortic root on trans thoracic echocardiogram and therefore either ICE or TEE can be used. The advantage of both of these imaging modalities is that the fossa can be directly visualized. The disadvantage of ICE is that it often required additional vascular access and is generally quite expensive. TEE is extremely useful but requires the patient to be under general anesthesia and has the potential for esophageal injury. Tenting of the fossa ovalis can be seen on TEE in Fig. 2.50.

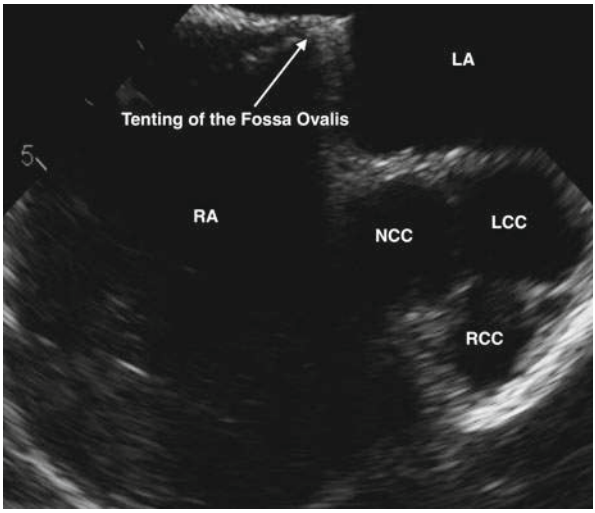

Fig. 2.50 Transesophageal imaging showing tenting of the Fossa Ovalis during trans-septal access. The right atrium (*RA*) and left atrium (*LA*) are seen as well as the non coronary cusp (*NCC*), left coronary cusp (*LCC*) and right coronary cusp (*RCC*) of the aortic valve

Important Points

1. Unipolar electrograms are amplified signals recorded between the distal pole of the catheter (+) and Wilsons Central Terminal (−).
2. Bipolar signals are amplified signals recorded from two closely spaced unipoles. In general the distal pole is negative while the proximal pole is positive.
3. All signals are amplified and filtered. The amplified signal first passes through a high pass filter which allows higher frequency signals to pass through while removing signals below a designated frequency. This then passes through an isolation amplifier which isolates the current from the patient and is subsequently transmitted through a low pass filter. This allows lower frequency signals to be transmitted while filtering out higher frequencies.
4. SNRT is measured using the principle of overdrive suppression in which pacing is performed close to the sinus node at a rate faster than the sinus rate and the time taken from the last paced beat to the first intrinsic sinus beat is measured. A sinus node recovery time, taken as the longest interval after pacing at any cycle length is generally considered abnormal if longer than 1500 ms.
5. SACT is the conduction time from the SN to the RA tissue. A normal SACT is considered to be to be 50–125 ms.

6. The AH interval is measured from the onset of the local atrial electrogram recorded in the His catheter to the onset of the His signal and represents conduction through the AV node. The normal range is anywhere from 50 to 120 ms. A prolonged AH interval may occur as a result of intrinsic AV nodal dysfunction or a result of antiarrhythmic drugs. A short AH interval generally occurs in the presence of catecholamines.
7. The HV interval is measured from the onset of the local His signal to the local ventricular signal on the His catheter (Fig. 2.24). This generally reflects the conduction time through the proximal His, bundle branches and the Purkinje system. The normal range is considered to be between 30 and 55 ms. Intrinsic His dysfunction or antiarrhythmic drugs may prolong the HV interval. A short HV interval may be seen with accessory pathway conduction which may even be negative. Care must be taken not to confuse the right bundle electrogram as the His electrogram may artificially lead to what may seem like a short HV interval.
8. The effective refractory period (ERP) is the longest coupling interval in which the stimulus fails to stimulate the myocardium at twice the diastolic threshold.
9. The AV Wenckebach point is defined as the longest cycle length which results in 2:1 AV block.
10. If the tachycardia cycle length prolongs with induction of BBB then this implies that the arrhythmia is AVRT with a VA connection on the same side as the BBB known as Coumel's sign.
11. Entrainment is the continual resetting of a re-entry tachycardia by pacing at a site close to or within the circuit at a cycle length slightly shorter that the tachycardia cycle length. During an SVT entrainment from the RV results in a shorter PPI-TCL for AVRT versus AVNRT.
12. If a PVC delivered at the same time as the antegrade His signal results in an advancement of the next atrial activation with no change in the AAS this implies the presence of an accessory pathway which participates in the circuit. A change in the AAS implies that the accessory pathway is not participating in the tachycardia. If a His refractory PVC does not affect the following atrial beat then there is either no AP or the PVC has not conducted retrogradely up the AP. This may occur if the AP has decremental retrograde conduction or is anatomically far from the location of delivery of the PVC.
13. If a tachycardia cannot be easily induced parahisian pacing may be helpful to study retrograde conduction properties. In the presence of VA conduction using only the AV node loss of direct His capture results in a prolongation of stimulus to atrial activation interval. In general there is no change in the HA interval although this may shorten in cases of dual AV nodal physiology. In VA conduction using an AP loss of direct His capture does not prolong the stimulation to atrial activation as the AP conduction is not dependent on conduction through the His. The HA interval often

shortens. The AAS may or may not change depending on the atrial insertion point of the AP and occurs as a result of fusion of retrograde VA nodal and AP conduction.

14. Trans septal access may be obtained using a fluoroscopic approach or with the addition of echocardiographic guidance. In the fluoroscopic image the coronary sinus catheter shows the direction in which the transseptal needle should pass in an LAO projection. This is parallel and inferior to the direction of the transseptal needle. The distal end of the coronary sinus also marks the lateral wall of the left atrium.

This can also be demonstrated in the left lateral position with the His catheter pointing anterior and the CS posterior. As shown in Fig. 2.49 pointing the needle at 1 o'clock is reasonable in this view for engagement of the fossa ovalis. The proximal His recording identifies the central fibrous body at the most inferior aspect of the noncoronary aortic cusp.

Chapter 3
Electroanatomic Mapping

Benedict M. Glover and Pedro Brugada

Abstract Electroanatomic mapping (EAM) involves the rapid acquisition of multiple electrical and anatomical points in order to create a 3 dimensional map encompassing this data. These systems use **magnetic**, **impedance or a combination** of the two for the non-fluoroscopic location of the catheters. Data can be displayed on a recreated anatomic structure. This data includes activation times, voltage recordings and entrainment mapping. One of the original mapping systems the Localisa (© Medtronic plc 2015) has been replaced by three systems which are used most commonly in clinical practice which include CARTO (© Biosense Webster, Inc), NavX (St Jude Medical, St Paul, MN, USA) and Rhythmia (Boston Scientific Way Marlborough, MA, USA). Despite advances in the automation of these systems it is important to examine electrogram quality and annotation otherwise the map may not make any sense.

General Principles of EAM Mapping

Although the current mapping systems differ in the specific technology employed for catheter localization and electrogram acquisition and processing there are several important general principles for all aspects of mapping systems. It is important that useful data are processed. In the electrophysiology laboratory the most common mapping includes activation (isochronal), voltage (isopotential) and entrainment mapping. If respiratory gating is used all points in all systems are generally recorded during the same phase of respiration which is generally end expiration.

Reference Point

A stable reference point is required for activation mapping so that all points can be measured relative to the same electrogram. An ideal reference electrogram should be stable with an obvious positive or negative peak for measurement. The trigger is then set on either the most positive or negative change in voltage over time (dV/dT). In the ventricle a surface QRS can be used for this or the electrogram from the RV apical catheter. In the atrium the surface P wave is not satisfactory and therefore the coronary sinus catheter is generally used given its relative stability. It is important that this is positioned in a stable position with a clear atrial signal.

Window of Interest

It is important to ensure that every point taken for an arrhythmia is related to the same beat. For a **focal arrhythmia** such as PVC's, focal VT and many AT's the window of interest is set relative to the onset of the P wave or QRS. **The earliest component may be set at 80 ms ahead of the surface signal and 30 ms after the offset**.

For a **re-entry tachycardia** such as atrial flutter (both typical cavotricuspid isthmus dependent and atypical), some atrial tachycardia's and scar related VT the window of interest is chosen as **90 % of the tachycardia cycle length** (TCL) to allow for a degree of cycle length variability. The earliest component in the window is half of the value prior to the onset of the P wave or QRS and the latest component is half of the value after the onset of the P wave or QRS. The early and late signals in this method are arbitrary and only used to have an understanding of the mechanism and anatomical regions involved in the circuit. The best location for ablation may therefore not be the earliest recording on this map but a critical isthmus within it.

In order to perform an activation map which helps to locate the isthmus in an atrial re-entry circuit a slightly different technique is used while setting the window of interest. The **earliest component** of the window is set for **mid diastole of the beat of interest and the late component of the window is set for mid diastole for the following beat**. [1] This means that the region where early meets late is the **mid-diastolic region**.

The P wave duration is measured from the surface ECG at 100 mm/s with or without the administration of intravenous adenosine. The early component of the window is calculated by subtracting the P wave duration from the tachycardia cycle length and dividing by two. As the window is being set from the reference signal the distance from the reference to the onset of the P wave is subtracted if the reference occurs before the p wave or added if its occurs after the P wave. This should correspond with mid-diastole. In order to calculate the late component to the window the duration of the early window is subtracted from the tachycardia cycle length and multiplied by 90 % (Fig. 3.1).

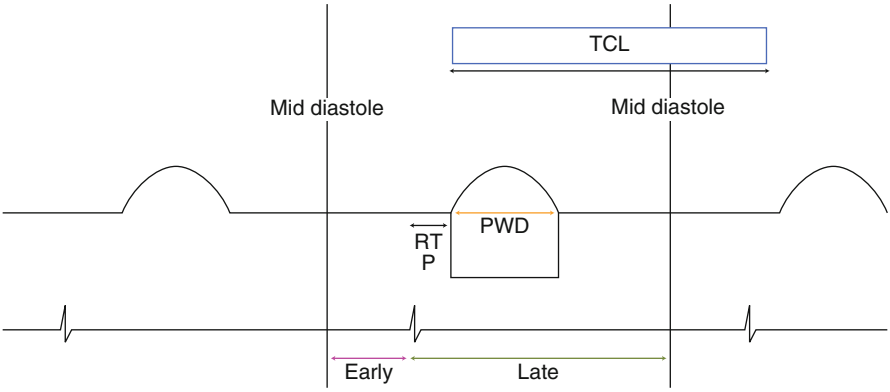

Fig. 3.1 Calculation of window of interest in a re-entry tachycardia. *TCL* tachycardia cycle length, *PWD* P wave duration, *RTP* reference to onset of P wave

Activation Mapping (Isochronal)

One of the many advantages of electroanatomic mapping is the ability to acquire multiple electrogram signals during a tachycardia and color code these so that an activation map can be acquired. Following selection of an appropriate reference signal and window of interest points are acquired and selected relative to the reference signal. Electrograms can be individually viewed and a marker is used to designate the onset of the signal which can then be moved if required. These signals are then color coded so that early is designated as red followed by yellow, green blue, and purple which indicates later activation. In focal arrhythmias regions which are coded red tend to be reasonable areas to explore and consider ablation particularly for the very earliest signal with a QS and no R wave on the unipolar electrogram. In unipolar electrograms the distal pole of the catheter (anode) is connected to a remote electrode known as the indifferent electrode (cathode). Depolarization towards the distal electrode results in a positive deflection while depolarization away from the electrode results in a negative deflection. A QR therefore implies that the wave of depolarization is moving away from the electrode. In cases of poor electrode contact a slurred S wave may also be present which implies that better catheter manipulation is required.

In macro re-entry circuits the earliest site as designated by red is not generally targeted with ablation. Rather the activation sequence should be examined in order to understand the basis of the arrhythmia and further mapping with the catheter should be performed in order to help localize the critical isthmus with mid diastolic signals. As shown in the activation map in Fig. 3.2 a re-entry circuit is seen rotating around a right atrial lateral wall atriotomy scar. Ablation (light and dark red dots) is performed along the lateral wall from the superior vena cava to the inferior vena cava after pacing for phrenic nerve stimulation is performed and marked as a white line. This resulted in termination of the tachycardia.

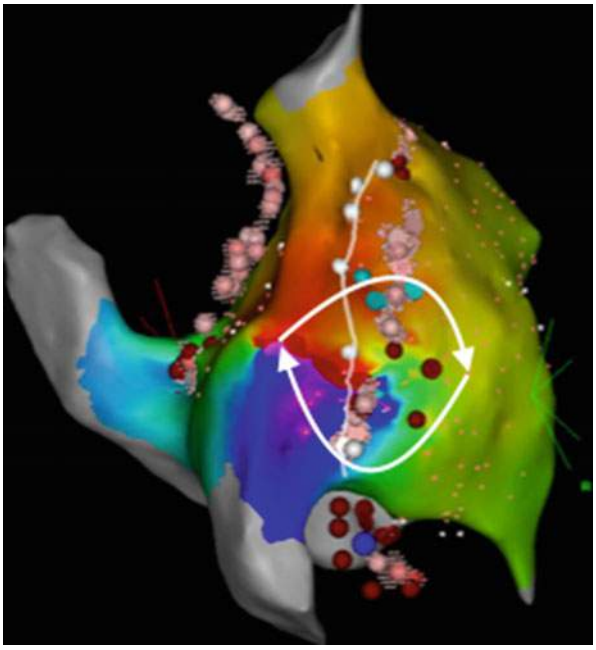

Fig. 3.2 Activation map showing a macro re-entry circuit around an atriotomy scar in a patient who previously underwent mitral valve surgery. The earliest activation is seen as *red* followed by *yellow*, *green*, *blue* and then *purple*. The *white arrow* shows the overall direction of conduction. Prior to ablation high output pacing was performed and the approximate location of the right phrenic nerve was mapped out (shown as a *white line*). Ablation was performed (*light and dark red dots*) from the superior vena cava to the inferior vena cava with termination of the tachycardia. The *light blue* dots indicate fractionated potentials. Also seen on the *left side of the image* in the background is an ablation line along the left interatrial septum which resulted in termination of a second tachycardia and at the inferior aspect of the image a cavotricuspid ablation line which terminated a third tachycardia

Prior to delivery of ablation in this region entrainment can be performed to ensure that the location is within the circuit. If the tachycardia terminates pace mapping may be performed and compared with the clinical arrhythmia. In order to perform pace mapping the minimum output is used from the distal electrodes of the ablation catheter and the paced beats are compared with the clinical arrhythmia. It is possible to have multiple different pace maps by pacing from the same site as the same isthmus may have multiple exit sites. In VT a long stimulation to onset of QRS with an excellent pace map generally indicates close proximity to the isthmus which then conducts to the exit site. Data acquired from an activation map can be used to create a propagation map. This demonstrates a wavefront of activation color coded red with a background blue image. This demonstrates conduction velocity and the overall direction of depolarization for both focal and re-entry circuits.

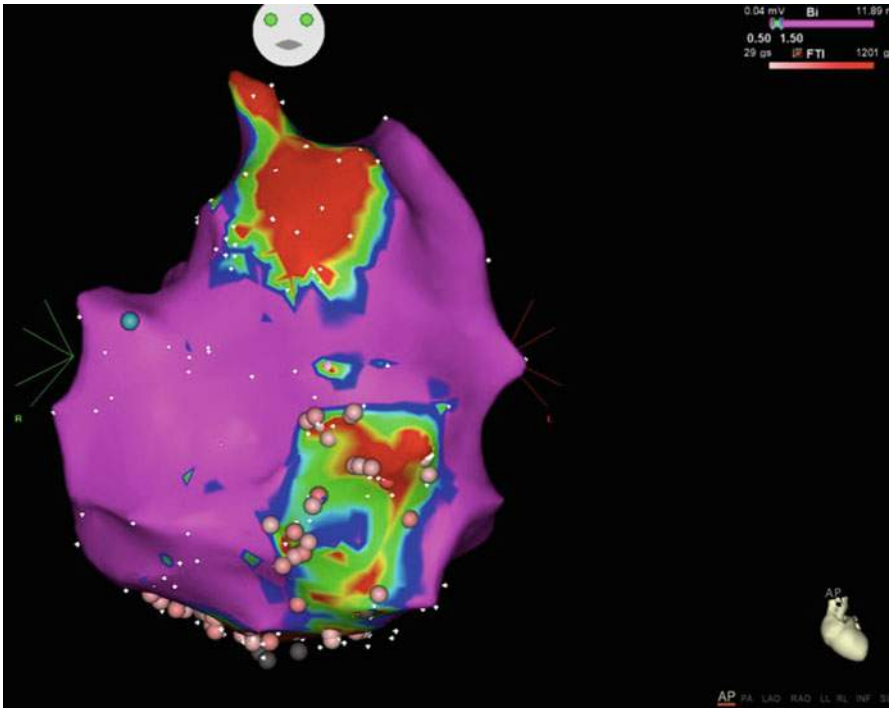

Fig. 3.3 Voltage map of the right ventricle in a patient with a history of tetralogy of fallot. Two regions of dense scar are seen, one in the anterosuperior tricuspid annulus and the other in the anteroapical region. Both of these are surrounded by heterogenous tissue. The inducible VT was found to circulate around the anteroapical scar which terminated with ablation

Voltage Map (Isopotential)

Is used to map local potentials during either sinus rhythm, tachycardia or pacing. The concept is that low amplitude endocardial signals are more indicative of regions of scar while higher amplitudes imply relatively healthy myocytes. As well as the amplitude of the signal the degree of fractionation and duration of the signal are very important as this may imply regions of slow conduction, which are often targeted for ablation.

The amplitude of each signal can be color calibrated so that red implies scar with orange, yellow, green, blue and purple indicating progressively higher amplitudes.

In the right ventricle normal bipolar electrograms have an amplitude of 3.7 ± 1.7 mV and in the left ventricle 4.8 ± 3.1 mV with **1.5 mV or less defined as scar and 0.5 mV or less dense scar**. [2] An example of a voltage map in a patient with tetralogy of Fallot is shown in Fig. 3.3.

In the left atrium normal bipolar amplitudes are considered to be greater than 0.5 mV [3] although in patients with AF this cutoff may be 0.45 mV. [4]

A **late potential** is defined as an isolated potential occurring greater than 10 ms after the end of the surface QRS complex while a **mid diastolic potential** is defined as a high frequency localized potential occurring between two QRS complexes with an isoelectric line either side. **Fractionated potentials** are defined as low amplitude signals with multiple sharp deflections with an overall duration greater than or equal to 70 ms. **Complex fractionated atrial electrograms** (**CFAE's**) are defined as low amplitude fractionated atrial electrograms with a cycle length of less than 120 ms.

Entrainment Mapping

Entrainment mapping can be performed by pacing from the ablation catheter in various locations where the tachycardia circuit location is suspected. By overdrive pacing at a cycle length shorter than the tachycardia cycle length the tachycardia is continuously reset without terminating to the same cycle length with manifest and concealed entrainment. In general the pacing cycle length is 20–30 msec shorter than the tachycardia cycle length although in certain circumstances such as an orthodromic reciprocating tachycardia a rate just slightly less than the tachycardia cycle length is chosen from the RV apex as faster rates may penetrate the AV node and result in termination of the tachycardia.

A short PPI – TCL generally indicated closer proximity to the circuit. This difference can then entered onto the mapping system as a color coded time where red is less than 30 msec followed by yellow, green, blue and finally purple where the difference is greater than 100 msec. This is an effective strategy to help map out the regions of the chamber involved in the re-entry circuit. It does not provide data on where exactly to ablate and this decision must be made based on the location of the isthmus or by joining various anatomic structures. In a diseased atrium where multiple ablations have been performed it may be difficult to capture all areas as well as the potential to terminate the arrhythmia as well as initiation of a different tachycardia.

Specific Mapping Systems

CARTO Mapping System (© Biosense Webster, Inc)

This system uses a combination of magnetic and impedance based technology for catheter localization and data acquisition. A locator pad composed of three coils is positioned under the table and emits very low intensity magnetic fields between 5×10^{-6} to 10^{-5} T. As demonstrated in Fig. 3.4 each coil emits a slightly different field strength which is then detected by a sensor in the proximal tip of the ablation catheter. The relative magnetic field from each coil is then fed back to the system with a three dimensional location in the x,y and z axis and catheter orientation in three

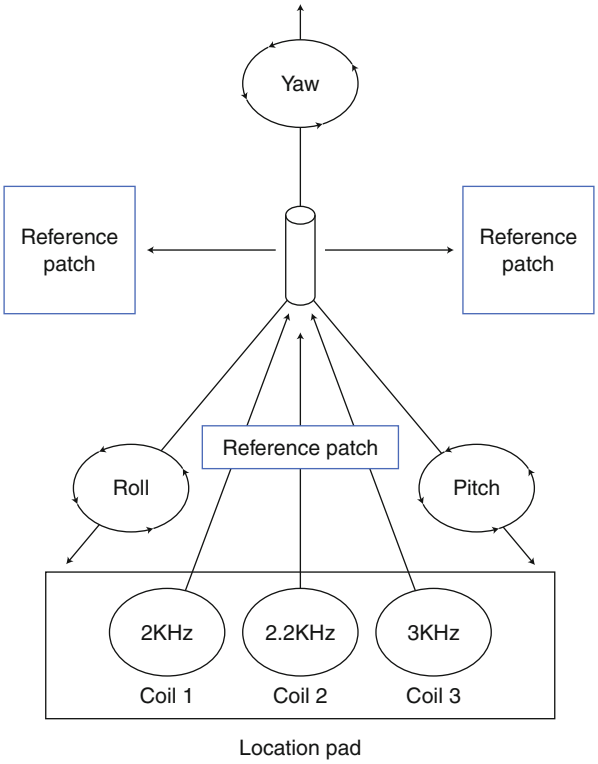

Fig. 3.4 Concept of Electroanatomic mapping using the CARTO system (© Biosense Webster, Inc)

planes termed roll, pitch and yaw. The ablation and diagnostic catheters also emit a low level current which is detected by six reference patches. Although the locations of diagnostic catheters can be visualized the electrogram's can unfortunately only be seen in specific catheters designed by the company such as the Lasso, the Pentarray and the Decanav.

The Lasso is a 10 or 20 pole circular deflectable catheter (Fig. 3.5) which is predominantly used for left atrial mapping and in particular pulmonary vein isolation. The circular component is flexible with a 4.5 Fr diameter and a shaft which fits through an 8 Fr sheath.

The Pentarray catheter consists of 20 electrodes on 5 arms (Fig. 3.6). Each arm is soft with a 3 Fr diameter and a shaft, which can be positioned through a 7 Fr sheath and comes in different curves. Each individual electrode is 1 mm in length with varying electrode spacing; either 4 mm spacing or 2-6-2 mm spacing.

The Decanav catheter is a 10 pole catheter in which each electrode is 2 mm in length and with electrode spacing of 2-8-2 mm (Fig. 3.7). This allows the rapid acquisition of multiple points during mapping and can be useful for both atrial tachycardia and ventricular tachycardia including outflow tract tachycardia. Like

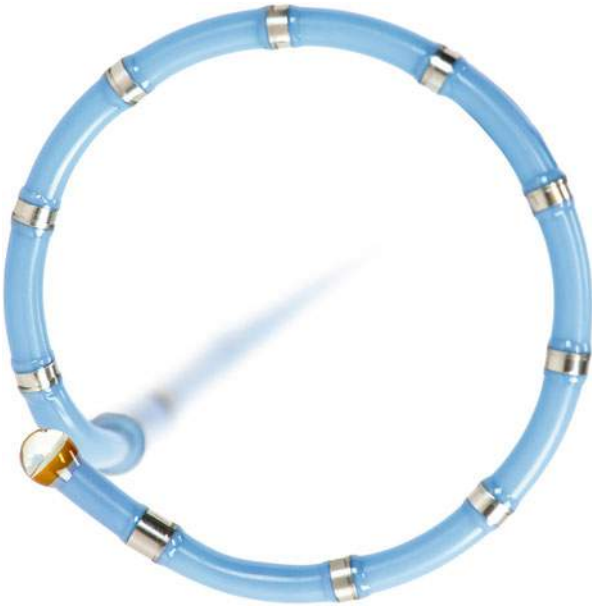

Fig. 3.5 Showing bipolar electrodes on the circular Lasso Catheter with 10 poles on the catheter (© Biosense Webster, Inc)

Fig. 3.6 Image of the Pentarray Mapping Catheter (© Biosense Webster, Inc) showing 20 electrodes on 5 arms with variable spacing

the Pentarray it can be advanced through a 7 Fr sheath and is available in both a D and an F curve.

The location patches also transmit low level current to each other, which helps to record chest impedance allowing for respiratory gating. This is calibrated at the start

of the procedure so that points are taken during end expiration and is particularly useful for accurate fast anatomic mapping. In order to gate the circular mapping catheter should be in contact with the wall of the left atrium. This can easily be achieved by positioning the catheter along the mitral annulus or in one of the pulmonary veins. A threshold for respiratory gating can be set with lower values resulting in more accurate but slightly slower data acquisition.

Merging the Baseline CT/MRI onto the Anatomic Map

Often baseline imaging is useful in order to assess pulmonary vein anatomy and assess for aberrant pulmonary veins. The baseline CT or MRI of the left atrium can also be superimposed on the left atrial shell obtained during fast anatomic mapping in order to create a merge. In order to perform this the baseline CT has to be imported onto the mapping system. This is then segmented so that the chamber of interest is enhanced. Following creation of the map the CT or MRI can be integrated by using a combination of both landmark and surface registration. As shown in Fig. 3.8 select points are chosen on the map and the same points on the CT which are used during the merge process. Inaccuracies may exist between the CT and the map due to changes in time with alterations in either the rhythm or hydration affecting the LA geometry.

Additional Features of Carto

This system has several software features which may be considered to be clinically useful.

Visitag (© Biosense Webster, Inc) uses automation in order to create 4 mm^2 points on the map which fulfill specific pre-programmed parameters. These parameters consist of the minimum time at a particular point, the maximum range of movement of the catheter tip, the minimum force applied as well as the percentage time that the force was obtained for. Impedance and temperature changes can also be tracked. Additionally a grid feature marks 2 mm^2 points along the entire ablation lesion.

Paso (© Biosense Webster, Inc) software has been introduced into the Carto 3 platform in order to help to perform accurate pace mapping. This provides a numerical value for each lead and provides an overall assessment of the accuracy between the clinical arrhythmia and the paced beat. Although the overall efficacy has yet to be studied it appears to have a useful clinical role in particular for focal PVC's as shown in Fig. 3.9 and VT.

CartoUnivu (© Biosense Webster, Inc) allows real time catheter movement to be tracked on a pre-recorded cine angiogram. This is particularly useful for AF ablations where a 3 dimensional rotational angiogram of the left atrium is performed at the start of the procedure following the administration of intravenous adenosine or with rapid ventricular pacing. This image can then be integrated onto the map and viewed in any angle. Coronary angiograms can also be integrated for epicardial ablation as well as LVOT ablations. This may have an overall effect in lowering the total radiation exposure for the entire case, however, data proving this statement are still missing.

Ensite Velocity System (St Jude Medical, Minnesota 55442, USA)

This system emits a 8.136 kHz current between three pairs of surface electrodes in three different planes; cranial to caudal, right to left and posterior to anterior. This is detected by the ablation and diagnostic catheters which use the current degradation to estimate the location of the catheters in the x, y and z axis and allows the processing of up to 128 electrodes on up to four catheters. Impedance variability can lead to an inaccuracy in localising the catheter location and an intracardiac reference is therefore preferred as opposed to the external reference in CARTO. This may be partially compensated for by using field scaling which uses the inter-electrode spacing to attempt to compensate for inconsistencies in the map. Respiratory motion is also compensated for by recording variations in transthoracic impedance during respiration. One of the major advantges of Ensite over CARTO is the ability to acquire data from any catheter rather than a catheter designated by the system. Another attractive feature is the ability of the system to review data while still acquiring further data. An example of a velocity map using the Tacticath is shown on Fig. 3.10.

Fig. 3.9 Paso Software (© Biosense Webster, Inc) Used to compare a paced ventricular beat (*yellow*) with intrinsic ectopic beat (*green*) in the anterior mitral valve annulus

A further incorporation called **Mediguide** (**St Jude Medical**, **Minnesota 55442**, **USA**) now allows visualisation of catheters on a fluoroscopic image acquired at the start of the procedure. This employs a electromagnetic field with a sensor in the catheter and a reference sensor on the patients chest allowing imaging of catheter positions on a pre-acquired cine loop. The electromagnetic transmitter unit is installed in the fluoroscopy detector.

Rhythmia Mapping System (Rhythmia Mapping, Rhythmia Medical, Boston Scientific Inc., Marlborough, MA, USA)

This system uses a combination of magnetic and impedance degradation in order to localize catheters. A magnetic sensor in the tip of the Orion mapping catheter is the predominant guide to location with impedance used for additional clarification of

Fig. 3.10 Velocity Mapping system ((St Jude Medical, Minnesota 55442, USA) with Tacticath contact force catheter showing the left atrium from the mitral annulus on the left and right lateral image showing the left superior and left inferior pulomnary veins posteriorly (*left of the image*) and the left atrial appendage anteriorly (*right of the image*)

Fig. 3.11 Orion Mapping Catheter (Rhythmia Mapping, Rhythmia Medical, Boston Scientific Inc., Marlborough, MA, USA) fully deployed (*left*), intermediate deployment (*middle*) and minimally deployed (*right*)

location on each of the electrodes. As any diagnostic or ablation catheter can be used catheter localization for all other catheters is based on impedance. The Orion catheter requires irrigation at a rate of 1 ml/min.

One of the major advantages to this system appears to be the ability to rapidly acquire a high spatial resolution map using the Orion mapping catheter. This is a 64 electrode small basket catheter mounted on 8 splines in which each electrode is separated by 2 mm. Signals as small as 0.01 mV can be collected. The catheter is deflectable and can be advanced through an 8.5 Fr sheath. As shown in Fig. 3.11 mapping can be performed with the catheter either fully closed (3 mm diameter), fully opened (22 mm diameter) or any range between these two extremes. Anatomic data is only acquired if the electrode is deemed to be within 2 mm of the

Fig. 3.12 Rhythmia (Rhythmia Mapping, Rhythmia Medical, Boston Scientific Inc., Marlborough, MA, USA) screen setup. A surface lead is chosen on the *top left image*. Below this is the CS which is used as a reference electrode. As well as using the electrode timing a change in activation is also recorded in order to minimize the chance of a change in the activation sequence. Both the RAO image on the *left* and LAO in the *right* show the RA during normal sinus rhythm

endocardial surface. Each electrode has a surface area of 0.4 mm^2 with an inter-electrode separation of 2.5 mm. This catheter is irrigated and it is recommended that heparin is administered for all procedures where this catheter is used with an ACT of 300 s.

The setup of Rhythmia is shown in Fig. 3.12. The surface ECG is seen on the top left with reference signals from the CS below this and a combination of electrograms from the Orion catheter below this. Each electrode is code by letter and number. An RAO image of the RA and LAO of the RA are shown during normal sinus rhythm.

Given that multiple signals are acquired simultaneously this system must have the ability to rapidly self annotate signals and in particular activation times. This is achieved by recording the maximum deflection on the bipolar signal or the most negative dV/dT on the unipolar electrogram. There is continuous and automatic electrogram acquisition based on beat acceptance criteria.

In order to set up the system at the start of the case the chamber of interest and type of map is programmed as well as the rhythm (sinus, paced, tachycardia) and the reference. Although the mechanism of the arrhythmia should be programmed at the start i.e. either focal or re-entry this can be changed during or after completion of the map. The system makes recommendations based on analysis of the last 10 s of the intracardiac signals and calculates the tachycardia cycle length and therefore calculates the mapping window as well as suggesting the reference electrograms. An example of mapping across a previous CTI ablation by pacing from the proximal CS during sinus rhythm is seen in Fig. 3.13.

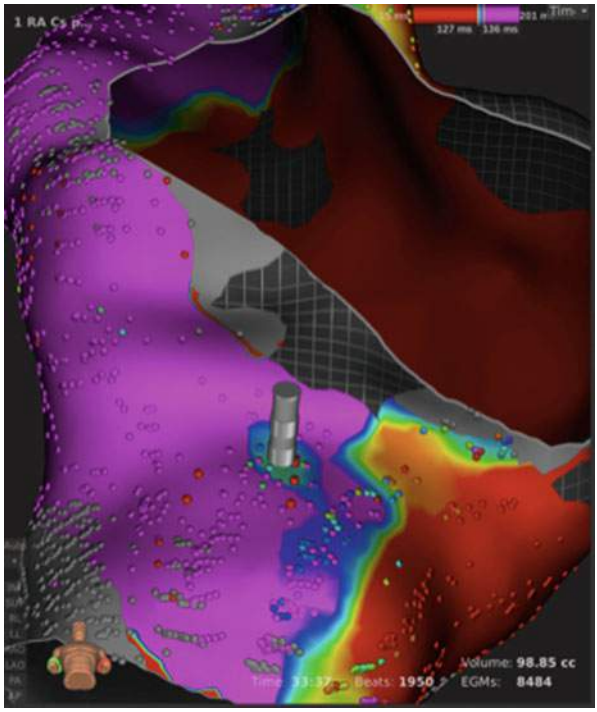

Fig. 3.13 Activation mapping using Rhythmia (Rhythmia Mapping, Rhythmia Medical, Boston Scientific Inc., Marlborough, MA, USA) with pacing from the proximal coronary sinus and mapping the right atrium in a patient with a recurrence of atrial flutter following a previous CTI ablation. The image is taken from an inferior angle with the tricuspid annulus at the *top of the image* and the inferior vena cava at the *bottom*. Although conventional pacing maneouvres suggested clockwise block there is a region of slow conduction in the mid CTI which required further ablation

Important Points

1. A stable reference point is required for activation mapping so that all points can be measured relative to the same electrogram. An ideal reference electrogram should be stable with an obvious positive or negative peak for measurement. The trigger is then set off either the most positive or negative change in voltage over time (dV/dT).
2. The window of interest is set according to whether the arrhythmia mechanism is focal or re-entry. For a focal tachycardia the earliest component may be set at 80 msec ahead of the surface signal and 30 msec after the offset. For a re-entry tachycardia the window of interest is chosen as 90 % of the tachycardia cycle length to allow for a degree of cycle length variability.
3. In activation mapping electrical signals are color coded according to how early or late they are in the window of interest. The earliest is coded as red followed by yellow, green blue, and purple which indicates later activation. In focal arrhythmias early signals are generally targeted. In re-entry ablation is often performed where early meets late.
4. In voltage mapping bipolar signals of 1.5 mV or less defined as scar and 0.5 mV or less dense scar in the ventricle.
5. CFAE's are defined as low amplitude fractionated atrial electrograms with a cycle length of less than 120 msec.

Chapter 4
AV Nodal Re-entry Tachycardia (AVNRT)

Benedict M. Glover and Pedro Brugada

Abstract AVNRT is the most common paroxysmal supraventricular tachycardia seen in adults. It occurs as a result of dual AV nodal physiology in which an ectopic beat from the atrium or the ventricle conducts along either a slowly conducting or fast pathway and retrogradely along the other pathway which is no longer refractory. In the case of a typical AVNRT this occurs antegradely along the slow pathway and retrogradely along the fast pathway resulting in a short RP tachycardia. In an atypical AVNRT conduction occurs antegradely along the fast pathway and retrogradely along the slow pathway resulting a long RP tachycardia. It is important to carefully map during tachycardia and perform the relevant maneuvers in order to help establish the diagnosis. AVNRT is treatable with catheter ablation and this is highly successful with a low recurrence rate.

Introduction

AVNRT is the most common paroxysmal supraventricular arrhythmia in adults, accounting for approximately 60 % of all SVTs [1]. It generally presents at an age less than 40 years (median age 28 years) and is more common in females than males [2–4]. Presentation tends to occur with intermittent palpitations of acute onset and termination with vagal maneuvers and a normal baseline ECG. During tachycardia the RP interval for typical AVNRT is short and atrial activation is often in or at the terminal end of the QRS complex. The P wave is generally negative and narrow indicating an inferior to super activation from the retrograde fast pathway location.

Anatomy

The relevant anatomy for AVNRT is contained within the triangle of Koch, bounded anteriorly by the septal leaflet of the tricuspid valve, posteriorly by the tendon of Todaro and inferiorly by the superior aspect of the coronary sinus os [5]. The compact AV node is located at the base of the inter atrial septum. Surrounding the compact AV node there is a zone of transitional cells which connect the compact node to the atrial myocytes. This transitional zone is composed of cells which share similar feature to both nodal and atrial myocytes [6]. There are three atrial extensions from the compact AV node to the atria as well as a single common pathway which connects to the ventricular aspect. The ventricle is not part of the circuit involved in AVNRT and helps to distinguish this from AVRT. AVNRT can therefore continue in the presence of AV block.

The superior extension equates to the fast pathway and is located in the anterior portion of the triangle of Koch, the rightward inferior extension which is located anteriorly to the coronary sinus and is often termed the slow pathway and the leftward inferior extension which is directed towards the mitral annulus (Fig. 4.1).

Mechanism

Mechanistically AVNRT involves at least two connections between the atria and the ventricles, often referred to as dual AV nodal conduction. These pathways are classified according to the speed of velocity through the tissue. The **slow pathway** has slower conduction velocity but a shorter refractory period and is located posteriorly along the tricuspid annulus, closer to the coronary sinus os. The **fast pathway** has a faster conduction velocity and is formed by transitional cells crossing the tendon of Todaro superiorly. It has a longer refractory period.

Classification

Slow/Fast AVNRT (Typical AVNRT)

This occurs when a premature atrial complex (PAC) travels antegradely down the slow pathway (right inferior extension) between the CS os and the tricuspid annulus followed by retrograde conduction along the fast pathway. Less commonly in approximately 5 % of cases antegrade conduction may occur along an anatomically different slow/intermediate pathway (left inferior extension). These are generally associated with an AH interval greater than 200 ms. As shown in Fig. 4.2 there is generally a short septal VA interval. The HA interval should be less than 90 ms i.e., AH > HA.

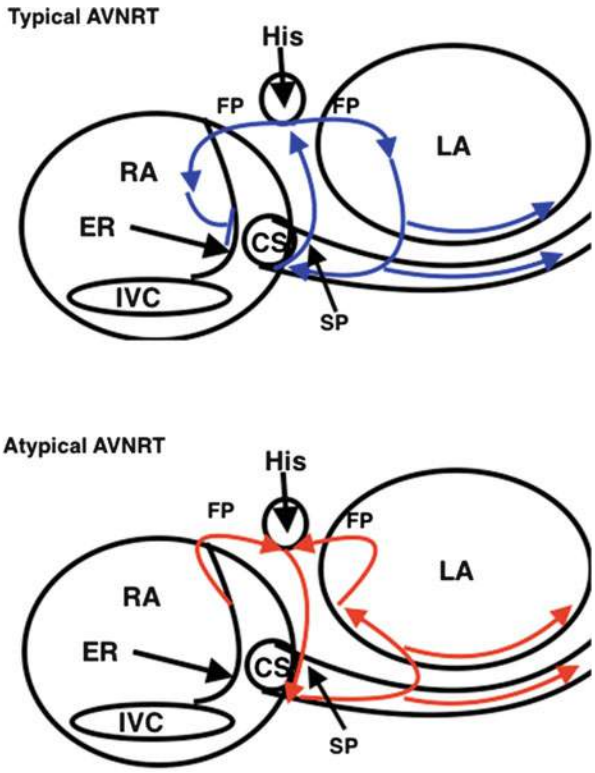

Fig. 4.1 Schematic of the AVNRT circuit in an LAO view showing a typical slow/fast AVNRT utilizing an antegrade slow pathway (*SP*) and retrograde fast pathway (*FP*) (*top image*) and in the *bottom image* an atypical fast/slow AVNRT utilizing the fast pathway antegradely and the slow pathway retrogradely

The earliest atrial activation occurs along the superior septum posterior to the Tendon of Todaro which helps to differentiate this from a Slow/Slow AVNRT. Activation on the left side of the septum continues laterally and inferiorly activating the coronary sinus. Activation on the right side of the septum is blocked by the Eustachian ridge and conducts towards the slow pathway with propagation of the circuit.

Fast/Slow AVNRT (Atypical AVNRT)

As demonstrated in Fig. 4.3 antegrade conduction occurs down the fast pathway and retrograde conduction occurs up the right inferior extension (slow pathway) with earliest atrial activation at the inferior septum. Occasionally retrograde conduction occurs up the left inferior extension (leftward slow pathway). The AH

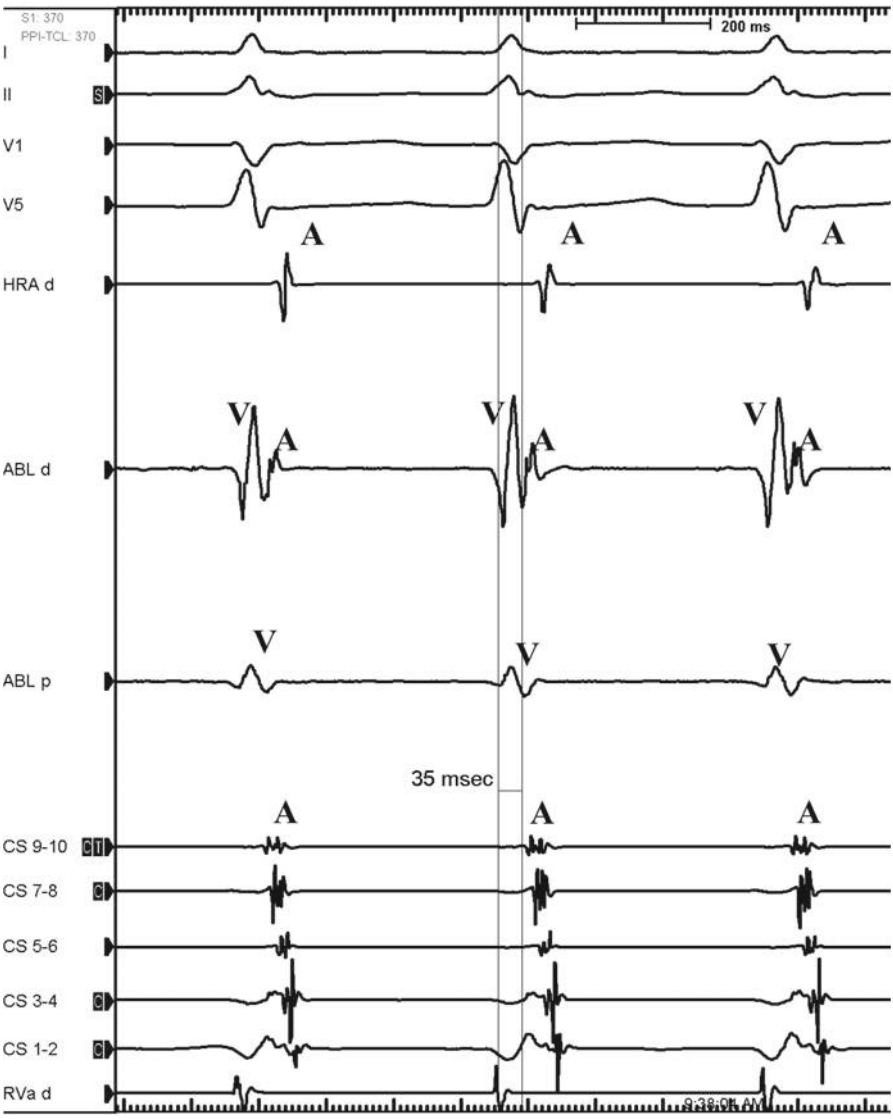

Fig. 4.2 Typical AVNRT. Earliest atrial activation is in the proximal coronary sinus with a short septal VA interval of 35 ms. This could also be a septal AP or an AT and further maneuvers are required to diagnose this. (HRA d is positioned in the high right atrium, Ablation catheter is positioned on the His, CS 9 10 are positioned in the proximal CS with CS 1 2 in the distal CS and RVA d are positioned in the RV apex)

interval is shorter than the HA interval. As the RP interval is long it is straightforward to identify the P wave which is negative in II, III, aVF and V 6 and positive in V1. This should be differentiated from an AT from close to the CS Os or a septal AP.

Fig. 4.3 Initiation of an atypical AVNRT. Decremental pacing from the RV apex results in retrograde conduction along the fast pathway for the first two beats as evidenced by the earliest activation recorded in the His with a septal VA interval of 62 ms. The third beat results in a prolonged VA interval of 306 ms with the earliest atrial activation in the proximal coronary sinus in keeping with a retrograde jump from the fast to the slow pathway. This subsequently conducts antegradely along the fast pathway and back up the slow pathway with a long RP tachycardia. (HRA d is positioned in the high right atrium, ablation catheter is positioned on the His, CS 9 10 is in the proximal CS with CS 1 2 in the distal CS, RVa d is in the RV apex)

Slow/Slow AVNRT

In general in Slow/Slow AVNRT conduction occurs antegradely down the rightward inferior extension and retrogradely up the leftward inferior extension. The earliest retrograde atrial activation is therefore often the roof of the coronary sinus although it may also be between the coronary sinus and the tricuspid annulus if retrograde conduction occurs along the rightward inferior extension. There are often multiple AH jump's reflecting multiple slow pathways. The AH interval is generally greater than 200 ms and is longer than the HA interval.

Electrophysiological Evaluation

Baseline Data

The ECG generally shows a QRS duration less than 120 ms with a short RP interval in the case of a typical AVNRT and a long RP interval in the case of an atypical AVNRT. If aberrancy is present then this more frequently is a RBBB morphology.

A p wave superimposed closely on the QRS is generally suggestive of a typical AVNRT. A negative p wave with a long RP interval in the precordial and inferior leads is more suggestive of an atypical Slow/Slow AVNRT. If the RP interval is longer than the PR interval this is more suggestive of a Fast/Slow AVNRT. RR alternans may occur in AVNRT due to a potential figure of eight type circuit involving the right and left inferior extensions along with the fast pathway.

Risks of EP Study and Ablation

As for all SVT studies the risks of an EP study and ablation include groin haematoma, vascular injury, cardiac tamponade, thrombo-embolism and AV block. The risk of AV block is generally considered to be the most significant complication and has an incidence of less than 0.5 %. AV block is more common if the distance between the slow pathway and fast pathway is less, if a more superior approach is required for successful ablation, if more ablation lesions are required and in patients with retrograde block in association with a junctional rhythm. It is therefore important to monitor these signs during application of RF and stop if necessary. It is generally good practice if the risk of AV block is considered high to stop and discuss further with the patient.

The acute success of a slow pathway ablation is approximately 97 % with a recurrence rate of 0.7–5.2 %.

Procedure

The diagnostic EP evaluation is generally performed with minimal sedation in order to maintain normal physiological parameters of the pathways involved and therefore maximize the chance of arrhythmia induction. Mapping catheters are positioned in the right ventricle, His, coronary sinus and high right atrium. Decremental pacing is first performed from the RV in order to assess retrograde conduction, the atrial activation sequence, and to search for evidence of dual VA nodal conduction. Following this, decremental atrial pacing is performed in order to search for the presence of dual or multiple AV nodal pathways and to try to induce AV nodal re-entry tachycardia. It is extremely uncommon for a ventricular paced beat to initiate AVNRT as the bundle of His is generally refractory to retrograde conduction. This is in contrast with accessory AV pathways, where induction of the re-entry arrhythmia by ventricular pacing is common.

Dual AV nodal physiology is demonstrated by the presence of an AH or HA jump, the presence of an atrial or ventricular echo beat or the induction of AV nodal re-entry tachycardia. An **AH jump** is defined as an increase in the AH interval of **greater than or equal to 50 ms at the moment when the coupling of the atrial extrastimuli is reduced by 10 ms during decremental atrial pacing or**

during single premature stimuli testing [7, 8]. This jump is the result of a change in antegrade conduction from the fast pathway to the slow AV nodal pathway. During ventricular pacing a HA jump of greater than or equal to 50 ms generally represents a retrograde switch from the fast to the slow pathway. Although this may suggest the possibility of AV nodal re-entry tachycardia this finding is common in the general population as the majority of people have superior and inferior atrial extensions into the compact AV node. The administration of intravenous sedation may depress fast pathway conduction thus increasing the incidence of a jump to the slow pathway. Conversely, in some patients with dual AV nodal physiology an AH jump may not be seen particularly if the conduction properties are similar between the two pathways such as an antegrade intermediately conducting left inferior extension pathway [9]. Additionally, the administration of isoproterenol may increase fast pathway conduction which may mask the appearance of an AH jump.

If tachycardia cannot be induced with multiple atrial extrastimuli or decremental atrial pacing then isoprenaline should be administered at a dose of 1–4 microgrammes/min. Isoprenaline should be stopped prior to ablation because it causes hypercontractility of the heart leading to catheter instability.

Differentiation Between AVNRT and AVRT

The fact that the AVRT circuit involves the ventricle as a component can be used to differentiate these arrhythmias from AVNRT in terms of basic observations as well as the maneuvers, that may be performed for the differential diagnosis.

The VA conduction time is generally less than 50 ms in Slow/Fast AVNRT and occasionally Slow/Slow AVNRT and greater than 50 ms in AVRT.

The delivery of ventricular extrastimuli in order to assess the effect on atrial activation is the most straightforward method to help differentiate between the two arrhytnmias. A pacing catheter is positioned in the RV corresponding closely with the location of the earliest atrial activation. If the earliest atrial activation is the inferior aspect of the triangle of Koch the optimal position for introducing ventricular extrastimuli is the inferobasal RV. If the earliest atrial activation is the superior septum close to the apex of the triangle of Koch then this is better positioned close to the His. These positions help to ensure that ventricular activation occurs first with subsequent retrograde His activation via the apex of the RV making much easier to interpret the individual signals.

In order to perform this maneuver a ventricular extrastimulus is delivered 50 ms after the onset of the His electrogram during tachycardia and advanced in 10 ms decrements. Any advance in atrial activation with no advance in the His electrogram implies the presence of an accessory pathway. If the atrial activation sequence of the advanced beat is identical to the tachycardia sequence and the next His electrogram is delayed then this proves that the accessory pathway is part of the arrhythmia mechanism.

As previously described, RV entrainment, delivery of a His synchronous PVC and parahisian pacing should also be performed.

Differentiation of AVNRT from Atrial Tachycardia

In general a typical AVNRT can be distinguished from a septal atrial tachycardia by the short duration of the RP interval. It may be more difficult to distinguish an atypical AVNRT as the RP interval is generally longer and entrainment from the RV apex may be more useful.

As shown in Fig. 4.4 following entrainment of the tachycardia from the RV apex the following sequence is an A followed by V. In the case of an atrial tachycardia this is generally seen as an A-A-V [10]. A pseudo A-A-V response may occur in the setting of a prolonged HV interval where the ventricular electrogram is artificially delayed. If the tachycardia is terminated during ventricular pacing and if the ventricular beat resulting in termination did not conduct to the atrium then atrial tachycardia can be excluded as the critical circuit is outside of both atria.

Several other useful techniques may also be used. If tachycardia can be induced then the AH interval can be recorded during tachycardia and compared with the AH interval during pacing from the high right atrium at the same cycle length. In cases

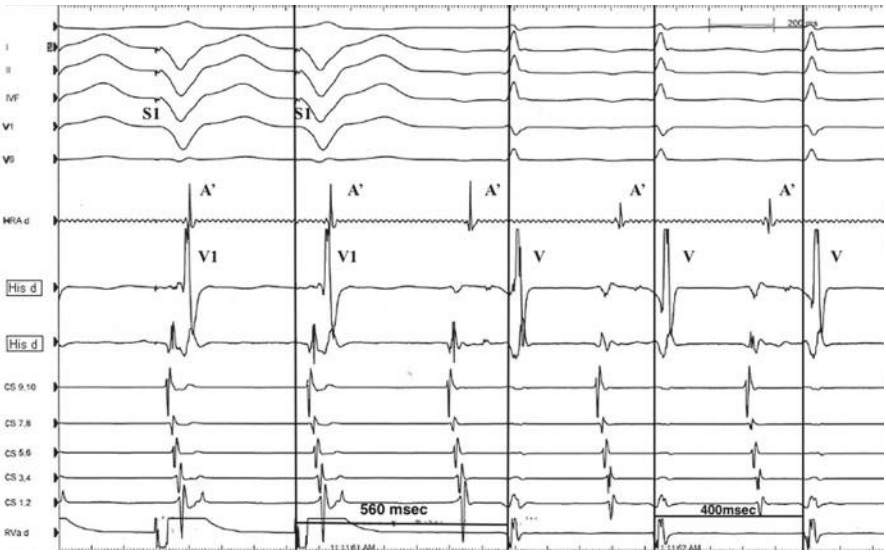

Fig. 4.4 A-V Response to Right Ventricular Entrainment during tachycardia. The tachycardia cycle length (TCL is 400 ms pacing is performed from the RV apex at 370 ms The PPI-TCL is 160 ms which is more suggestive of an AVNRT

of atypical AVNRT the AH interval during atrial pacing is longer by more than 40 ms compared to tachycardia [11].

In cases of either atrial tachycardia or AVRT with a slowly conducting retrograde pathway there is very minimal different in the AH during high right atrial pacing compared with tachycardia.

Additionally pacing from the high right atrium at different rates during tachycardia can be performed and the VA interval recorded. If the VA interval at different rates is unchanged then atrial tachycardia can be excluded.

If ventricular extrastimuli advance the retrograde His without affecting the atrial activation then atrial tachycardia is the most likely diagnosis.

Ablation Techniques

Following confirmation of the diagnosis a 4 mm non-irrigated ablation catheter is positioned in the right ventricle and withdrawn with flexion on the catheter in order to maintain a posterior septal position to the level of the coronary sinus. This is demonstrated on the fluoroscopic images on Fig. 4.5 which shows the ablation catheter position in an RAO and LAO view.

Mapping is then performed between the coronary sinus os and the tricuspid annulus. An A:V ratio of 1:2 to 1:10 should be recorded in which the atrial signal is approximately 20 ms later than the A on the His. As shown in Fig. 4.6 a small discrete slow pathway potential may be recorded in the ablation catheter. If this is seen the latest and highest frequency slow pathway potential should be targeted. Often a degree of clockwise rotation is required while trying not to fall into the coronary sinus. This is required to counteract the counterclockwise force of the Eustachian ridge which tends to rotate the catheter away from the septum during systole.

RF is generally started at 30 W with a maximum temperature set at 55–60 C. This can be increased to 40 W and occasionally 50 W is required.

Junctional beats during ablation are generally considered a indicator of slow pathway modification. These are seen in Fig. 4.7. These beats are likely due to conduction of current injury from the slow pathway to the AV junctional area enhancing diastolic depolarization of the cells in this region [12, 13]. Other potential explanations for junctional beats include an increase in AV junctional automaticity as a result of post ganglionic noradrenaline release exceeding the increase in vagal tone associated with RF application in this region therefore increasing the rate of diastolic depolarization [14] as well as a possible heat sensitive region close to the AV node which may lead to increased junctional activation [15].

Accelerated junctional beats occurring at a cycle length of less than 350 ms or with transient VA are an indicator of potential AV block [16]. It is also useful to monitor the AH interval during ablation. Ablation should stop in the event of any prolongation of the AH interval or if there is a sudden increase or reduction in impedance.

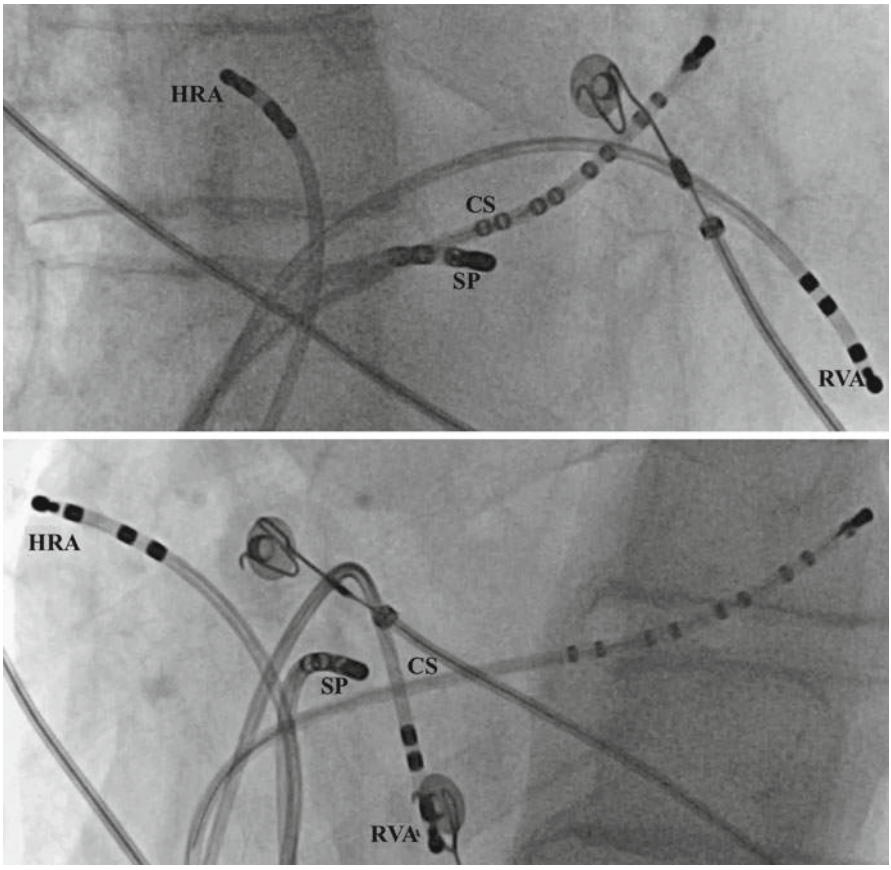

Fig. 4.5 Fluoroscopic location of ablation catheter when mapping the slow pathway. The ablation catheter is recording a A:V ratio with a small slow pathway potential. The *top image* is an RAO view and on the *bottom image* is an LAO view. In both views the ablation catheter is seen anterior to the coronary sinus os. Also seen in the image is a quadripolar catheter in the high RA, RV apex and a decapolar catheter in the coronary sinus

If there are no junctional beats during ablation alternative sites should be chosen. This generally involves a more superior position although this increases the risk of AV block and caution above the level of the roof of the coronary sinus should be taken.

Other potential locations for the slow pathway are the leftward inferior extension which can often be successfully ablated in the proximal coronary sinus.

If AVNRT develops ablation should stop due to catheter instability as well as a difficulty in establishing early signs of AV block.

AV block may be due to ablation injury of the compact AV node or may reflect underlying poor fast pathway conduction. AV block occurring at a more inferior position, including within the coronary sinus os may occur due to a posterior fast pathway variant or as a result of the effects of ablation on the AV nodal artery.

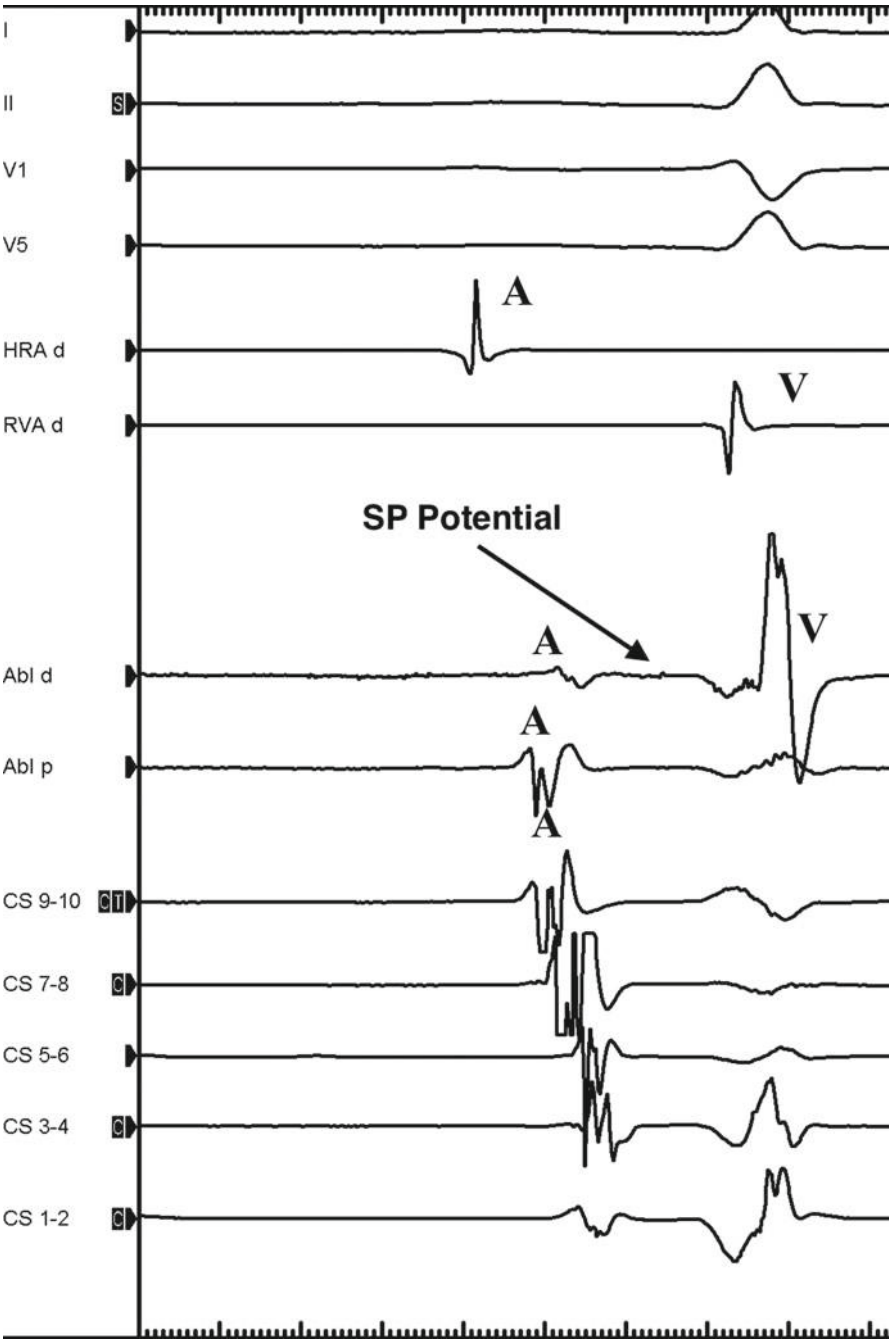

Fig. 4.6 Mapping of the slow pathway. The ablation catheter is positioned anterior to the coronary sinus with an A:V ratio of 1:6. On the first beat there is a small discrete potential recorded on the distal ablation catheter where is in keeping with a slow pathway potential. Ablation at this location was successful in slow pathway modification with no further inducible AVNRT

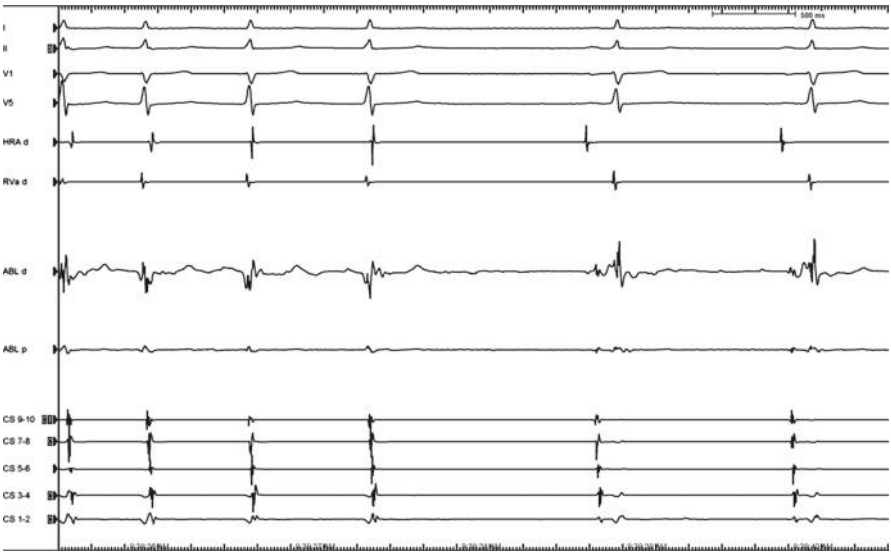

Fig. 4.7 Junctional beats seen during RF ablation at the site of a slow pathway ablation. Following the first 4 beats of junctional rhythm normal sinus rhythm resumes with 1:1 AV conduction. This is generally considered a sign of a good ablation. (HRA d is positioned at the high right atrium, RVa d is positioned at the RV apex, CS 9 10 is positioned at the proximal CS while CS 1 2 is positioned at the distal CS)

Ablation Endpoints

Following application of RF with good target temperatures and junctional beats a repeat EP study should be performed to try to re-induce the tachycardia using the same protocol as pre-ablation. If tachycardia cannot be re-induced this is a good endpoint. The presence of an AH jump or an atrial echo beat can still be considered reasonable as these may often be due to other slow pathways which may be clinically not significant such as a left inferior extension.

Isoprenaline should always be administered at the end of the procedure even if it was not required for induction of the tachycardia at baseline.

Trouble Shooting the Difficult Cases

The main anatomical difficulties which may arise are often related to a large coronary sinus os, difficult to reach slow pathways, close proximity between the slow and fast pathways and variability in the location of the slow pathway.

In general a slight clockwise rotation is required when applying ablation to the slow pathway. In cases where the CS os is large it can be difficult to maintain a

stable position and often a balanced clockwise with counterclockwise rotation is required. In extreme cases a long sheath may be helpful in order to maintain catheter stability.

Occasionally ablation at the conventional slow pathway location results in junctional beats but with still further inducible AVNRT. In these cases a more superior approach is required. This most likely targets the junction of the right and left inferior extensions rather than just the right inferior extension. If a higher position is unsuccessful the roof of the proximal coronary sinus (1–3 cm from the coronary sinus os) may result in a successful ablation.

In some very rare cases the slow pathway has a left sided insertion point and therefore cannot be successfully ablated from any sites on the right side of the interatrial septum. In these cases either transseptal or trans aortic access if required with mapping of the earliest atrial activation during AVNRT along the mitral annulus. This may range from septal to inferolateral mitral annulus.

Important Points

1. The triangle of Koch is bounded anteriorly by the septal leaflet of the tricuspid valve, posteriorly by the tendon of Todaro and inferiorly by the superior aspect of the coronary sinus os.
2. The fast pathway is located in the anterior portion of the triangle of Koch. The slow pathway is generally located anteriorly to the CS although may have a variable course including within the CS.
3. An AH jump is defined as an increase in the AH interval of greater than or equal to 50 ms in association with a reduction in an atrial extrastimuli of 10 ms during decremental atrial pacing.
4. Discontinuous AV conduction curves are not present in all patients with proven AVNRT
5. The presence of two or more AV nodal pathway may be present in patients without AVNRT
6. In Slow/Fast AVNRT (Typical AVNRT) a PAC travels antegradely along the SP with retrograde activation along the FP. This generally results in a short VA tachycardia with the earliest atrial activation along the superior septum posterior to the Tendon of Todaro
7. In Fast/Slow AVNRT (Atypical AVNRT) antegrade conduction occurs down the FP and retrograde conduction occurs up the SP with a long VA time during tachycardia.
8. In Slow/Slow AVNRT antegrade conduction occurs antegradely down the rightward inferior extension and retrogradely up the leftward inferior extension with a long VA time and the earliest activation often anterior to the CS.
9. SP ablation is generally performed using a 4 mm non-irrigated ablation catheter is positioned between the CS os and the tricuspid annulus with

an A:V ratio of 1:2 to 1:10 and ideally a SP potential. RF is generally started at 30 W with a maximum temperature set at 60 C. This can be increased to 40 W and occasionally 50 W is required.

10. Junctional beats during ablation are most likely due to conduction of current injury from the SP to the AV junctional area enhancing diastolic depolarization of the cells in this region and are generally considered a indicator of SP modification.
11. Accelerated Junctional beats occurring at a cycle length of less than 350 msec or with transient VA are an indicator of potential AV block.
12. The most useful endpoint following SP ablation is lack of inducibility of the tachycardia. The presence of an AH jump or an atrial echo beat can still be considered reasonable as these may often be due to other slow pathways which may be clinically not significant such as a left inferior extension.

Chapter 5
Accessory Pathway (AP) Conduction

Benedict M. Glover and Pedro Brugada

Abstract Ventricular pre-excitation occurs as a result of an extranodal accessory pathway connecting the atrium with the ventricle along the AV groove. Although the baseline ECG may be normal, the common features seen are a short PR interval during normal sinus rhythm, slurring of the initial portion of the QRS complex resulting in a delta wave, a QRS duration greater than 120 ms in adults, and secondary ST and T wave changes, all of which result from a combination of eccentric accessory pathway and midline AV nodal conduction. Ventricular pre-excitation in association with a history of palpitations is named the Wolff–Parkinson–White (WPW) syndrome.

Anatomy

Accessory pathways are muscle fibers which connect the atrium to the ventricle through the fibrofatty and fibrous parietal AV junctional regions. They are generally up to 3 mm in diameter and up to 1 cm in length [1].

They are generally not found in the aortomitral continuity due to the distance between the atrial and ventricular tissues in this region [2]. It has been shown that the majority of accessory pathway's contain ventricular myocytes which function in a similar fashion [3].

Thin extensions of atrial myocardium overlie thicker ventricular myocardium at the right anterior, mid, and posterior septum. The left anterior and left mid septal regions tend to have fibrotic tissue and therefore it is unusual to find AP's in this location.

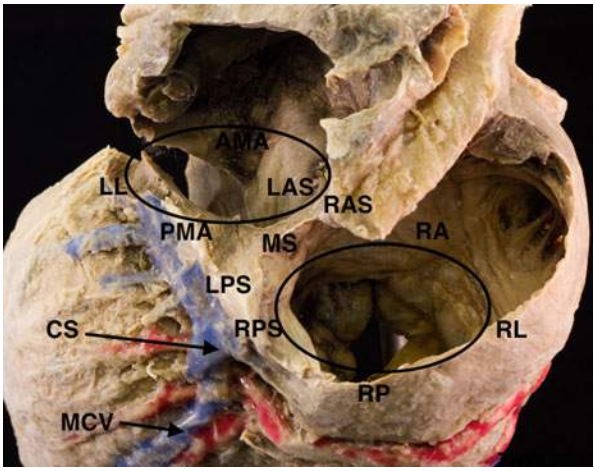

Fig. 5.1 Anatomical specimen with the posterior wall of the right atrium and left atrium removed. *On the left side* AP's may be located in the left lateral (*LL*), anterior mitral annulus (*AMA*), posterior mitral annulus (*PMA*) as well as left anteroseptal (*LAS*) and left posteroseptal (*LPS*). *On the right side* accessory pathways may occur in the right anterior (*RA*), right lateral (*RL*), right posterior (*RP*), right anteroseptal (*RAS*) and right poseroseptal (*RPS*). Mid septal (*MS*) pathways are generally located on the right side but may also be left. Also shown on the image are the coronary sinus (*CS*) and the middle cardiac vein (*MCV*)

The majority of accessory pathways are located within the endocardial atrioventricular fat pad close to the atrioventricular junctions. The anatomy of the tricuspid and the mitral annuli is shown in Fig. 5.1 with the superimposed traditional locations of AP's.

The traditional description of accessory pathway locations has been dependent on a combination of anterior to posterior and left to right in which the coronary sinus is the most posterior landmark and the aortic valve the most anterior. In the LAO view posterior is therefore seen as being at the most inferior location along both the mitral and tricuspid annulus while anterior is located at the most superior aspect. In this view septal is in the centre of the image with lateral being located at the periphery. In reality what is described as anterior is actually superior. As the left atrium is actually posterior to the right atrium what is described as right lateral should in fact be described as right anterior while left lateral is in fact left posterior. This is shown in Fig. 5.2.

Less common accessory pathway locations are shown in Fig. 5.3.

Mechanisms

During normal sinus rhythm, conduction may occur antegradely down the AP as well as through the AV node, resulting in **manifest pre-excitation** on the ECG. Occasionally, this may not be evident as the time taken for conduction through

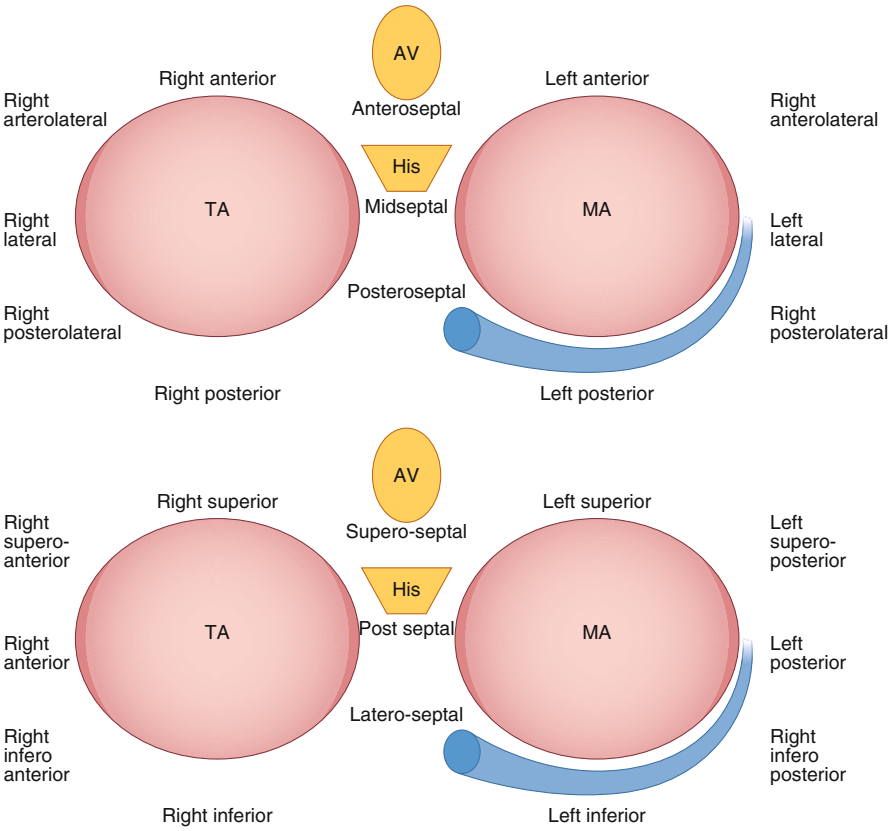

Fig. 5.2 Schematic in LAO view showing Attitudinally Correct (*top*) and historic (*bottom*) locations of Accessory Pathways along the Tricuspid and Mitral Annulus (*TA* tricuspid annulus, *MA* mitral annulus, *AV* atrioventricular)

the accessory pathway is so long that the ventricle has depolarized through the AV node such as in a slowly conducting left lateral accessory pathway. This is called **latent pre-excitation** as the 12-lead ECG during normal sinus rhythm may appear normal. If the AP conducts retrogradely during normal sinus rhythm the ECG will also appear normal and this is called **concealed pre-excitation**. Generally concealed accessory pathways are not capable of conducting AF with pre-excitation. The majority of accessory pathways have antegrade and retrograde properties. Diagrammatic representation of the predominant direction of conduction of accessory pathways is shown in Fig. 5.4.

Orthodromic AVRT occurs when the antegrade accessory pathway is refractory and conduction occurs antegradely through the AV node activating the His and ventricle and retrogradely along the accessory pathway if it is no longer refractory. This is shown in Fig. 5.5. The VA time required for this to occur is generally greater

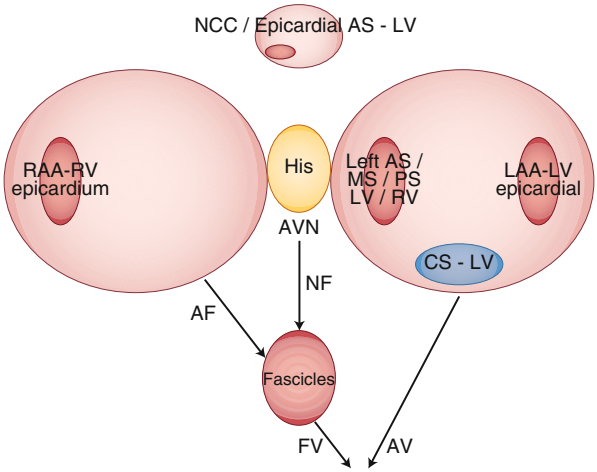

Fig. 5.3 Unusual locations of accessory pathway connections including right atrial appendage (*RAA*) to right ventricular (*RV*) epicardium, the non coronary cusp (*NCC*)/epicardial anteroseptal to left ventricle (*LV*), left sided anteroseptal, midseptal and posteroseptal to left ventricle or right ventricle, left atrial appendage (*LAA*) to left ventricular (*LV*) epicardium, coronary sinus (*CS*) to left ventricle (*LV*) as well as atriofascicular (*AF*), nodofascicular (*NF*), atrioventricular (*AV*) and fasciculoventricular (*FV*) pathways

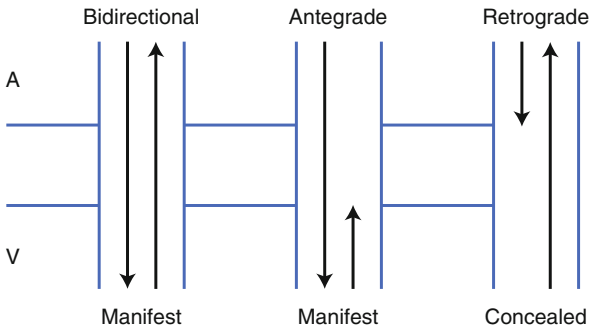

Fig. 5.4 Direction of conduction in accessory pathways. Bidirectional (antegrade and retrograde) resulting in manifest pre-excitation, antegrade only resulting in manifest pre-excitation and retrograde only resulting in concealed conduction

than 70 ms. Despite slight changes in antegrade conduction via the AV node the VA time which represents the time taken to conduction along the accessory pathway is generally stable and does not change.

In antidromic AVRT conduction occurs antegradely via the accessory pathway as the AV node is refractory. This is generally associated with a pre-excitated QRS as conduction is only via the accessory pathway. Ventricular conduction and retrograde His conduction may conduct via the AV node provided it is no longer refractory. HA times are generally greater than 70 ms as conduction is via the VA node. This is more commonly seen in left lateral accessory pathway's as the longer conduction is required to allow the AV node to recover.

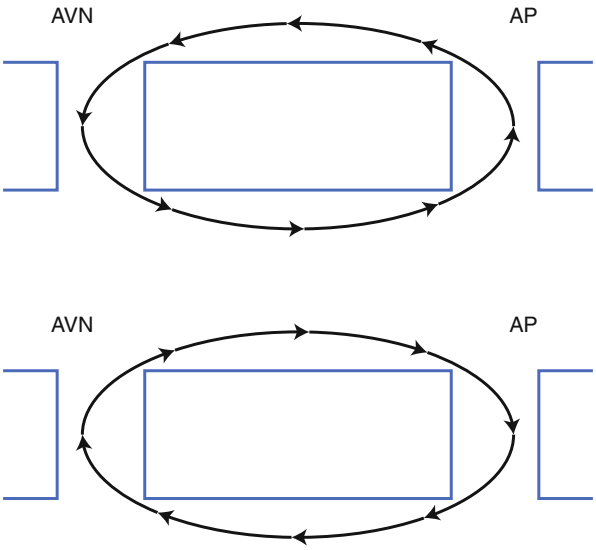

Fig. 5.5 Mode of conduction of circuit in AVRT. Orthodromic reciprocating tachycardia (*Top image*) in which antegrade conduction occurs through the AV node and retrograde through the accessory pathway and Antidromic Reciprocating Tachycardia (*Bottom image*) in which antegrade conduction occurs down the accessory pathway and retrograde through the AV node

Classification

Accessory pathway's are classified according to their anatomical location, direction of conduction, conduction properties and mechanism of action during tachycardia.

Anatomically these are divided into septal (paraseptal) which include posteroseptal, midseptal and anteroseptal, left lateral (left posterior), left posterolateral (left infero-posterior), left posterior (left inferior), left anterolateral (left superoposterior) and left anterior (left superior). The equivalent locations are also possible on the right side using similar nomenclature. Additionally some accessory pathways may be directly connected into the specialized conduction system such as atriofascicular, atrioventricular, nodoventricular and fasciculoventricular pathways. Accessory pathway's may also be located in unusual anatomical locations involving epicardial connections between the coronary sinus and the left ventricle, the non-coronary cusp of the aortic valve to the left ventricle, the right atrial appendage to right ventricle or left atrial appendage to left ventricle.

Accessory pathways can also be described according to the direction of conduction. While most accessory pathway's may conduct in both directions concealed retrograde accessory pathways are more common in the left lateral position. Almost all accessory pathways exhibit rapid and non-decremental conduction but a few paraseptal pathways may have slow decremental conduction somewhat like the AV node.

Finally accessory pathways may be described according to the direction of conduction during tachycardia with orthodromic AVRT much more common than antidromic AVRT.

Electrophysiological Evaluation

Baseline ECG

The location of the accessory pathway can be estimated from the ECG based on the polarity of the delta wave. This is measured 20 ms from the onset from the delta wave. Additionally an exercise stress test and Holter may be used for non invasive monitoring. The presence of intermittent pre-excitation on an ECG or Holter during sinus rhythm suggests that rapid antegrade conduction of atrial fibrillation through the AP is less likely to occur. The shortest pre-excited R-R interval (SPERRI) may be measured on an ECG or Holter although it is more commonly assessed during invasive EP measurements. A measurement less than 220 ms or 220–250 ms may be associated with a higher risk of rapid antegrade conduction during AF and ventricular fibrillation. Abrupt loss of preexcitation on an exercise stress test indicates preferential AV node conduction rather than antegade AP conduction with increasing sympathetic stimulation.

Algorithms

Localization of the accessory pathway on the 12 lead ECG is useful in order to help plan the EP study and ablation. Several algorithms have been developed to help predict the location of the accessory pathway based on the 12 lead ECG during normal sinus rhythm. These generally use the axis of the delta wave, the R wave transition and the QRS morphology which is dependent on the ventricular insertion point of the accessory pathway and the degree of fusion of accessory pathway conduction with AV node conduction. Given the variability in anatomy, as well as differences in underlying ECG patterns, the possibility of more than one accessory pathway and variability in the conduction properties of the AV node as well as the accessory pathway itself no algorithm is 100 % accurate. An example of a useful and practical algorithm for accessory pathway localization is shown in Fig. 5.6.

The polarity of the delta wave is measure 20 ms after the initial onset and is described as either positive, negative or isoelectric.

In general a negative or isoelectric delta wave in certain ECG leads implies that the ventricular activation is originating from that location.

A negative or isoelectric delta wave in leads I, aVL and V6 implies a left lateral accessory pathway or less commonly an anteroseptal accessory pathway. In order to differentiate between these, the QRS morphology should be examined. An atypical

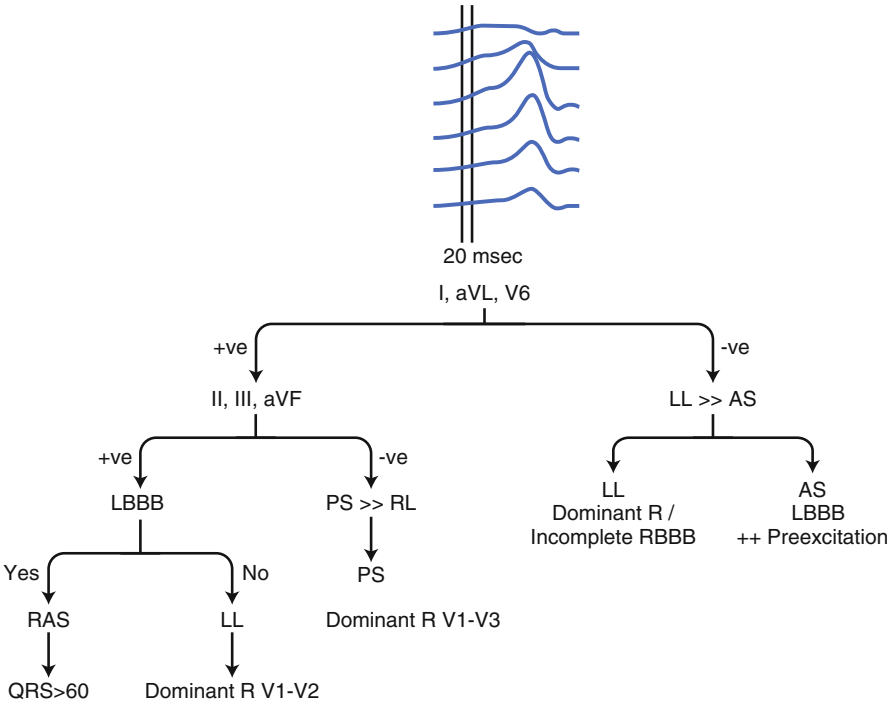

Fig. 5.6 Algorithm to estimate the location of an accessory pathway from the delta wave polarity. The first stage relies on interpretation of the delta wave in leads I, aVL and V6. If this is negative then the accessory pathway is located either in the left lateral (*LL*) location of less likely in an anteroseptal (*AS*) location. A left lateral location is more likely to have either a dominant R wave in V1 or V2 or an incomplete RBBB. An anteroseptal accessory pathway is more likely to have a LBBB pattern and more prominent pre-excitation when compared with a left lateral accessory pathway. If the delta wave is positive in leads I, aVL and V6 then the inferior leads II, III and aVF should be examined. A negative delta wave in these leads indicates either a posteroseptal (*PS*) or right lateral (*RL*) location. A posteroseptal location is more likely than a right lateral and tends to have a dominant R wave in V1–V3. If the delta wave is positive in the inferior leads then the ECG is analyzed for a LBBB pattern. The absence of a LBBB is likely to represent a left lateral location in which there is a dominant R wave in V1–V2. If there is a LBBB this is likely a right anteroseptal (*RAS*) location in which the QRS axis tends to be greater than 60°

LBBB and the presence of more manifest pre-excitation generally points towards a right anteroseptal accessory pathway. The presence of an incomplete RBBB or a dominant R wave in V1 generally points towards a left lateral accessory pathway. More posterior locations tend to have a negative or isoelectric delta wave in the inferior leads as these are more inferior locations while more anterior locations will have a positive delta wave in the inferior leads as these locations are more superior.

If the delta wave is positive in the lateral leads then the inferior leads should be examined. If the delta wave in the inferior leads is negative or isoelectric in the presence of a positive delta wave in the lateral leads then the accessory pathway is most

likely posteroseptal or less commonly right lateral. In order to differentiate a posteroseptal accessory pathway from a right lateral there is more of a tendency for a dominant R wave in V1–V3 in posteroseptal accessory pathway's.

If the delta wave is positive in the lateral leads and positive in the inferior leads then the ECG should be examined for the presence of a LBBB. If there is a LBBB with a QRS axis greater than 60° then the accessory pathway is likely to be located in the right anteroseptal position [4]. The absence of a LBBB with a dominant R wave in V1 or V2 implies that this is likely a left lateral accessory pathway.

ECG Features of Posterospetal Accessory Pathway's

As shown in Fig. 5.7 the delta wave in posteroseptal accessory pathway's is generally negative in III, with a smaller R than S wave in lead II and an R:S ratio in V2 greater than 1. Not all posteroseptal pathways follow this exact pattern.

The majority of posteroseptal accessory pathway's have negative P waves in the inferior leads during tachycardia.

The majority of posteroseptal pathways can be ablated from the right side. It is important to try to differentiate right sided and left sided posteroseptal accessory pathway's. Although this is difficult to conclude from an ECG it has been suggested that a negative delta wave in V1 may favor a right sided AP while a positive delta wave in V1 maybe more suggestive of a left sided AP [5]. An R wave greater than S wave in V1 is suggestive of a left sided accessory pathway as is a narrower QRS in V1. A positive delta wave in II with a negative delta wave in III is also more suggestive of a right sided posteroseptal accessory pathway.

Fig. 5.7 ECG of posteroseptal accessory pathway. There is a negative delta wave in lead III. Although the positive delta in V1 is suggestive of a left sided location the fact that the R wave in V1 is less than the S wave and the positive delta wave in lead II with a negative delta in lead III are more suggestive of a right sided posteroseptal pathway

Coronary Sinus Accessory Pathways

Some posteroseptal accessory pathways are within the coronary sinus. These accessory pathways tend to utilize electrical connections between the ventricle and the coronary sinus and the coronary sinus and the atria. Although the majority of accessory pathways involving coronary sinus connections do not occur in the presence of a coronary sinus diverticulum it is worth checking for this anomaly (Fig. 5.8). These diverticula contain fibres which connect to the coronary sinus myocardial coat and the ventricle. The coronary sinus myocardial coat is generally connected to both atria unless previously disconnected by ablation. There are certain ECG features which may help suggest that a CS connection is involved. The most reliable of them is the presence of a negative delta wave in lead II. As shown in Fig. 5.7 this is not, however, always present. Other features include a steep positive delta wave in lead aVR as well as a deep S wave in V6.

ECG Features of Anteroseptal Accessory Pathway's

Given that anteroseptal accessory pathway's connect from the RA to the RV paraseptal region the delta waves are positive in the inferior leads II, III and aVF as well as the lateral leads I, aVL and V3–V6. An example of an ECG in a patient with an anteroseptal accessory pathway is shown in Fig. 5.9.

ECG Features of Mid-Septal Accessory Pathway's

There is a greater degree of variability in the ECG patterns of mid-septal accessory pathway's reflecting the variability in the atrial and ventricular insertion points and course within this region. In general there are positive delta waves in lead II as well as in the lateral leads with an earlier praecordial transition from V2–V6. Unlike anteroseptal accessory pathways the delta wave is negative in lead III.

ECG Features of Left Lateral Accessory Pathway's

The most important ECG feature of a left lateral accessory pathway is a negative delta wave in leads I, aVL and V6. Additionally, the delta wave in V1 is positive with an R wave greater than S wave in V1. Figure 5.10 shows an example of a left anterolateral accessory pathway. More posterior left lateral accessory pathways are negative in the inferior leads. Anterior accessory pathways are positive in the inferior leads. A negative P wave in lead I during tachycardia is a feature of an ORT involving a left lateral accessory pathway. The first beat shows pre-excitation with a positive delta and R wave in V1 and a positive delta wave in lead II. With the application of RF the next beat shows loss of pre-excitation.

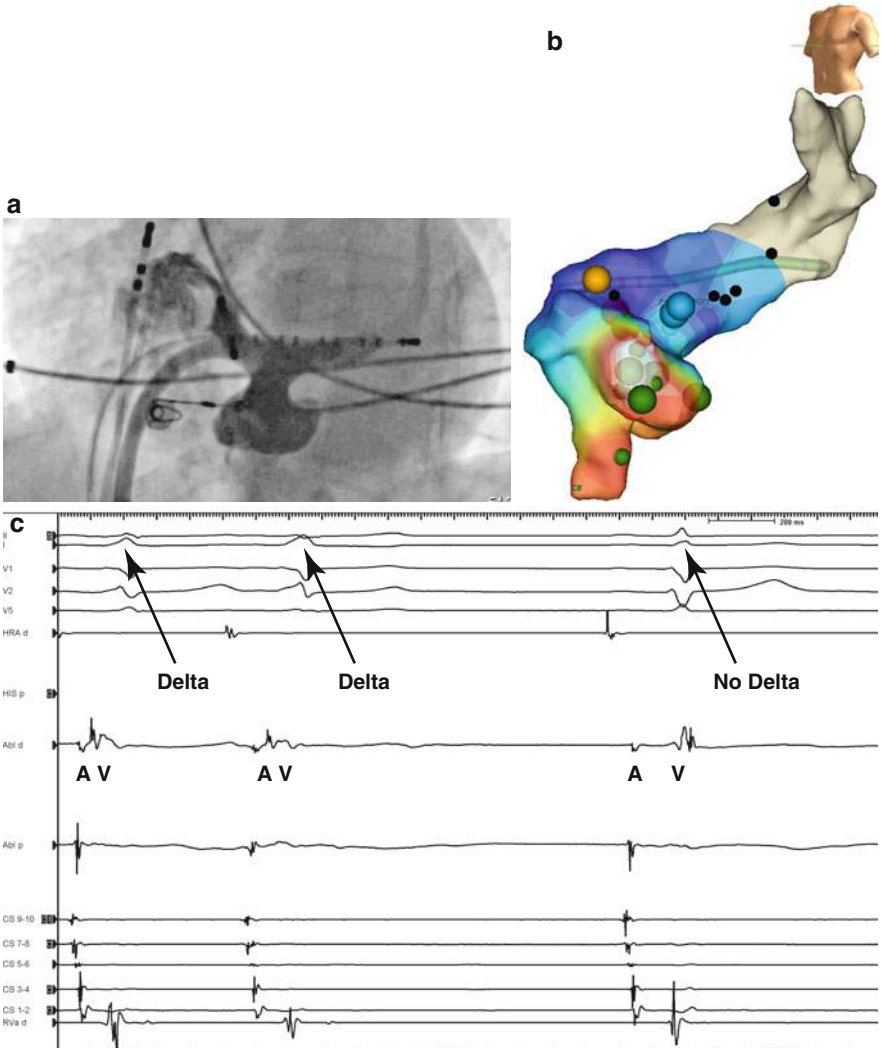

Fig. 5.8 Pre-excitation involving an accessory pathway located on the epicardial surface of a CS diverticulum. Panel **a** shows a venogram of the diverticulum in a PA view which is also shown in the electroanatomic map (Panel **b**). The ECG (Panel **c**) shows clear pre-excitation with a positive delta wave in lead II followed by a slight negative deflection. There is loss of pre-excitation during the third beat with an increase in the AV interval

ECG Features of Right Freewall Accessory Pathways

It can be difficult to differentiate right free wall accessory pathway's from other accessory pathway's. This is because a positive delta wave in V1 may also occur in left lateral accessory pathway's. In order to differentiate these the R wave in V1 should be less than the S wave with a late precordial transition. The delta wave is also positive in the lateral leads I and aVL. The presence of a positive p wave in lead I

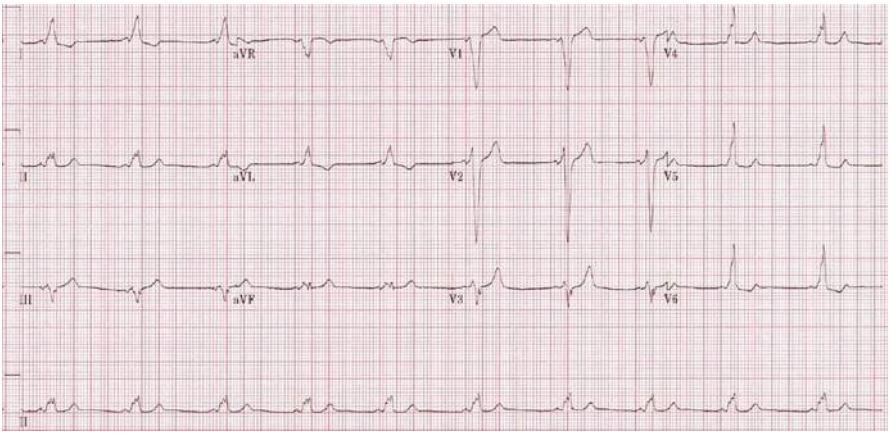

Fig. 5.9 ECG of anteroseptal accessory pathway. There is a LBBB type pattern. The delta wave is positive in lead I and the lateral precordial leads as well as leads II and aVF

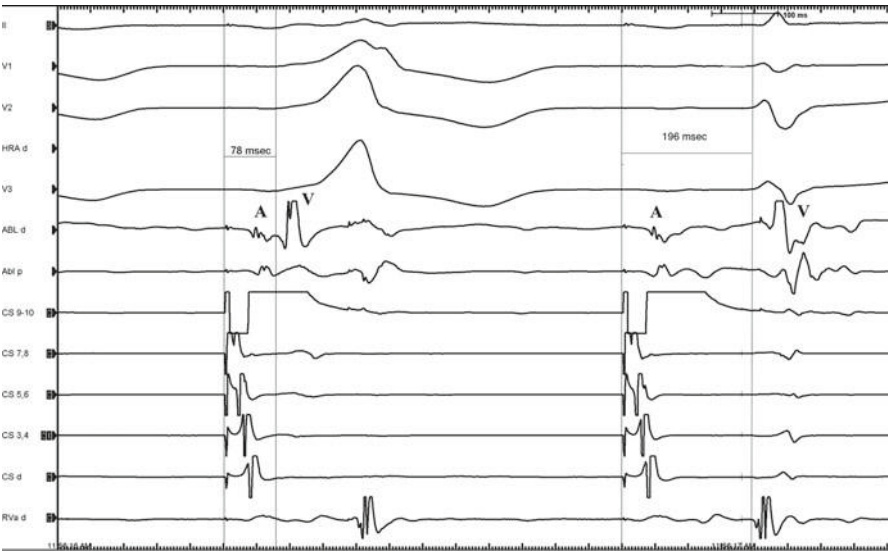

Fig. 5.10 ECG and intracardiac electrograms of ablation being performed for a left anterolateral accessory pathway. The first beat is pre-excited with a positive delta and R wave in lead V1 and a positive delta wave in lead II. Coronary sinus activation is from proximal to distal as a result of atrial pacing with ventricular activation earliest in the distal coronary sinus. There is a short AV interval at the site of the ablation catheter The second beat shows loss of pre-excitation with RF ablation. The surface ECG normalizes with AV prolongation and although the atrial activation in the CS is the same the ventricular activation is proximal to distal implying activation through the AV node. The atrial stimulation to surface QRS is measured and is prolonged from the pre-excited beat at 78–196 ms during normal AV conduction. (CS 9–10 is positioned in the proximal CS while CS 1 2 is located in the distal CS, RVa d is located in the RV apex)

Fig. 5.11 ECG of right lateral accessory pathway. There is a large S wave in lead V1 with a small R wave. Precordial transition occurs in lead V3. There is a positive delta wave in leads I, aVL and the lateral precordial leads

during tachycardiais suggestive of a right freewall accessory pathway. An example of pre-excitation in a patient with a right freewall accessory pathway is seen in Fig. 5.11.

Risks of EP Study and Ablation

The most common complication is that of groin haematoma and vascular injury in approximately 1.4 % [6], particularly if a transaortic retrograde approach is used. The overall risk of thrombo-embolism is 0.6–0.8 % [7], which is generally not of any clinical significance on the right side but on the left side could result in a cardio-embolic stroke or TIA.

The risk of AV block is highest for septal pathways and virtually zero for left lateral accessory pathway's (provided that AV nodal conduction is intact at baseline).

Ablation, particularly if performed within the coronary sinus may result in coronary stenosis or spasm. The incidence of coronary artery injury is 0.06–0.1 % in adults. This generally occurs acutely or shortly after an ablation. Delayed coronary injury as a result of intimal hyperplasia which may increase the risk of coronary thrombosis may present weeks later.

The overall success rate for ablation is approximately 85–95 % and is highest for a left lateral AP and lowest for a posteroseptal accessory pathway.

Diagnostic EP Study

A quadripolar catheter is positioned in the RV septum, a quadripolar in the HRA and a decapolar catheter in the coronary sinus. The RV quadripolar or ablation catheter can be positioned along the His in order to measure the AH and HV intervals. In

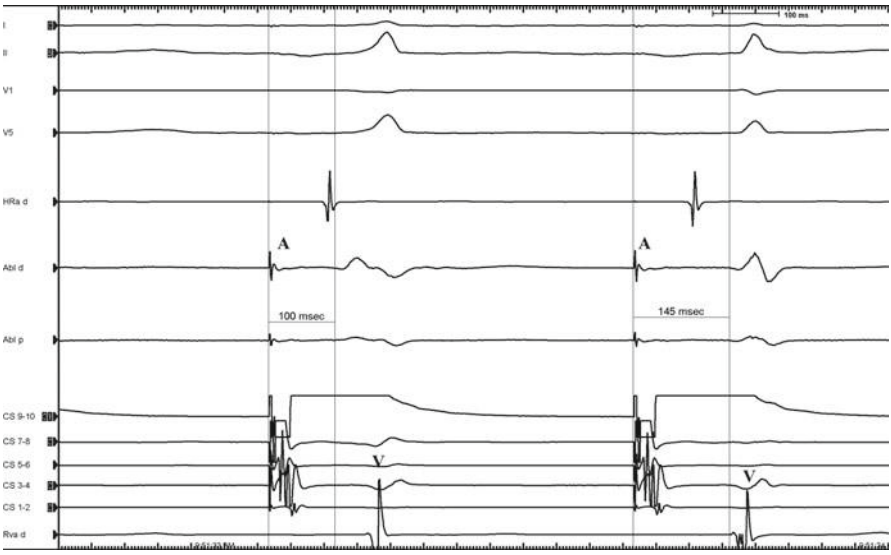

Fig. 5.12 Effective refractory period of the accessory pathway. Decremental pacing from the proximal coronary sinus shows that the first beat is pre-excited with an AV interval of 100 ms. The following beat shows a normal QRS complex with a longer AV interval of 145. At this point antegrade conduction is through the AV node and the accessory pathway is refractory at a cycle length of 480 ms

cases of manifest pre-excitation baseline measurements show a **HV interval that is less than 35 ms** which may even be negative. In order to calculate the accessory pathway ERP an atrial extrastimulus is performed. As the S2 is reduced the AH interval prolongs however the HV interval shortens so that the AV interval is unchanged provided that there is still antegrade accessory pathway conduction. The **antegrade accessory pathway ERP** is defined as the maximum atrial cycle length which results in lack of conduction along the accessory with conduction only along the AVN. This is seen as loss of pre-excitation with normalization of the AH and HV intervals. Figure 5.12 demonstrates loss of pre-excitation with decremental pacing and prolongation of the AV interval as antegrade conduction moves from a combination of AV node and accessory pathway to AV node only. If AV conduction is lost with no normalization of the QRS then the AVN RP is less than or equal to the AP ERP.

Atrial pacing should be performed from both the catheter in the right atrial appendage and the distal coronary sinus as pre-excitation may be more prominent depending on the direction of antegrade atrial pacing. Additionally, there will be a change in the morphology of the QRS or direction of ventricular activation if more than one accessory pathway is present.

Ventricular pacing will reveal the predominant activation sequence of retrograde conduction and may help to localize the accessory pathway as well as calculate the retrograde accessory pathway ERP.

Following this, attempts are made in order to induce AVRT. During decremental atrial pacing antegrade block of the accessory pathway may occur with conduction

antegradely through the AV node. This then activates the ventricle and may conduct retrogradely up the accessory pathway if it is no longer refractory. This may conduct further antegradely through the AV node if it is no longer refractory resulting in an orthrodromic AVRT. Less commonly, with atrial pacing the AV node is refractory and conduction occurs antegradely down the accessory pathway with conduction retrogradely through the AV node resulting in an antidromic AVRT.

Differentiation Between AVNRT and AT

Parahisian pacing may be performed during normal sinus rhythm in order to differentiate between VA nodal conduction and retrograde accessory pathway conduction. Decremental ventricular pacing during sinus rhythm may be useful in order to assess for decrement versus non decremental conduction but is not foolproof as some accessory pathway's have decremental retrograde conduction and also the accessory pathways may not be involved in the tachycardia mechanism. If a tachycardia can be induced a His refractory PVC may be introduced in order to assess if this has any effect on the atrial activation. A His refractory PVC which advances or delays the next atrial depolarization without changing the activation sequence is indicative of an AVRT. Also a His refractory PVC which terminates the tachycardia is indicative of an AVRT. If the PVC advances the next atrial depolarization only by advancing the local His i.e., the His is no longer refractory by an amount slightly greater than the degree of His advancement, then the most likely mechanism is an AVNRT. As shown in Fig. 5.13 in the case of a posteroseptal accessory pathway RV entrainment can be performed during tachycardia with a V-A-V response and a PPI-TCL less than 115 ms.

Mapping the Accessory Pathway

If an accessory pathway is perpendicular to the AV groove then mapping can be performed by localizing the earliest atrial signal during ventricular pacing or mapping the earliest ventricular signal during sinus rhythm or during atrial pacing.

When mapping along the annulus an atrial and ventricular signal are evident. When the catheter is positioned at the location of the accessory pathway then the atrial and the ventricular signals are close together and often merged.

The shortest AV or VA is not always the perfect location for ablation particularly given that a significant percentage of accessory pathway's are oblique and therefore an ideal electrogram also has an accessory pathway potential. This should be recorded between these signals prior to ablation being performed. If this signal disappears with loss of pre-excitation then it is likely an accessory pathway potential.

In order to check whether the potential is an accessory pathway potential ventricular and atrial extrastimuli can be delivered. During mapping of an accessory pathway

Fig. 5.13 Atrial activation is earliest on the proximal coronary sinus followed by the distal ablation (positioned on the His). The tachycardia cycle length is 279 ms Entrainment is performed from the RV apex at 250 ms The post pacing interval is 323 ms The PPI – TCl is therefore 44 ms which is indicative of an AVRT rather than an AVNRT (HRA p is positioned in the high right atrium, the ablation catheter is positioned in the location of the His, CS 9 10 is located at the proximal CS while CS 1 2 is located in the distal CS and RVa d is located in the RV apex)

during antegrade conduction a late ventricular extrastimuli will advance the ventricular electrogram with no effect on the accessory pathway potential. An early ventricular extrastimuli will advance the accessory pathway potential with no effect on the local atrial electrogram. For mapping of the accessory pathway with retrograde conduction a late atrial extrastimuli will advance the atrial electrogram with no effect on the accessory pathway potential while an early atrial extrastimuli will advance the accessory pathway potential with no effect on the atrial electrogram.

An accessory pathway potential may be mapped in 89 % of all cases provided appropriate pacing maneouvres are performed in order to separate out the signals [8]. In order to separate out the local atrial and ventricular signals and expose the accessory pathway potential pacing can be performed from two different locations in either the atrium of the ventricle. A difference in the local AV interval of greater than or equal to 15 ms without moving the mapping catheter when pacing from two different sites implies an oblique accessory pathway. In order to perform this from the atrium pacing can be performed from the right atrial appendage and the distal coronary sinus. The locations of pacing from the ventricular aspect depends on the location of the accessory pathway.

For left lateral, anterolateral, posteroseptal and RV free wall accessory pathway's a counterclockwise activation is achieved from pacing from the inferobasal RV while in anteroseptal and right anterior septal accessory pathway's counterclockwise activation is achieved by pacing from the parahisian location.

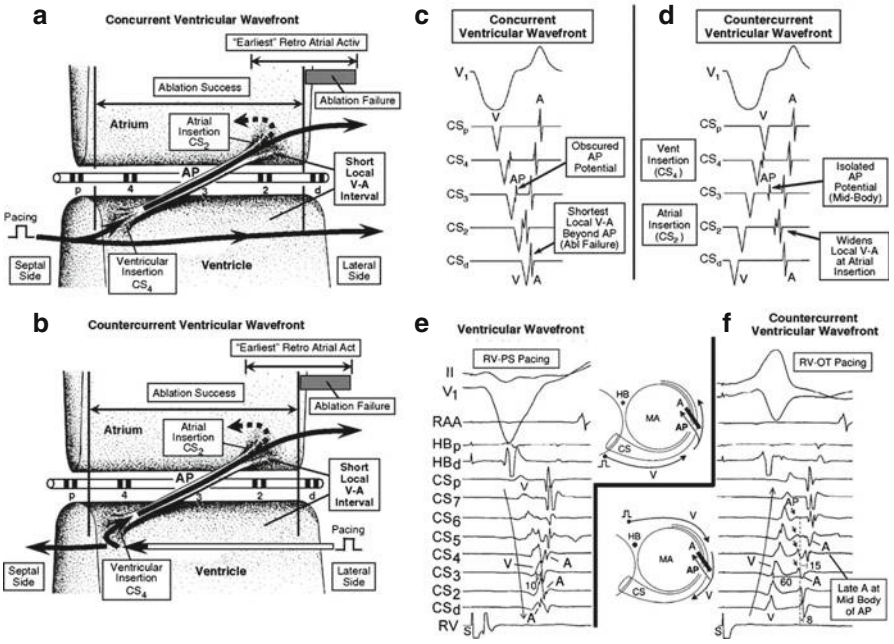

Fig. 5.14 Effects of the oblique course in a left free-wall accessory pathway on the timing of ventricular (*V*), atrial (*A*), and accessory pathway potentials by reversing the direction of the ventricular wave front. (**a**–**d**) Schematic representations. (**e**, **f**) Recordings from a patient with a left lateral accessory pathway. Reversing the ventricular wave front from the concurrent direction (**e**; posteroseptal basal RV pacing [RV-PS]) to the counter current direction (**f**; distal RV outflow tract pacing [RV-OT]) increased the local VA interval at the site in the coronary sinus of earliest atrial activation (electrogram CS3) from 10 to 60 ms and exposed the accessory pathway potential. The ventricular insertion (*left*) was located 15 mm septal to the atrial insertion (*right*). RAA indicates right atrial appendage (**c**–**f**) (Reproduced with permission from Nakagawa and Jackman [9], Wolters Kluwer Health, Inc)

As shown in Fig. 5.14 pacing from lateral to medial in a concurrent direction to the direction of the accessory pathway prolongs the local VA time and therefore exposes the accessory pathway potential. Targeting this region where a potential can be recorded results in a successful ablation of the accessory pathway.

Clockwise activation for left lateral and anterolateral accessory pathway's is achieved by pacing from the RVOT, for posteroseptal accessory pathway's clockwise activation is achieved by pacing from a lateral coronary vein with ventricular capture. For right free wall accessory pathway's clockwise activation is achieved by pacing from the base of the RV septum while for anteroseptal and right anterior septal accessory pathway's clockwise activation is achieved by pacing from the basal anterolateral RV free wall. The optimal ablation location is around the middle of this oblique pathway. In order to separate these potentials pacing can be performed in the opposite direction to course of the accessory pathway [9].

Occasionally mapping has to be performed during tachycardia. This is frequently the case during mapping of an ORT with unreliable VA conduction during RV

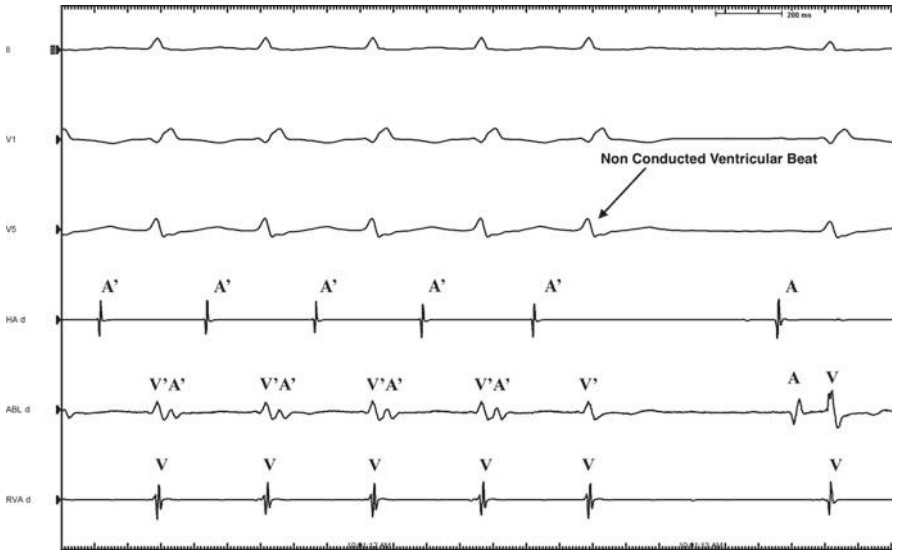

Fig. 5.15 Ablation during orthodromic reciprocating tachycardia in a concealed retrograde left lateral accessory pathway. Mapping is performed during tachycardia looking for the shortest VA interval. Ablation results in block with a non conducted ventricular beat. Thereafter there is sinus rhythm with a normal AV interval is observed. (HRA d is positioned in the high right atrium, ABL d is positioned along the left lateral accessory pathway location and RVa d is located in the RV apex)

pacing. As shown in Fig. 5.15 ablation can be performed during tachycardia looking for the shortest VA interval. If ablation is performed during tachycardia the catheter often falls off the annulus on termination of tachycardia. In order to maintain catheter stability on termination of tachycardia either ventricular pacing can be performed at a faster rate to avoid an abrupt change in the rate and loss of catheter position or further ablation can be performed in the anatomic region during sinus rhythm.

Accessory pathway potentials may be recorded on a unipolar or bipolar electrogram. Both of these can be recorded at the same time but the sharp unipolar signal is more accurate as it reflects the distal pole of the ablation catheter where RF is delivered.

Ablation of Accessory Pathway's

Posteroseptal Accessory Pathway's

These are located between the inferior wall of the right atrium and the superoposterior aspect of the left ventricle [10]. The left border of this region is the left posterior paraseptal region, the right border the right posterior paraseptal region and the anterior and superior border the midseptum.

Local electrograms in this region tend to show a small atrial signal with a large ventricular signal. This occurs as the thin atrial myocardium in this region overlies the thicker ventricular myocardium.

An accessory pathway in this region is posterior to the coronary sinus os and may be either on the tricuspid annular or mitral annular side of the septum. Pacing from the RV catheter and mapping the earliest atrial signal is often unreliable in posteroseptal accessory pathway's. Near simultaneous atrial and ventricular activation in this region results in an AV interval which appears ideal but is not. The optimal approach is targeting of an accessory pathway potential.

As shown in Fig. 5.16 mapping is first performed on the right side of the septum posterior to the coronary sinus and only moved to the left if the accessory pathway cannot be mapped or successfully ablated. Pacing the atrium from either side of the atrial insertion point while mapping for an accessory pathway potential is generally the most accurate method of mapping. Ablation can be performed with 30 W with a target temperature of 60 °C and the power can be titrated up if necessary for a minimum period of 60 s. In general, ablation should be performed during atrial or ventricular pacing during sinus rhythm rather than during AVRT as following cessation of the AVRT the catheter tip can move as sinus rhythm is restored. The patient can be monitored for a period of 30 min with atrial and ventricular pacing to ensure that accessory pathway conduction has not recovered.

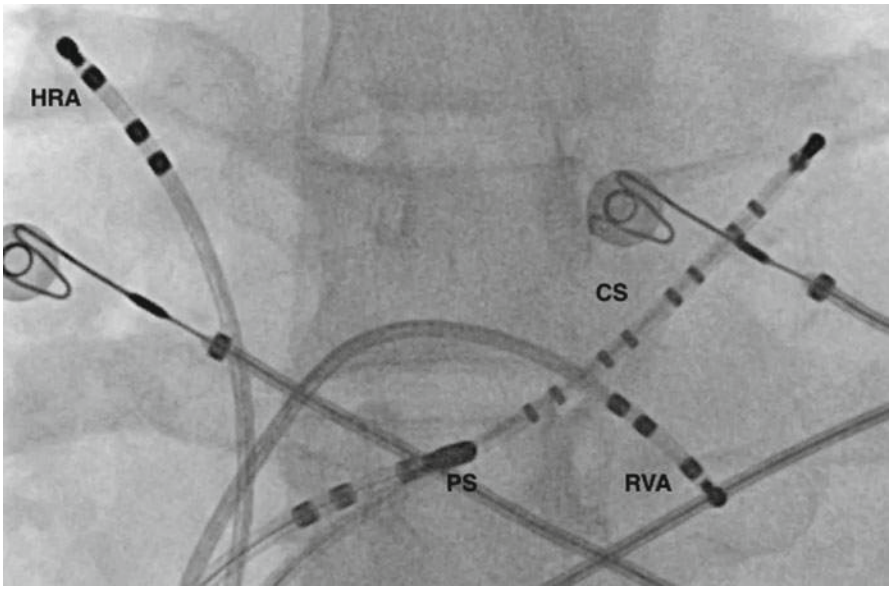

Fig. 5.16 LAO view of a successful site for a right sided posteroseptal accessory pathway. The ablation catheter is posterior to the coronary sinus catheter. A catheter is also positioned in the HRA and the RV Apex

Posteroseptal Accessory Pathway: Difficult Case

Occasionally posterospetal accessory pathways may be subepicardial and involve myocardial connections between the coronary sinus os or within the middle cardiac vein and the epicardium of the left ventricle. In these cases endocardial mapping does not reveal any sites of early activation and the mapping catheter should be advanced into the coronary sinus looking for early ventricular activation during atrial pacing as well as an accessory pathway potential. It is useful to perform a coronary sinus venogram in order to assess for diverticula where accessory pathways may be located. A coronary angiogram should also be performed and ablation should not be attempted if the coronary artery is within 5 mm of the site of ablation. If ablation has to be performed within the coronary sinus at a lower power to 10 W up to a maximum of 25 W irrigated and ablation should be stopped immediately in the event of a rise in the impedance.

Anteroseptal Accessory Pathway

These accessory pathway's are located anteriorly along the central fibrous body close to the His bundle. They are manifest in 80 % of cases in concealed in 20 % and are less common than posteroseptal accessory pathway's.

The difficulty with anteroseptal accessory pathway's is the ability to map them separately from AV nodal conduction and the proximity to the AV node with the potential risk of AV block. The actual His bundle is relatively well insulated and therefore ablation close to the His is generally not high risk. The actual risk is essentially related to potential damage to the compact AV node.

Ablation of an anterospetal accessory pathway can be performed by positioning the ablation catheter in the RV and then curved back on the tricuspid annulus looking for an accessory pathway potential. There is often a small His potential in this region. Mapping can be performed looking for the earliest ventricular signal during sinus rhythm or atrial pacing. The ventricular electrogram should precede the surface delta wave by up to 40 ms.

Midseptal Accessory Pathway

Midseptal Accessory pathway's occur between the His and the CS close to the compact node and therefore carry the highest risk of AV block. In order to minimize this risk the ablation catheter should be positioned with a more dominant ventricular signal. If ablation is unsuccessful despite good contact and a stable position the left side may be mapped.

Mahaim Accessory Pathways

Atriofascicular accessory pathways are the most common of these and account for approximately 80 %. Uncommonly nodofascicular and nodoventricular connections may occur. Fasciuloventricular connections do not seem to present a true clinical issue. Mahaim accessory pathways tend to connect from the lateral tricuspid annulus to or close to the right bundle close to the apex of the right ventricle.

ECG Features

Given that the ventricular insertion point is so close to the right bundle the baseline ECG generally has minimal or no pre-excitation. The degree of pre-excitation increases as the distal insertion point is further from the conduction system. Subtle ECG findings may include a lack of Q waves in the lateral leads V5 and V6. Sometimes a LBBB is present with a normal PR interval. Latent pre-excitation may be seen in Mahaim accessory pathways. Examples of the baseline ECG and the ECG with atrial pacing for atriofascicular and atrioventricular accessory pathways are shown in Fig. 5.17.

EP Study and Mapping of Mahaim

As pre-excitation is often minimal at baseline pacing from the right atrium tends to result in a greater degree of pre-excitation and generally the development of LBBB. Decremental pacing from close to the atrial insertion point tends to result in increasing LBBB as conduction occurs antegradely along the accessory pathway and retrogradely up the right bundle. There is an increase in the AH interval reflecting the decremental conduction and a shortening of the HV interval. If tachycardia is induced the morphology is a LBBB with a superior directed axis.

As these accessory pathways only conduct antegradely the tachycardia is always an antidromic AVRT. The activation sequence is therefore through the pathway into the fascicle followed by retrograde conduction up the right bundle and His followed by the AV node. This activation sequence is useful in order to establish the diagnosis. If an atrial extrastimulus is introduced along the lateral tricuspid annulus whenever the atrial septum is refractory and the extrastimulus advances the tachycardia then there is likely to be a atriofascicular accessory pathway. In order to prove that this accessory pathway participates in the tachycardia a late atrial extrastimulus can be delivered from close to the atrial insertion point of the accessory pathway. If this is advances the ventricular activation and in particular does not advance the His signal during tachycardia then this accessory pathway is participating in the circuit.

Mapping of an atriofascicular accessory pathway may be difficult. Although the right atrium can be paced and the ventricular insertion point can be mapped this does not always prove successful and may cause injury to the right bundle branch with an incessant tachycardia with a longer cycle length conducting retrogradely up the left bundle.

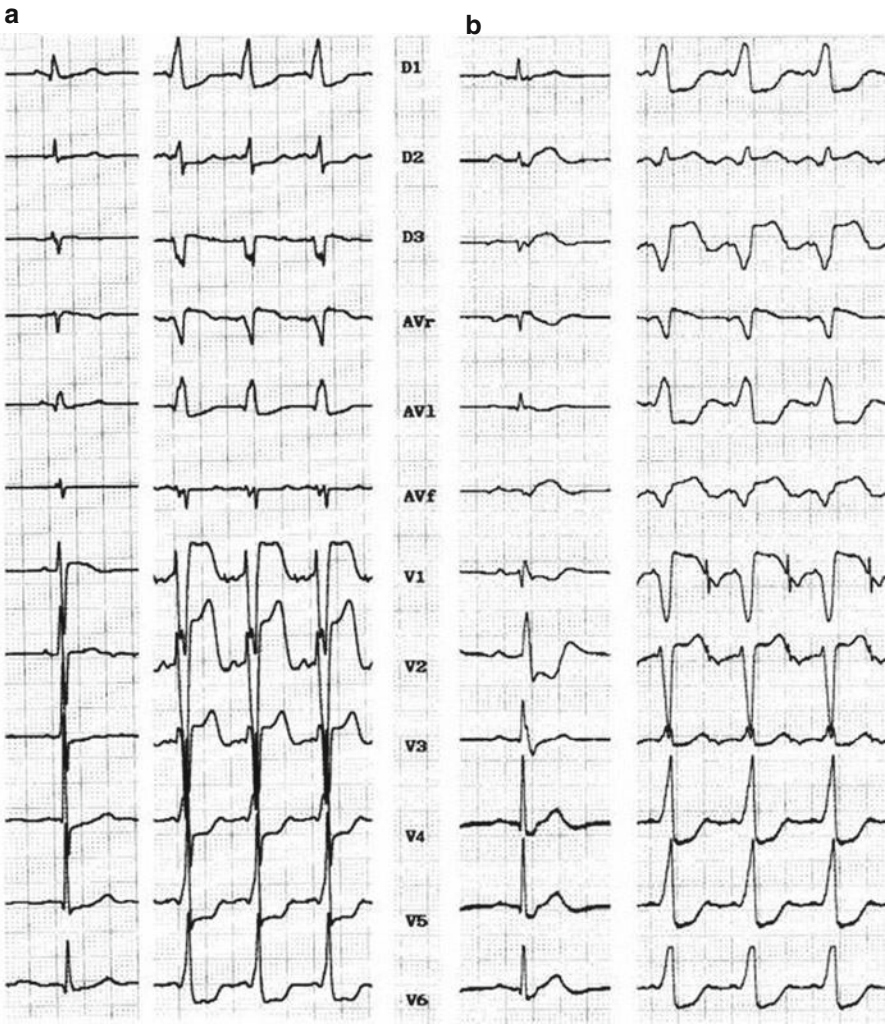

Fig. 5.17 ECG at baseline and with atrial pacing at a faster rate for an atriofascicular pathway in (**a**) and an atrioventricular pathways in (**b**). For an atriofascicular accessory pathway there is minimal preexcitation with a PR interval of 120 ms A LBBB develops with atrial pacing at a faster rate. For an atrioventricular pathway the baseline PR interval is normal with a RBBB. With atrial pacing at a faster rate there is manifest pre-excitation with a LBBB (Courtesy of Sternick [13])

Additionally, given that these pathways do not conduct retrogradely mapping the earliest atrial activation during ventricular activation cannot be performed. The most ideal method is therefore to use a 20 pole catheter along the tricuspid annulus in order to map for a Mahaim potential which is recorded along the length of the accessory pathway.

A Mahaim potential is seen as a sharp deflection between the A and the V which are both widely separated due to the distance between the atrial and ventricular

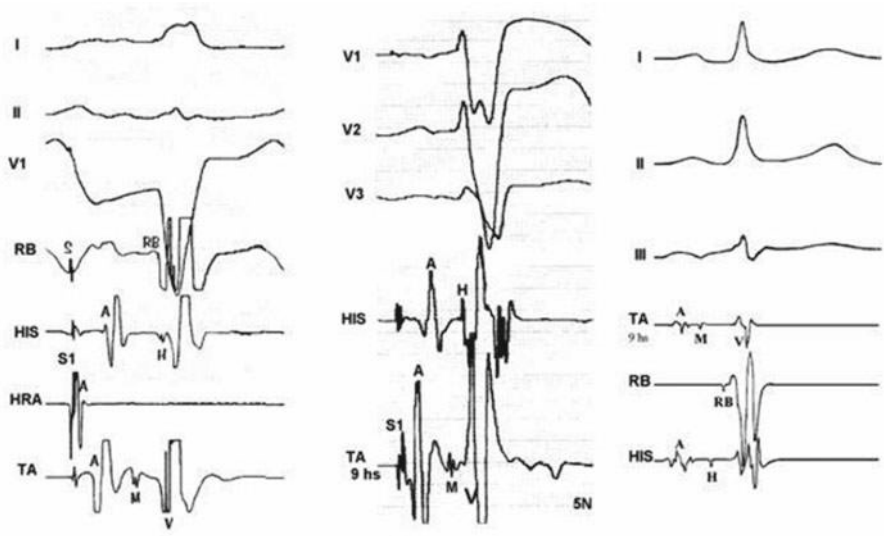

Fig. 5.18 Mahaim (*M*) potentials from left to right: first two cases with His-like potentials and the third with narrow and low amplitude potential. Ablation was successful in each of those sites (*TA* tricuspid annulus electrograms) (Courtesy of Sternick [13])

insertion points. Examples of these are shown in Fig. 5.18. The interval between this potential and the ventricular potential is constant with decremental atrial pacing. Care must be taken when positioning this catheter that the accessory pathway is not bumped and therefore cannot be mapped.

If the Mahaim potential does disappear while bumped with the ablation catheter this is a reasonable location to apply RF. During ablation there is often a slow accelerated rhythm for several seconds known as Mahaim automaticity [11]. This is generally considered a good sign during the application of RF.

Often a sheath is helpful in order to maintain catheter stability along the tricuspid annulus. During ablation transient Mahaim junctional acceleration may occur as shown in Fig. 5.19 which is similar in morphology to the tachycardia. Although a multipolar catheter can be positioned along the tricuspid annulus in order to map the Mahaim potential occasionally electranatomic mapping may also be helpful.

Left Lateral Accessory Pathway

These are the most common accessory pathways with the highest success rate for ablation of 95 % [12]. They may have either minimal pre-excitation given the distance of the ventricular insertion point from the AV nodal conduction. They also have the highest rate of concealed retrograde conduction of all accessory pathway's.

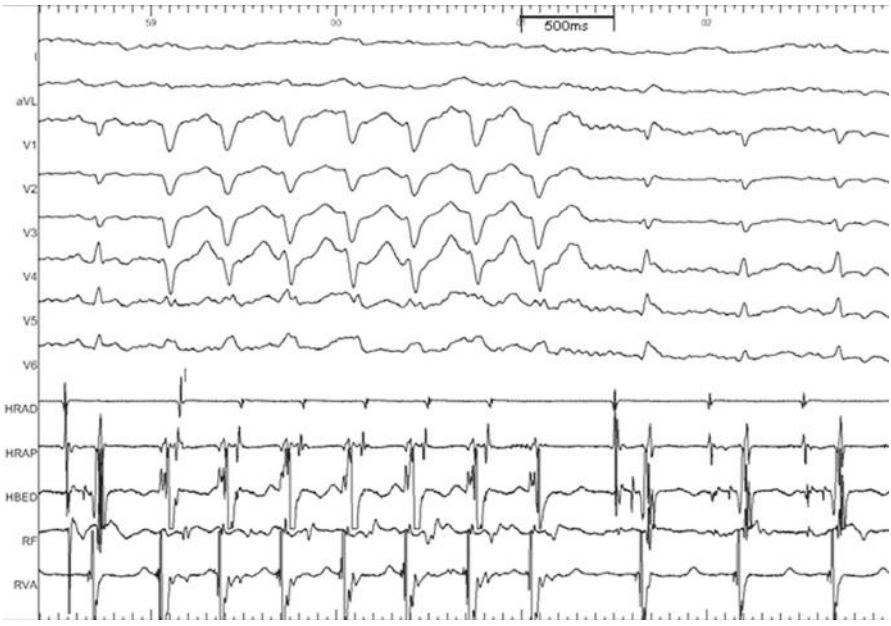

Fig. 5.19 Radiofrequency ablation at the site of Mahaim fibre location resulting transient Mahaim junctional acceleration. The QRS morphology is similar to Mahaim tachycardia. HRAP, high right atrium proximal (Courtesy of Bohora et al. [14]. Oxford Press)

Mapping of the accessory pathway is guided by the coronary sinus catheter which is slightly superior to the mitral annulus but runs along in the same direction as the annulus and therefore gives an approximate idea of where the accessory pathway may be located. Following confirmation of the accessory pathway further mapping can be performed with an ablation catheter either via a transseptal or retrograde approach. The electrodes are parallel to the CS electrodes and the catheter is moved along the catheter with ventricular pacing on order to assess the earliest atrial signal and an A:V ratio of 1:1.

Transseptal access is generally relatively straightforward through the fossa ovalis as the atrial anatomy is normal and can be achieved with a Brockenborough needle and a long non deflectable sheath. For a retrograde approach femoral arterial access is gained and the ablation catheter is prolapsed across the aortic valve in an RAO view with the curve pointing in an anterior direction to the right of the image. After crossing the aortic valve the catheter is then rotated counterclockwise with the curve maintained bringing it in a posterior alignment toward the coronary sinus in the plane of the posterior mitral annulus. The curvature is then slowly released in order to move along the annulus. In order to achieve a greater atrial signal the catheter is withdrawn slightly with an A:V ratio of approximately 1:10 and an atrial electrogram amplitude of 0.4–1.0 mV. Although a retrograde approach may be associated with greater catheter stability it is generally more straightforward to maneuver the catheter via the transseptal access.

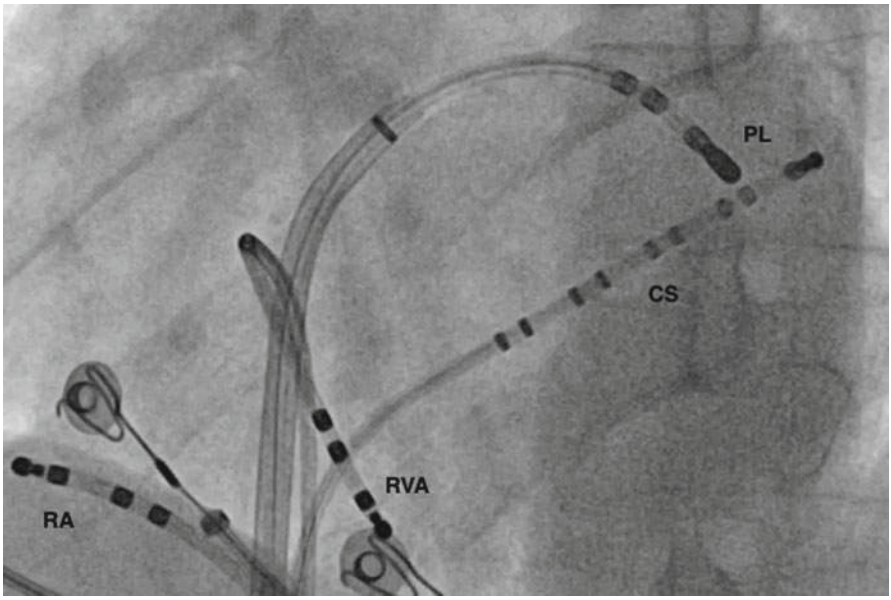

Fig. 5.20 Ablation catheter position on the posterolateral concealed retrograde accessory pathway

As soon as either transseptal access has been obtained or the aortic valve has been crossed heparin should be administered at an initial dose of 100 units/kg aiming for an ACT greater than 300 s. A continual infusion of heparinized saline should be infused through the side arm of the long sheath. Provided there is retrograde conduction along the accessory pathway the most straightforward method of mapping is to pace the ventricle and map for the earliest atrial activation. Pacing from different locations can be used in order to separate out the A and the V so as to record an accessory pathway potential. The ablation catheter can be moved along the mitral annulus. An example of the optimal position for an ablation catheter in a concealed retrograde posterolateral accessory pathway is shown in Fig. 5.20.

Mapping for the earliest ventricular electrogram can also be performed during atrial pacing. For a left lateral accessory pathway the local ventricular electrogram should preceded the surface delta by up to 10 ms. A negative QS in a unipolar electrogram is also a sign of a good position.

It is not ideal to ablate during tachycardia as the catheter can move considerably following termination of the tachycardia although it some cases of incessant tachycardia there is no other option.

Catheter stability may not be as good as a retrograde approach but this method is associated with a lower incidence of vascular complications. Additionally the transseptal approach is better for accessing extreme lateral and anterolateral accessory pathway's.

For a retrograde approach femoral arterial access is achieved with a 7Fr sheath. The ablation catheter is directed up the descending aorta and a curve placed in the catheter as it is advanced around the aortic arch.

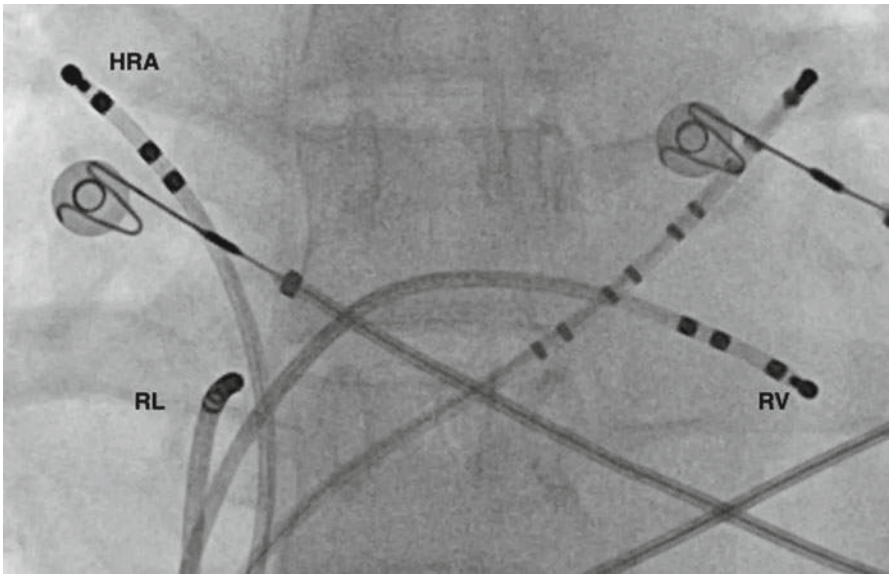

Fig. 5.21 Mapping of an accessory pathway along the tricuspid annulus. The ablation catheter is positioned in the right posterolateral annulus where ablation was successful. Also shown in this image is a catheter in the HRA, RV and CS

Right Free Wall Accessory Pathway

These are considered to be the most difficult accessory pathways to map and successfully ablate. This is due to a combination of catheter instability, the presence of other structural abnormalities such as Ebstein's and the lack of a structure which may assist mapping of the annulus. A 20 pole catheter is often positioned in the RA in order to help map the tricuspid annulus. A deflectable sheath may be helpful for catheter stability and the catheter is moved looking for an early atrial or ventricular signal with an A:V ratio of 1:1 as well as an accessory pathway potential. The local ventricular signal should be compared with the surface delta wave and should be earlier by up to 20 ms [5]. An example of mapping of the tricuspid annulus using an ablation catheter in a right sided accessory pathway is shown in Fig. 5.21.

Accessory Pathway General: Difficult Case

The most common cause for failure to successfully ablate an accessory pathway is the inability to manipulate the ablation catheter to the atrial or ventricular insertion point. For left lateral accessory pathways this may be overcome by switching from retrograde to a transseptal access or vice versa. Changing the curve on the ablation catheter and occasionally the use of a long sheath may also help to maneuver the catheter and provide stability.

The inability to deliver a successful lesion limited by power or temperature may be overcome by repositioning the catheter or changing the angulation of the catheter. If this does not work then switching to an irrigated catheter may help.

If an accessory pathway potential cannot be mapped or is small then the coronary sinus should be mapped. If this is the case then ablation can be performed at lower power from within the coronary sinus.

If the patient is in incessant AVRT ablation can be performed during tachycardia. It is important that ablation is continued after termination of the tachycardia as often the catheter moves during reversion to sinus rhythm.

Important Points

1. Accessory pathway's are muscle fibers which connect the atrium to the ventricle through the fibrofatty and fibrous parietal AV junctional regions. The majority are located within the epicardial atrioventricular fat pad close to the atrioventricular junctions,
2. Anatomically these are divided into septal (paraseptal) which include posteroseptal, midseptal and anteroseptal, left lateral (left posterior), left posterolateral (left infero-posterior), left posterior (left inferior), left anterolateral (left superoposterior) and left anterior (left superior). The equivalent locations are also possible on the right side using similar nomenclature. Additionally some accessory pathways may be directly connected into the specialized conduction system such as atriofascicular, atrioventricular, nodoventricular and fasciculoventricular pathways. Accessory pathway's may also be located in unusual anatomical locations involving epicardial connections between the coronary sinus and the left ventricle, the non-coronary cusp of the aortic valve to the left ventricle, the right atrial appendage to right ventricle or left atrial appendage to left ventricle.
3. Orthodromic AVRT occurs when the antegrade accessory pathway is refractory and conduction occurs antegradely through the AV node activating the His and ventricle and retrogradely along the accessory pathway if it is no longer refractory. The VA time required for this to occur is generally greater than 70 ms.
4. Antidromic AVRT conduction occurs antegradely via the accessory pathway as the AV node is refractory. This is generally associated with a pre-excitated QRS as conduction is only via the AP. VA times are generally greater than 70 ms as conduction is via the VA node.
5. The Shortest Pre-Excited R-R Interval (SPERRI) less than 220 ms or 220–250 ms may be associated with a higher risk of antegrade conduction during AF and may be an indication for catheter ablation.
6. In order to help maximize pre-excitation during an EP study pacing may be performed from different locations on different catheters. This may also help to reveal an accessory pathway potential which should be targeted for ablation.

Chapter 6
Atrial Tachycardias

Benedict M. Glover and Pedro Brugada

Abstract Atrial tachycardia is a **focal or macro re-entry supraventricular arrhythmia which does not directly involve the AV node**. Overall it accounts for approximately 7 % of all SVT's [1].

Focal atrial tachycardia occurs as a result of either micro re-entry, increased automaticity or triggered activity while macro re-entry occurs over a region of tissue surrounding a region of conduction block. Focal atrial tachycardia due to increased automaticity can usually be initiated with isoprenaline while decremental atrial pacing tends to initiate and terminate micro and macro re-entry.

Although atrial tachycardia's may occur anywhere within the right atrium or left atrium there are more common locations and in particular where anisotropic conduction occurs in which there is rapid linear conduction and slowed transverse conduction. The most common locations are the **crista terminalis**, **coronary sinus os**, **the pulmonary veins and antral regions**, **the tricuspid and mitral annuli**, **the right and left atrial appendages and the interatrial septum**. The location is to an extent dependent on the patient's age, history of structural heart disease, prior ablations or surgery and the presence of other arrhythmias.

Focal Versus Macro Re-entry

It is useful to establish if an atrial tachycardia is either focal or re-entry prior to mapping as this dictates the parameters that are set for mapping as well as interpretation of the mechanism. As shown in Fig. 6.1 a focal atrial tachycardia tends to have a

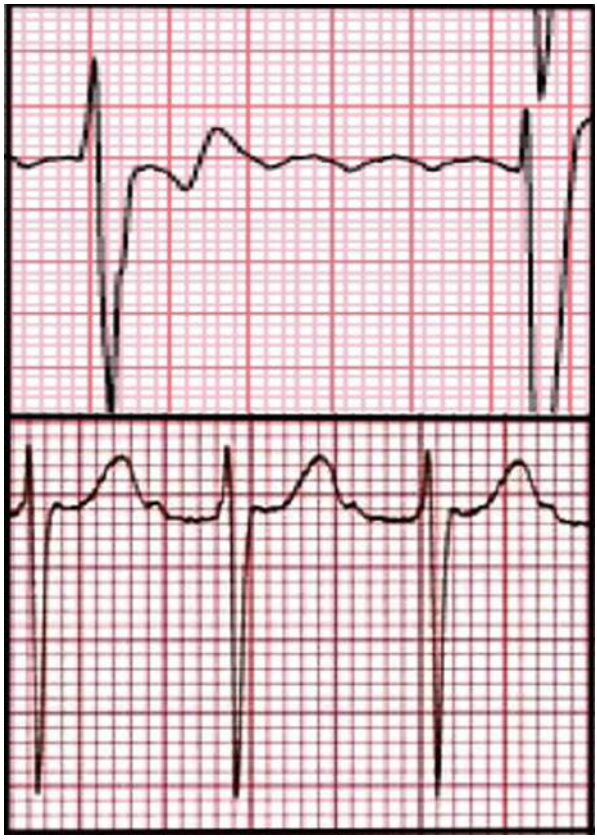

Fig. 6.1 ECG showing macro re-entry tachycardia (*top*) where there is almost continual atrial activation and focal AT (*bottom*) with a clear isoelectric line between atrial activity

very distinct P followed by an isoelectric AV interval while a macro re-entry mechanism tends to have continual atrial electrical activity which may be superimposed on the QRS complex.

If this is unclear vagal maneuvers can be performed or adenosine administered in order to decipher atrial activity more clearly. Of note adenosine may occasionally terminate atrial tachycardia by activation of adenosine sensitive potassium channels [2].

In the electrophysiology laboratory activation mapping can be performed and will easily show whether the entire tachycardia cycle length occupies a region rather than a single focus. Entrainment can also be performed in two anatomically distinct regions to assess if the circuit is macro re-entry, for example the septal and lateral mitral isthmus in mitral annular flutter or anterior and posterior to the roof line in left atrial roof dependent flutter.

For focal atrial tachycardia an early, possibly fractionated signal is often seen as a good target. Fractionation occurs as a result of slow conduction from a region of increased automaticity or micro re-entry connecting into normal atrial tissue [3]. Unipolar electrograms also have a QS pattern [4]. The local signal should be at least 40 ms ahead of the earliest P wave. If the RA is mapped and the earliest signal is no

more than 20 ms ahead of the earliest P wave with septal activation earliest then the left atrium should be mapped because the arrhythmia may originate in the right sided pulmonary veins.

In macro re-entry the critical isthmus is targeted as an area of early meets late during activation mapping. This can easily mapped by performing entrainment in locations likely to contain the isthmus looking for a closely matching PPI-TCL.

Locations of Atrial Tachycardias

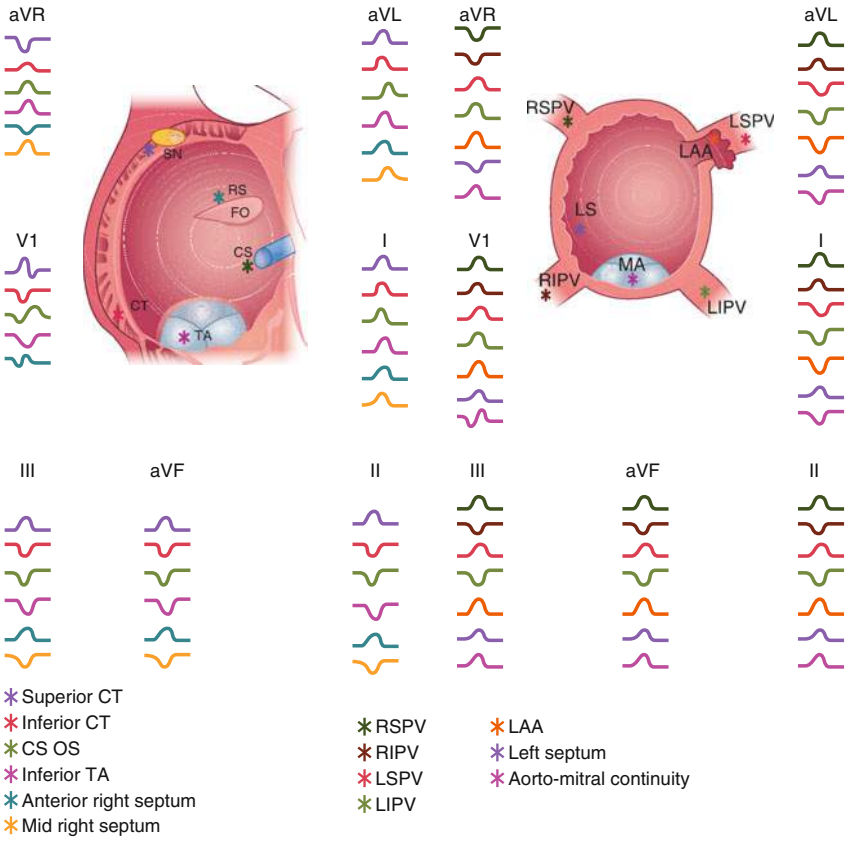
It is useful to use the ECG to predict whether the atrial tachycardia is left or right sided prior to performing an ablation. The most useful leads to examine are V1 and aVL. As the left atrium is more posterior than the right atrium **left sided atrial tachycardia's tend to have a positive P wave in V1. A negative P wave is seen more commonly in V1 in right sided atrial tachycardias. A positive P wave in aVL generally indicates a right sided atrial tachycardia while a negative P wave in aVL generally indicates a left sided atrial tachycardia**. These are general observations and variations exist with anatomy, underlying pathology and previous ablations [5, 6]. The ECG features of atrial tachycardias in the most common anatomic locations are shown in Fig. 6.2.

Crista Terminalis

The crista terminalis runs from the anteromedial high right atrium inferiorly along the lateral RA wall where it ends at the posteroinferior right atrium at the eustachian valve. The majority of right sided atrial tacycardias occur in the region of the crista terminalis. At the superior aspect this may be due to an increase in automaticity as a result of the close proximity of the sinus node. Throughout the structure micro re-entry may occur as a result of anisotropic conduction [7].

Atrial tacycardias originating from this region often have a similar P wave morphology to sinus rhythm and can be confused with sinus tachycardia. Sinus node re-entry tachycardia can also occur at the junction of the sinus node and the crista terminalis. As this is a micro re-entry tachycardia it can be initiated with atrial pacing [8]. As shown in Fig. 6.2 the P wave morphology in atrial tacycardias originating from the crista terminalis depends on the location. Atrial tachycardias from the superior crista terminalis have a similar P wave morphology to sinus rhythm in V1 which is positive and then negative with an inferior directed P wave axis. Atrial tachycardias located in the lower crista terminalis frequently have a negative P wave in V1 with a superior directed P wave axis.

In order to distinguish between atrial tachycardia from the crista terminalis versus sinus tachycardia an abrupt rather than gradual onset and termination with warm up and cool down over several beats favors atrial tachycardia.



Location		V1	II, III, aVF	aVL
CT		Negative if lower down Positive if closer to sinus node	Positive	Positive
Septum	Right	Isoelectric	Positive	Positive
	Left	Negative / Positive	Low amplitude positive	Negative
CS		Negative / Positive or Isoelectric / Positive	Negative	Positive
Annulus	TA	Negative	Negative for Inferoanterior Positive or biphasic for Superior	Positive or isoelectric
	MA	Negative / Positive	Positive	Negative or isoelectric
LSPV	LSPV	Positive	Positive	Negative
	LIPV	Positive	Negative	Negative
	RSPV	Positive	Positive	Positive
	RIPV	Positive	Negative	Positive
LAA		Positive	Positive	Negative

Given the focal nature of these tachycardias activation mapping can be performed looking for a discrete region of early activation. Prior to ablation pacing at high output should be performed in order to ensure that there is no right phrenic nerve capture.

Coronary Sinus os

Atrial tachycardias in this region tend to originate from the superior and posterior regions of the coronary sinus os [9]. The most likely explanation for this is due to anisotropic conduction where coronary sinus fibers connect into the right atrium [10]. This result in either micro re-entry, triggered activity or less commonly increased automaticity [11].

Atrial tachycardias which are located at the os of the coronary sinus have a negative followed by a positive deflection in V1 [9]. The p wave in aVL is positive with a superiorly directed p wave axis.

Given the central activation it is important to distinguish these from atypical AVNRT or AVRT using a septal accessory pathway. Activation mapping should be performed looking for the earliest region of activation. As shown in Fig. 6.2 this is where ablation should be delivered (Fig. 6.3).

Septal Atrial Tachycardias

It is often difficult to ascertain from the ECG as to whether a septal atrial tachycardia is right sided or left sided. Left sided septal atrial tachycardias generally have a positive p wave in V1 while an isoelectric p wave in V1 is more indicative of a right sided focus.

Low septal parahisian atrial tachycardiss are unusual but are associated with a significant risk of AV block. In general the right side is mapped first and if required the left side. Of note the non coronary cusp of the aorta should also be mapped as ablation from this region may reveal an earlier region of activation with a very low risk of AV block.

Fig. 6.2 Common locations of atrial tachycardias along with P wave morphology and ECG features (summarized on table below). In general left sided foci tend to be positive in V1 given the fact that the LA is posterior to the RA. Right sided foci tend to be positive in aVL. Atrial tachycardias originating from closer to the septum tend to be narrower. Superior locations such as the superior CT, anterior septum and superior PV's tend to be positive in the inferior leads while inferior locations such as the CS, inferior TA, inferior MA and inferior pulmonary veins tend to be negative in the inferior leads

Fig. 6.3 ECG of atrial tachycardia originating from the coronary sinus os. At the *top of the image* the surface ECG leads I, II, aVL, V1 and V5 are shown. The activation sequence of the tachycardia shows the earliest coronary sinus activation recorded on the proximal CS (CS 9–10). The ablation catheter is used to map and shows a local atrial electrogram with is 86 ms ahead of the proximal CS. This is recorded at the junction of the CS os with the low right atrium posterior to the CS. Ablation was performed in this region with termination of the tachycardia and no further inducible tachycardia

Tricupid and Mitral Isthmus Atrial Tachycardia

These are not common and on an ECG may mimic typical atrial flutter or mitral isthmus dependent atrial flutter. The majority of atrial tachycardias originating from the tricuspid annulus tend to be inferior and anterior.

The majority of atrial tachycardias from this region tend be caused by micro re-entry around the annulus. Less commonly as a result of increased automaticity which may occur as a result of AV nodal type tissue in this region [11].

In tricuspid annular atrial tachycardias the P wave is generally negative in V1 as the annulus is anterior with activation in a more posterior direction [12, 13].

Atrial tachycradias from the superior tricuspid annulus tend to have an inferiorly directed axis while those in the inferior annulus tend to have a superiorly directed axis. As shown in Fig. 6.4 a long sheath is often useful for catheter stability in the ablation of annular atrial tachycardias. In this case the addition of a long sheath helps to maintain stability for the ablation of a focal atrial tachycardia along the lateral tricuspid annulus.

Atrial tachycardias in the aorta mitral continuity are uncommon. As this is at the superior aspect of the mitral annulus atrial tachycardias originating from this region have an inferior directed axis and a biphasic P wave in V1 [14].

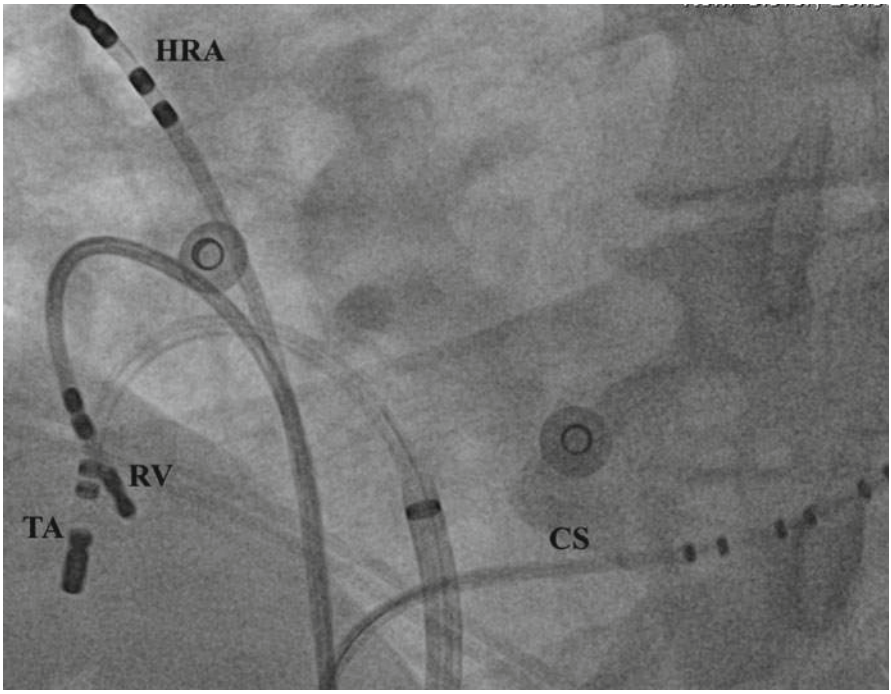


Fig. 6.4 Ablation of a focal atrial tachycardia along the lateral tricuspid annulus using a long sheath in order to maintain catheter stability. This image is taken in an LAO projection with the ablation catheter along the lateral aspect of the tricuspid annulus. Also shown in this image is a catheter in the high right atrium on the *top left of the image*, a catheter in the RV apex shown in the *bottom left of the image* and a catheter in the coronary sinus on the *right of the image*

Pulmonary Vein Atrial Tachycardia

It is generally accepted that ectopic foci from the pulmonary veins may act as initiators for AF in a significant percentage of patients. Atrial tachycardias originating from a single pulmonary vein are relatively common. This tends to occur as a result of increased automaticity but may also result from micro re-entry at the antral areas around the veins. The foci which result in atrial tachycardias tend to be more ostial than those which result in AF [15].

Atrial tachycardias originating from the pulmonary veins are positive in V1 and tend to remain positive across all precordial leads due to the posterior location [15]. Lead I is useful to help differentiate between atrial tachycardias from the right and the left pulmonary veins. The p wave is generally positive in right sided pulmonary veins and negative in left sided pulmonary veins. Atrial tachycardias originating from the left pulmonary veins tend to be broader as septal activation is more delayed when compared with right sided pulmonary veins [16].

It is often difficult to differentiate right superior pulmonary vein from the superior vena cava as the p wave is similar in V1, lead I and both have a similar axis. The p waves in the inferior leads tend to be more positive in atrial tachycardias originating from the superior vena cava.

In order to help differentiate between superior and inferior pulmonary veins the P wave axis should be examined. Atrial tachycardias originating from the superior pulmonary veins have an inferiorly directed P wave axis and those from the inferior pulmonary veins have a superiorly directed P wave axis

Left Atrial Appendage Atrial Tachycardia

Atrial tachycardias originating from the left atrial appendage have a similar morphology in V1 and lead I to those which originate from the left sided pulmonary veins. Given the more anterior position of the left atrial appendage the p waves transition becomes isoelectric in V2 [17].

Clinically atrial tachycardias originating from the LAA tend to be more incessant while those originating from the left superior pulmonary vein may be associated with paroxysmal AF [17]. These may originate from the proximal or distal left atrial appendage. If ablation is performed in the distal left atrial appendage power is usually set at 20–30 W with a target temperature of 45° [18]. This is kept low due to low flow in this region. Prior to ablation high output pacing should be performed in order to ensure that there is no capture of the left phrenic nerve. Access of the distal left atrial appendage may be difficult an a circular catheter may be required in conjunction with the ablation catheter in order to expose the region. Care must be taken to avoid catheter entrapment or perforation of the thin walled appendage.

Important Points

1. Focal atrial tachycardia occurs as a result of either micro re-entry, increased automaticity or triggered activity while macro re-entry occurs over a region of tissue surrounding a region of conduction block.
2. The most common locations are the crista terminalis, coronary sinus os, the pulmonary veins's and antral regions, the tricuspid and mitral annuli, the right and left atrial appendages and the interatrial septum.
3. For focal atrial tachycardia an early, possibly fractionated signal is often seen as a good target.
4. In macro re-entry the critical isthmus is targeted as an area of early meets late during activation mapping. This can easily mapped by performing entrainment in locations likely to contain the isthmus looking for a closely matching PPI-TCL.

5. In order to help decide whether an atrial tachycardia is right sided or left sided the most useful leads to examine are V1 and aVL. As the left atrium is more posterior than the right atrium left sided atrial tachycardias tend to have a positive P wave in V1. A negative P wave is seen more commonly in V1 in right sided atrial tachycardias. A positive P wave in aVL generally indicates a right sided atrial tachycardia while a negative P wave in aVL generally indicated a left sided atrial tachycardia.
6. The majority of right sided atrial tachycardias occur in region of the crista terminalis as a result of anisotropic conduction or changes in automaticity.
7. CS atrial tachycardias tend to originate from the superior and posterior regions of the CS os [9]. The most likely explanation for this is due to anisotropic conduction where CS fibers connect into the right atrial.
8. Tricupid and mitral isthmus atrial tachycardias are relatively uncommon and on an ECG may mimic typical atrial flutter or mitral isthmus dependent atrial flutter. The majority of atrial tachycardias originating from the tricuspid annulus tend to be inferior and anterior.

Chapter 7
Atrial Flutter

Benedict M. Glover and Pedro Brugada

Abstract Atrial flutter is caused by either macro or micro re-entry circuits within either the right atrium or left atrium. It is broadly divided into either typical or atypical forms. Typical atrial flutter involves the cavotricuspid isthmus as part of the circuit with either a counter-clockwise or clockwise activation. The cavotricuspid isthmus extends from the tricuspid valve to the inferior vena cava, which supports slow conduction.

Atypical atrial flutter involves non-cavotricuspid isthmus dependent circuits in the right atrium, septum or left atrium. Right atrial flutters which are not dependent on the cavotricuspid isthmus include upper loop re-entry, lower loop re-entry, right lateral wall incisional type atrial flutter and circuits around the fossa ovalis. Upper loop re-entry tends to occur around the superior vena cava with slow conduction through the upper component of the crista terminalis. Lower loop re-entry occurs around the inferior vena cava with slow conduction through the lower portion of the crista terminalis.

Left atrial flutters tend to occur around the mitral valve annulus, the ostia of the pulmonary veins or the fossa ovalis on the left side. Mitral annular flutter may propagate either in a clockwise or counterclockwise direction.

ECG analysis of the flutter wave is important in order to help localize the circuit and plan an appropriate ablation strategy for the patient as well as helping to predict the potential success of the procedure.

ECG interpretation does have its own limitations particularly in patients who have undergone prior atrial ablations or in patients with structural heart disease. The most important differentiation is between cavotricuspid isthmus dependent flutter and atypical atrial flutter as well as predict whether the circuit is in the right or left atrium.

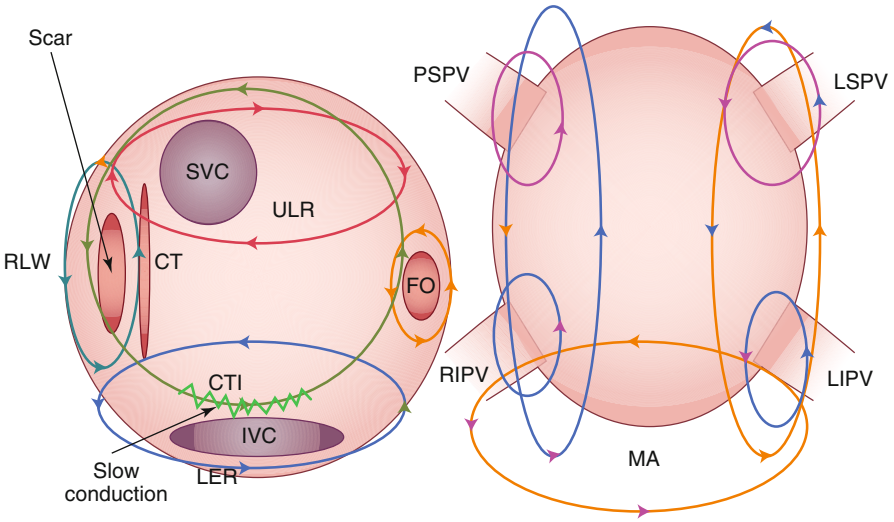

Fig. 7.1 Location of Atrial Flutters in the Right and Left Atrium. Cavotricuspid Isthmus (*CTI*) dependent circulates around the right atrium commonly with counterclockwise propagation (*green arrows*). Upper loop re-entry (*ULR*) rotates around the superior vena cava (*SVC*) with slow conduction through the crista terminalis (*CT*). Lower loop re-entry rotates around the inferior vena cava (*IVC*) also involving the crista terminalis (*CT*). Re-entry may also occur around the right lateral wall (*RLW*) often in post surgical cases where this is related to an incision as well as around the fossa ovalis (*FO*). In the left atrium atrial flutter may occur around the mitral annulus (*MA*) in either a clockwise or counterclockwise direction as well as around the pulmonary veins (*LSPV* left superior pulmonary vein, *LIPV* left inferior pulmonary vein, *RSPV* right superior pulmonary vein, *RIPV* right inferior pulmonary vein)

Cavotricuspid Isthmus Dependent Atrial Flutter

Overall this is the most common flutter circuit and should always be suspected even in cases of congenital heart disease and post atrial fibrillation ablation, even if the ECG does not look typical (Fig. 7.1).

Anatomy

The cavotricuspid isthmus is an important anatomical structure which acts as an area of slow conduction. As seen in the anatomic image in Fig. 7.2 it is located posteriorly to the tricuspid annulus and anteriorly to the Eustachian valve at the junction of the right atrium and the inferior vena cava. The coronary sinus is superior and medial to the cavotricuspid isthmus. During mapping and ablation of the cavotricuspid isthmus the catheter is generally positioned at 6 o'clock in an LAO projection (Fig. 7.3) which is the mid segment and is considered the thinnest portion where ablation can generally be performed. Moving towards the septum this region is shorter in distance but

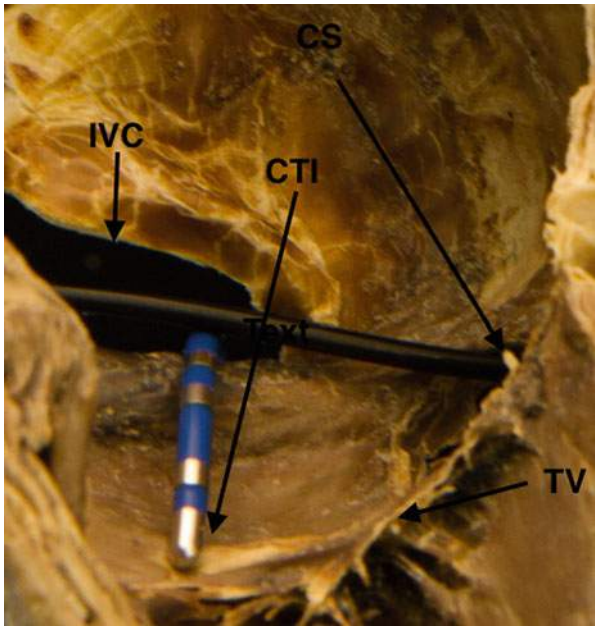

Fig. 7.2 Anatomical image showing the CTI, tricuspid valve (*TV*), inferior vena cava (*IVC*) and coronary sinus (*CS*). Also shown in this image are an ablation catheter in the location of the CTI and a catheter in the coronary sinus

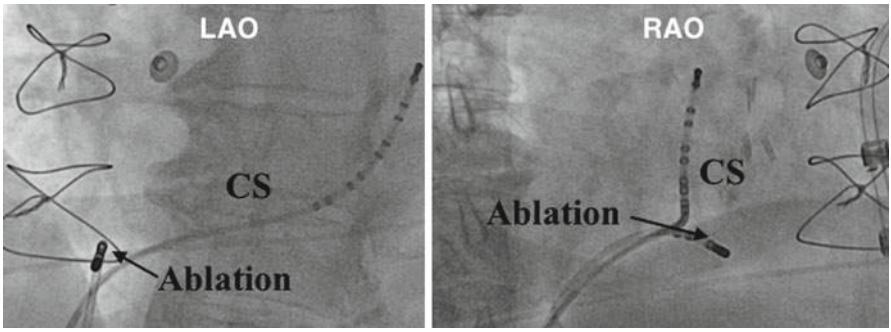

Fig. 7.3 Fluoroscopic image of the catheter location in the mid CTI in an LAO (*left*) and RAO (*right*) projection. The ablation catheter is positioned along the mid CTI. There is a 10 pole catheter positioned in the coronary sinus (CS)

thicker where the fibers merge with the coronary sinus. Inferolaterally it is broader and thicker. The anterior aspect at the tricuspid annulus is muscular while the posterior component at the junction with the inferior vena cava has minimal muscle and is generally fibro-fatty tissue. The cavotricuspid isthmus elevates into the eustachian ridge and this divides it into two components: the sub-eustachian isthmus (between the eustachian ridge and the tricuspid valve) and the crest of the eustachian ridge to the inferior vena cava, separated from the compact AV node by the coronary sinus.

Although the mid cavotricuspid isthmus is the thinnest component and therefore the best target for ablation the anatomy is variable: muscular fibers in this region

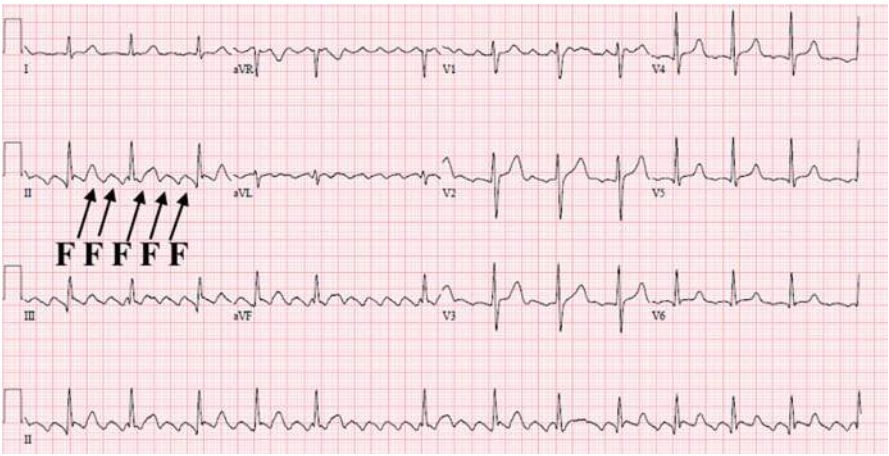

Fig. 7.4 ECG of counterclockwise cavotricuspid isthmus dependent atrial flutter. The flutter waves are negative in the inferior leads II. III and aVF implying activation from inferior to superior in the right atrium

result in irregularities which extend inferiorly and laterally from the coronary sinus wall or medially and superiorly from the crista terminalis. Between the muscular structures are thin membranes. Often these muscular fibres overlap at their superomedial and inferolateral origins and therefore in theory the most parallel segment is the medial cavotricuspid isthmus. The muscular fibers which pass through the cavotricuspid isthmus are of different sizes and therefore have different conduction properties. Narrower fibers in the mid isthmus tend to conduct more slowly than broader fibers in the septal and lateral positions.

ECG Features

Cavotricuspid isthmus dependent atrial flutter tends to have a saw tooth type appearance observed in the inferior leads and V1. The most common direction of conduction is counterclockwise which accounts for approximately 90 % of cases. As shown in Fig. 7.4 this result's in negative flutter waves in the inferior leads with an initial gradual and then steep downslope followed by a steep upslope and then a gradual downslope to baseline. The flutter wave is positive in V1 in counterclockwise activation with a gradual transition from V1 to V6 from positive to isoelectric to negative.

Clockwise (reversed) cavotricuspid isthmus dependent atrial flutter accounts for approximately 10 % of cases of typical atrial flutter. The activation sequence is the reverse of typical counterclockwise atrial flutter. The inferior leads therefore demonstrate a broad positive with a negative flutter wave in V1. There is a transition from V1 to V6 from negative to isoelectric to positive.

Ablation of the CTI for Typical Atrial Flutter

In general this can be performed with two catheters. A quadripolar or decapolar catheter is positioned in the coronary sinus while an ablation catheter can be used for ablation and mapping. Some operators use a multipolar catheter in the right atrium in order to help assess the activation sequence during the atrial flutter as well as to assess for isthmus block at the end of the procedure. This catheter may be positioned in order to map the septum with the proximal electrodes and the lateral wall of the right atrium with the distal electrodes and the mid electrodes spanning across the right atrial roof. The distal electrodes can also be positioned in the proximal coronary sinus with the mid poles spanning the cavotricuspid isthmus and the proximal poles spanning from the high to low right atrium along the crista terminalis in order to assess for bidirectional block at the end of the ablation. This is generally not required and can often lead to diagnostic errors if the catheter is not positioned exactly as described above.

A range of ablation catheters may be considered for ablation of the cavotricuspid isthmus ranging in size from 4 mm to 10 mm as well as the possibility of irrigation versus non-irrigation of the tip. The choice is operator dependent and generally a large curve is used in order to ensure adequate reach of the ventricular side of the isthmus.

It is our practice to use a decapolar catheter in the coronary sinus and a 4 mm irrigated catheter for ablation. A quadripolar catheter may be considered for back up right ventricular pacing in certain cases where the patient is in atrial flutter and there is a suspicion that the patient may develop bradycardia following termination of the arrhythmia.

The ablation catheter is normally positioned at the tricuspid annulus so that the atrial and ventricular electrograms are of equal amplitude. In the LAO projection the ablation catheter is at the 6 o' clock position where the cavotricuspid isthmus is at its narrowest. A more medial position increases the risk of AV block and potential ablation within the middle cardiac vein. A more lateral position generally requires a longer ablation line.

If the patient is in atrial flutter entrainment should be performed from this location at a rate 20 ms faster than the tachycardia cycle length looking for a PPI – TCL of less than 30 ms. An example of this is shown in Fig. 7.5. This patient presented with an atrial flutter following a prior PVI for AF. The tachycardia cycle length was 348 ms. Pacing from the ablation catheter which was positioned along the cavotricuspid isthmus was performed at 320 ms. The PPI was 348 ms which was exactly the same as the tachycardia cycle length indicating that the cavotricuspid isthmus was a part of the circuit.

While pacing from the cavotricuspid isthmus the stimulation to onset of atrial activation is generally quite long due to the slow conduction in the isthmus. This is obviously much shorter on the septal side of the isthmus.

Power settings for a 4 mm irrigated catheter are usually 30–40 W. The temperature limit is generally set at 60 ° C for non-irrigated catheters. Larger 8-mm

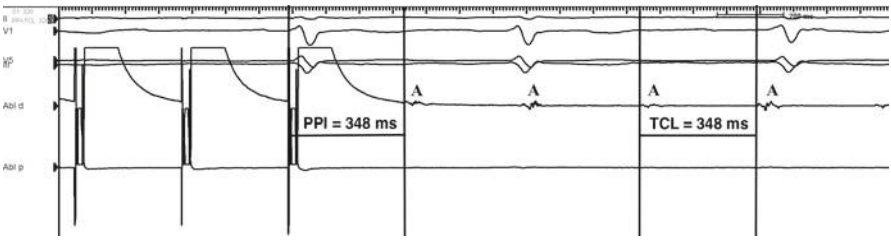

Fig. 7.5 PPI – TCL in Atrial Flutter during and after entrainment from the CTI. This patient presented with atrial flutter following a prior ablation for atrial fibrillation. The tachycardia cycle length was 348 ms. Pacing was performed from the ablation catheter which was positioned along the CTI at 320 ms. The post pacing interval was 348 ms. This was exactly the same as the tachycardia cycle length implying that the CTI was a critical component to the circuit

tip catheters require a higher power often up to 70 W with a maximum temperature of 60 ° C. Following a period of 60–90 s and with significant diminution of the local signal the catheter is moved to a more proximal location. Ablation can be performed either as a point by point technique or a continuous dragging technique from the tricuspid annulus to the junction with the inferior vena cava spending 60–90 s at each position looking for a reduction in local electrogram voltage. Some operators use lack of unipolar pacing to assess whether a lesion has been created prior to moving onto a more proximal location where capture occurs and further ablation is performed in this location. Often atrial flutter terminates prior to the development of bidirectional block across the CTI. If bidirectional block does not occur the same line can be repeated on a more medial or lateral position.

If the patient is in sinus rhythm at the start of the procedure ablation can be performed during proximal coronary sinus pacing assessing for double potentials along the ablation line [1, 2]. The proximal coronary sinus is generally paced at a cycle length of 600 ms and the ablation catheter is moved along the ablation line from the ventricular aspect to the junction with the inferior vena cava. The first potential is recorded from the medial aspect of the line while the second component is lateral to the line. As shown in Fig. 7.6 an interval of greater than 110 ms with minimal variability is generally associated with conduction block across the ablation line [3]. As shown in Fig. 7.7 this can be reversed so that pacing is performed lateral to the ablation line and the interval between this and the proximal coronary sinus can be measured. This is recorded and the ablation catheter is moved further away from the cavotricuspid ablation line and pacing performed. If moving further from the ablation line results in a shorter stimulation to proximal coronary sinus activation then this likely represents counterclockwise block.

When pacing from the proximal CS an interval of less than 90 ms indicates intact conduction across the line.

As shown in Fig. 7.8 the delay from the onset of the first to the second potential is 40 msec. The line between the two potentials is also not isoelectric. This represents intact conduction across the CTI.

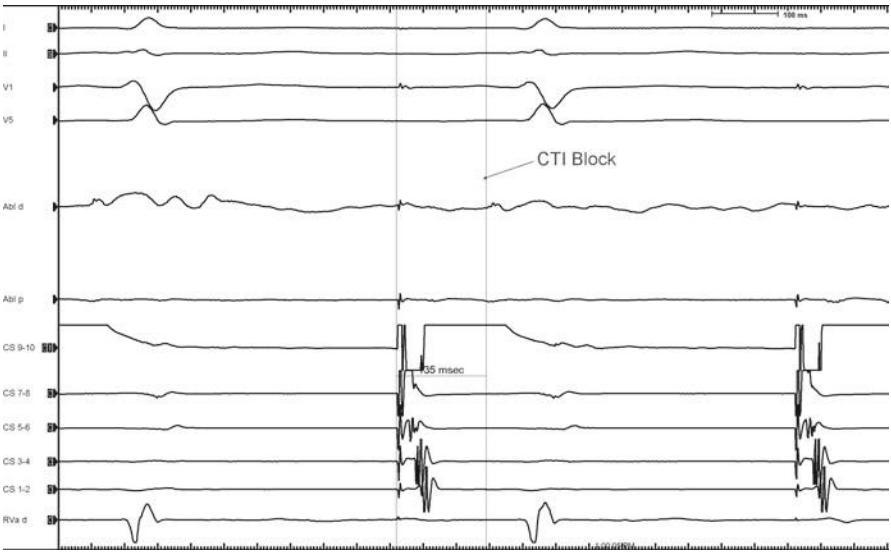

Fig. 7.6 Pacing is performed from the proximal CS (CS 9 10) at a rate of 600 msec. The ablation catheter is positioned along the CTI so that it is recording activation medial to the CTI line seen as the first deflection followed by an isoelectric line and then another atrial activation lateral to the CTI 135 msec later. This represents clockwise block across the CTI. CS 1 2 is located in the distal coronary sinus, RVa d is located in the RV apex

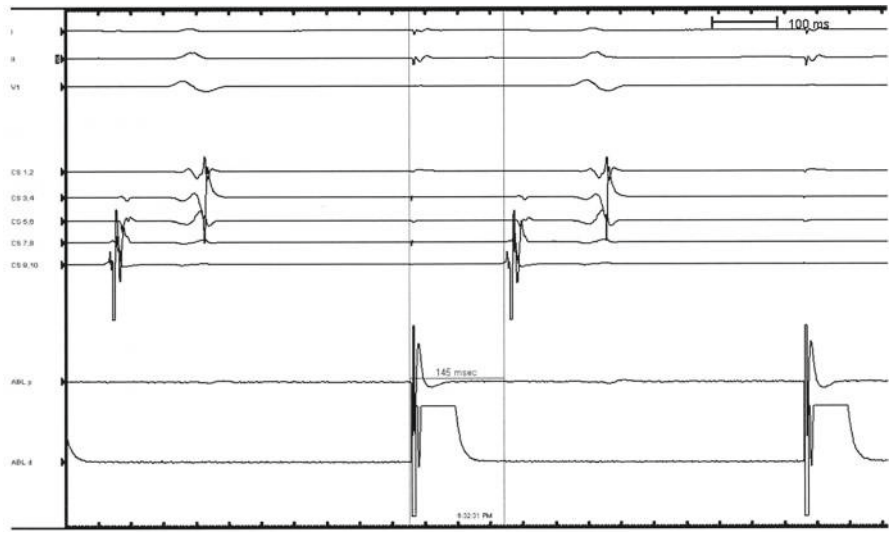

Fig. 7.7 Pacing is performed lateral to the ablation line and the stimulation to proximal CS (CS 9 10) is recorded as 145 msec representing a significant delay. The ablation catheter is moved more superior and lateral to this point and pacing is performed with a delay from stimulation to proximal CS activation of 128 msec (not shown in this image). This is suggestive of counterclockwise block across the CTI. CS 1 2 is positioned in the distal coronary sinus

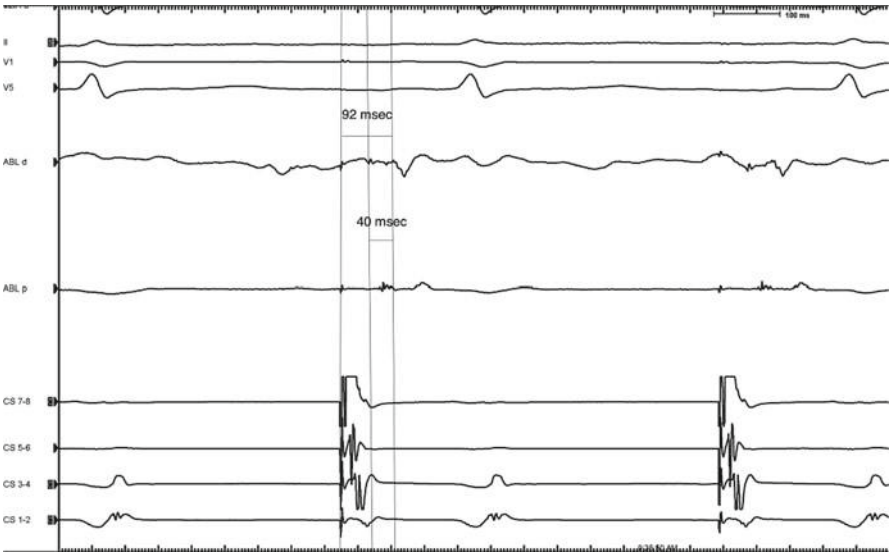

Fig. 7.8 Pacing is performed from the proximal CS (CS 7 8) with the ablation catheter positioned on the CTI. Double potentials are recorded on the ablation catheter. The first potential represents atrial activation medial to the CTI ablation line. The second component represents activation lateral to the CTI ablation line. The time from the proximal CS stimulation to the lateral atrial activation is recorded as 92 msec. The delay from the onset of the first potential to the onset of the second potential is 40 msec. The interval between the two potentials is not isoelectric. This represents intact conduction across the ablation line. CS 1 2 is positioned in the distal coronary sinus

If the interval between the two potentials is between 90 and 110 ms then the electrograms should be examined further. Features indicative of block include an isoelectric line between the first and the second component of the double potential with a negative second potential. The interval between the first and second components of the potentials is generally isoelectric in the presence of block. If this has a fractionated aspect or low amplitude signals there is generally slow conduction across the line.

In the presence of block the second component of the double potential is negative as a result of a change in the polarity of the activation wavefront. The change from positive to negative should be noted on completion of the gap.

The closer to a gap the shorter the distance between the two components. Wider splitting of the double potentials implies a distance further from the gap.

As shown in Fig. 7.9 where the ablation catheter is positioned on the cavotricuspid isthmus while pacing from the proximal CS. The duration from the pacing spike on the proximal CS to the onset of the second potential is 182 ms. The delay from the onset of the first potential to the onset of the second potential is 94 msec. There is a clear isoelectric line between the potentials and the second component is negative. This represents clockwise block across the CTI.

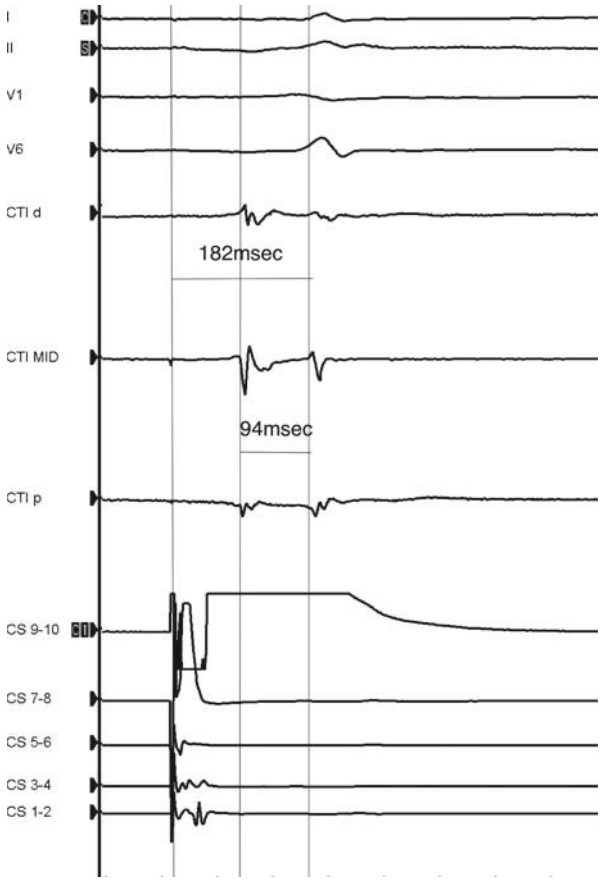

Fig. 7.9 Clockwise block across the CTI. Pacing is performed from the proximal CS (CS 9 10) while the ablation catheter is positioned along the CTI. The duration from the pacing spike to the onset of the second potential is 182 ms. The time from the onset of the first to the onset of the second potential is 94 ms. The line between both potentials recorded on ablation distal (CTId), middle (CTImid) and proximal (CTIp) is isoelectric. The second component of the double potential is negative on the ablation catheter. These features are suggestive of clockwise block across the CTI. CS 1 2 is positioned in the distal coronary sinus

Decremental Pacing

This technique is useful in cases where it is difficult to make a conclusion based on intermediate double potentials [4]. Ablation is performed along the cavotricuspid isthmus until double potentials are noted. Pacing is then performed from the proximal coronary sinus at 600 down to 250 ms while the ablation catheter is used to record double potentials along the ablation line. If the second component of the double potential does not increase by more than 20 ms with decremental pacing then this demonstrates clockwise block. This is then repeated from the lateral right atrial wall in order to prove counterclockwise block. A change in the second component by more than 20 ms with incremental pacing implies conduction through the CTI. A diagrammatic representation of this is shown in Fig. 7.10.

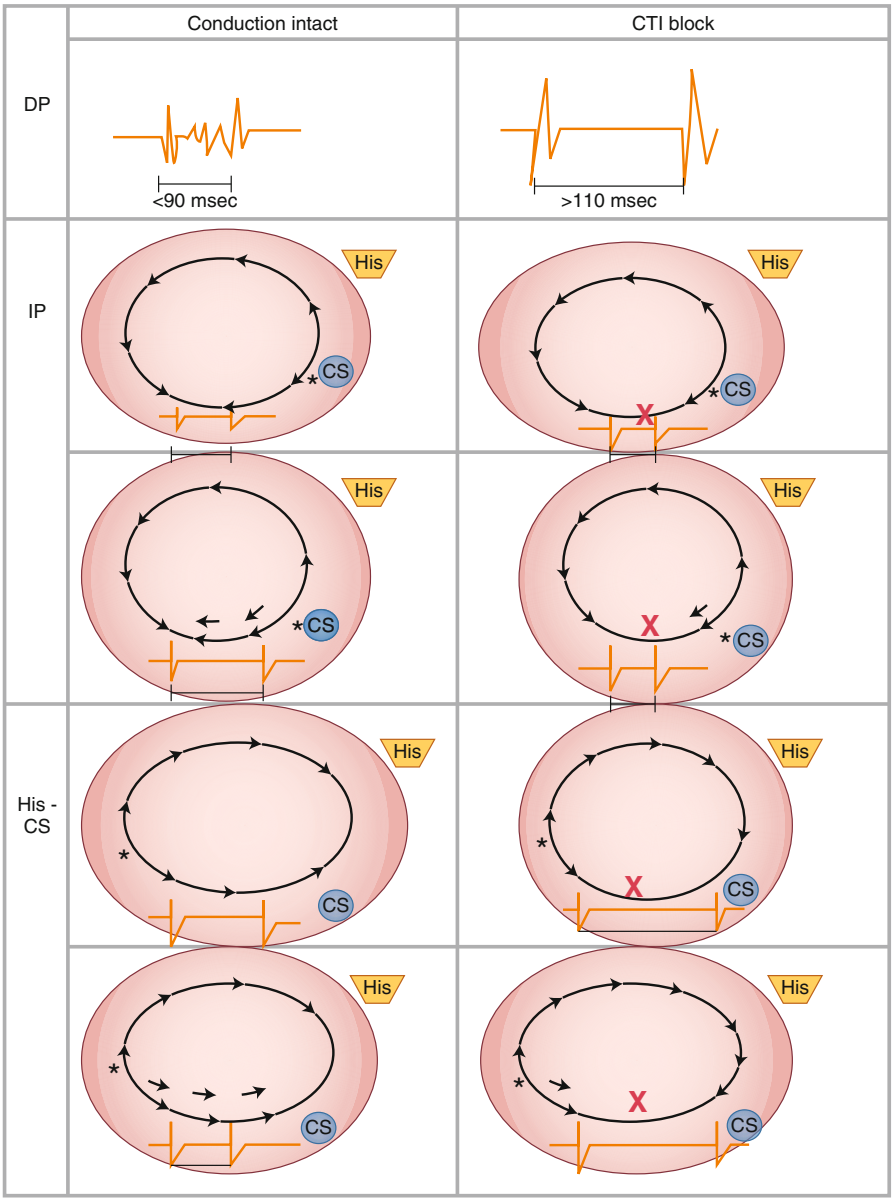

Fig. 7.10 Maneuvers used to prove CTI block. The presence of double potentials with an isoelectric line between potentials of greater than 110 ms is indicative of block across the CTI. Incremental pacing from the CS results in an increase in the separation of the double potentials by greater then 20 msec if CTI conduction is intact. If the CTI line is blocked then there is no significant change with incremental pacing from the CS (*middle images*). Alternatively the atrial signal can be recorded on the His and CS with pacing from the low lateral right atrial wall. If CTI conduction is intact the double potentials narrow with incremental pacing while if the CTI is blocked the potentials separate further but do not decrement with incremental pacing

Decremental His to Coronary Sinus Pacing

This is a modification of differential pacing in which pacing is performed from lateral to the CTI ablation line and activation of the atrial electrogram in the His region is compared with activation of the atrial electrogram in the proximal coronary sinus electrogram [5].

When pacing from the lateral lower right atrium when conduction across the CTI is intact activation occurs in a counterclockwise fashion across the isthmus, via the posteroseptal region followed by activation of the coronary sinus. Activation anterior to the tricuspid annulus results in atrial activation of the His region. Following CTI ablation anterior activation still occurs and the His is still activated which then spreads to coronary sinus which results in an increase in the His – CS timing of >40 ms from baseline. In the presence of CTI block the His to CS timing does not change significantly as activation occurs on the same rather than two pathways.

The advantage of this is that it does not rely on the accurate identification of double potentials which may be difficult to identify. This appears to be an effective strategy in helping to prove block across the CTI

An Alternative Ablation Technique: Maximum Voltage Guided Ablation

Given that different fibers of muscular have different orientations, dimensions and conduction properties there may be discrete regions with high voltage electrograms which can be selectively targeted for ablation [6].

As shown in Fig. 7.11 pacing is performed at 600 ms from the proximal coronary sinus while the ablation catheter is moved from the ventricular of the CTI to the inferior vena cava. The region of highest bipolar voltage is noted and RF delivered in this region for 60 s or shorter if the local potential reduces by more than 50% from baseline [7].

Following this the CTI is remapped looking for the maximum signal and ablated in a similar fashion. This is repeated until bidirectional block is obtained.

This technique appears to be as successful as a conventional line with reduced procedural and fluoroscopy time [8].

Potential Complications of Cavotricuspid Isthmus Ablation

There is a risk of AV block if the ablation performed is septal. This is close to zero if a lateral line is performed. Although the risk of thromboembolism is very low, the patient should be anticoagulated if they are in atrial flutter at the start of the procedure, either with heparin or with continuation of full anticoagulation. Like all catheter ablations there is always a risk of groin hematoma and cardiac perforation.

The risk of coronary artery damage, and in particular the PDA, is very unlikely.

Fig. 7.11 Maximum voltage guided ablation of the CTI. Pacing is performed at 600 msec from proximal CS. A 20 pole catheter (labeled Spi) is positioned in the RA showing earliest activation in the proximal and distal poles and subsequent activation across the RA with no evidence of block across the CTI. The ablation catheter is positioned along the CTI and is recording the region of maximum voltage which in this cases is recorded as 1.81 mV. CS 9 10 is positioned in the proximal coronary sinus with CS 1 2 in the distal CS

Difficult CTI Ablation

Although the majority of cavotricuspid isthmus ablations are relatively straightforward variability in anatomy may result in technical difficulties. The most common of these are difficulty in reaching the ventricular end of the isthmus which is overcome with a long sheath or persistent conduction at the junction between the right atrium and the inferior vena cava which generally requires catheter manipulation.

Additional issues which may not be obvious include prominent pectinate muscles, a prominent Pouch of Keith or prominent Eustachian ridge.

Prominent pectinate muscles in the region of the isthmus may impair the ability to create a line of block. It may be seen on the ablation catheter as large amplitude electrograms. In order to deal with this issue, either a more medial line of ablation can be performed or an irrigated catheter can be considered in order to achieve a deeper lesion.

The Pouch of Keith is located along the isthmus and lateral to the Thebesian valve at the CS orifice. Although this is generally a slight ridge in most patients, occasionally it may be a deep out pouching with poor blood flow, meaning that either the

catheter does not make sufficient contact or, if it does, power delivery is not sufficient to result in a satisfactory ablation line. A prominent Thebesian valve may be a clue to the Pouch of Keith. In order to deal with this problem the isthmus line can be made more laterally.

The Eustachian ridge is a fibrous structure which generally has no impact in an isthmus ablation but if very prominent may actually affect the rotation of the ablation catheter. This means that if the catheter is rotated in a clockwise manner towards the septum, the Eustachian ridge may cause a counter-clockwise rotation away from the septum. In order to counteract this issue a long sheath can be used.

Success of Cavotricuspid Isthmus Ablation

The overall success for an isthmus dependent atrial flutter is approximately 90%, provided bidirectional block has been demonstrated at the end of the ablation. The bigger issue is the occurrence of atrial fibrillation where the reported rate is as high as 82% after 39 months in patients with isolated atrial flutter and no other arrhythmias [9].

Upper and Lower Loop Re-entry

Upper loop re-entry occurs around the superior vena cava with a breakthrough in a gap in the crista terminalis. It often has a similar ECG appearance to clockwise cavotricuspid isthmus dependent flutter with positive flutter waves in the inferior leads. In order to help distinguish upper loop re-entry from clockwise cavotricuspid isthmus dependent flutter lead I can be examined. If the flutter wave in lead I is negative or isoelectric then it is more likely to be upper loop re-entry. If the flutter wave in lead I is positive it may be either. If the flutter wave is less than or equal to 0.07 mV in amplitude then it is more likely to be a result of upper loop re-entry [10]. As the circuit is shorter the tachycardia cycle length is often shorter than typical atrial flutter. It may occur as a result of typical atrial flutter or atrial fibrillation. If entrainment in this region is suggestive for an upper loop re-entry then ablation can be performed at the upper gap along the superior crista terminalis as this may be the narrowest part of the circuit.

Lower loop re-entry uses the cavotricuspid isthmus as part of its circuit but breaks through a gap in the lower portion of the crista terminalis. It is generally counterclockwise and therefore could be confused with typical counterclockwise atrial flutter. As it breaks through at a lower level along the lateral right atrial wall the flutter waves in the inferior leads tend to be less positive and the tachycardia cycle length in general is shorter. Ablation along the cavotricuspid isthmus should result in termination of this tachycardia.

Right Atrial Lateral and Postero-Lateral Wall Flutter

This may occur around areas of scar or low voltage areas such as in patients who have had prior cardiac surgery. It has a variable appearance on ECG depending on the conduction properties in this region, the direction of the circuit and subsequent

activation of the right atrium. Right atrial flutter originating from the lateral wall may often resemble cavotricuspid isthmus dependent flutter. The flutter wave is generally negative in V1. Right atrial flutter involving the septum tends to have an isoelectric or biphasic flutter wave in V1. In general these flutters require detailed mapping looking for regions of scar as well as the activation sequence. Entrainment should help to determine whether the region being mapped is part of the circuit although it may often be difficult to capture due to the presence of scar and low amplitude signals. Certain ablation lines can be performed. For lateral circuits on the lateral wall a line can be made from the region of scar to either the superior or inferior vena cava. If this is performed mapping of the right phrenic nerve should be performed prior to delivery of ablation energy.

Left Atrial Flutter

In order to differentiate a right from a left sided atrial flutter on ECG the most useful lead to examine is V1. If the **initial segment of the flutter wave is negative or isoelectric followed by a positive deflection or the entire flutter wave is negative it is more likely to be right sided while a positive flutter wave is more likely to be left sided**. If the entire flutter wave in V1 is isoelectric it is difficult to localize the flutter to either right or left sided. In left sided atrial flutters as well as these changes noted in V1 the flutter waves in the inferior leads tend to be positive but of low amplitude, generally a reflection of the underlying substrate.

The most simplistic way to distinguish left atrial flutter from atrial tachycardia is to assess the onset and termination of the tachycardia. Re-entry atrial flutter tends to be of acute onset and termination while focal atrial tachycardia tends to accelerate at the onset of the tachycardia and decelerate at the termination of the tachycardia.

Most left atrial flutter circuits either revolve around the mitral annulus in either a clockwise or counterclockwise direction or around the pulmonary veins.

Mitral Isthmus Dependent Atrial Flutter

This circulates around the mitral annulus in either a clockwise or counterclockwise direction and traverses the mitral isthmus. The relevant anatomy is demonstrated in Fig. 7.12. The mitral isthmus is posterior to the mitral annulus and anterior to the left atrial posterior wall. Mitral isthmus dependent flutter may occur following pulmonary vein isolation and in particular as a result of ablation lesions inferior and slightly anterior to the left inferior pulmonary vein.

In order to perform a mitral isthmus line a catheter is positioned in the coronary sinus so that the distal electrodes are slightly posterior to the line. An ablation

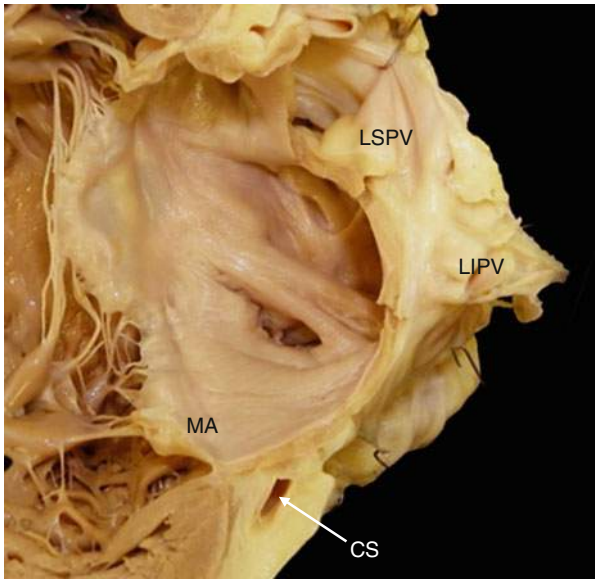

Fig. 7.12 Anatomical image showing the location of the mitral isthmus between the mitral annulus (*MA*) and the left inferior pulmonary vein (*LIPV*). The coronary sinus (*CS*) is also shown in close proximity to the MA

catheter is then positioned along the lateral mitral annulus with an A:V ratio of 1:2 at 4 o'clock in the LAO 30 view. In general a 4 mm irrigated catheter may be used with a power setting of 40 W at the annulus which can then be reduced to 30 W at the inferior pulmonary vein side. In order to move the catheter from the annulus which is anterior to the left inferior pulmonary vein which is posterior, clockwise rotation is applied to the ablation catheter. Following completion of the line pacing can be performed from either the distal coronary sinus or the left atrial appendage to confirm conduction.

If conduction persists then further mapping can be performed looking for early atrial signals during pacing from the left atrial appendage. If conduction persists despite this then ablation can be performed in the coronary sinus in the same location as the endocardial lesions with flexion towards the endocardial mitral isthmus lesions at 25 W. In order to prove block across the mitral isthmus line pacing can be performed from the left atrial appendage which is anterior to the line and the activation sequence examined in the coronary sinus catheter. Clockwise block is demonstrated by an activation from the proximal to the distal coronary sinus indicating counterclockwise activation around the mitral annulus. It is possible to electrically isolate the coronary sinus with resultant proximal to distal activation which may mimic isthmus block. Counterclockwise block is demonstrated by pacing from the distal coronary sinus which is posterior to the mitral isthmus line. Activation therefore occurs from the distal coronary sinus electrodes to proximal prior to activation of the left atrial appendage.

Additionally the ablation catheter can be moved along the mitral line during pacing from either the left atrial appendage or the distal coronary sinus looking for the presence of double potentials.

Chapter 8
Atrial Fibrillation

Benedict M. Glover and Pedro Brugada

Abstract AF is the most common sustained arrhythmia seen in clinical practice with an overall prevalence of 700–750 per 100,000 of the population in North America (Chugh et al. Circulation 129:837–47, 2014). As well as resulting in considerable adverse sequelae and an increase in hospitalizations there is a 5 fold increase in the risk of stroke associated with non-valvular AF (Wolf et al. Stroke 22:983–8, 1991) and by a factor of 17 in the presence of significant valvular heart disease (Fuster et al. Circulation 123:e269–367, 2011). The risk of AF increases markedly with older age affecting approximately 5 % of people over 65 years and 10 % of people age over 80 years (Miyasaka et al. Circulation 114:119–25, 2006).

Classification of AF

AF is classified as paroxysmal, persistent, longstanding persistent or permanent. **Paroxysmal AF is defined as two or more episodes of AF each of which terminate within seven days and commonly within 24 h. Persistent AF is sustained generally for greater than seven days** (or less if a cardioversion was performed in this time) and requires chemical or electrical cardioversion for termination of the arrhythmia. **Longstanding persistent refers to cases in which AF has been present for more than 1 year and previously may have been designated as being permanent**; **however**, **an electrical cardioversion or ablation strategy is being**

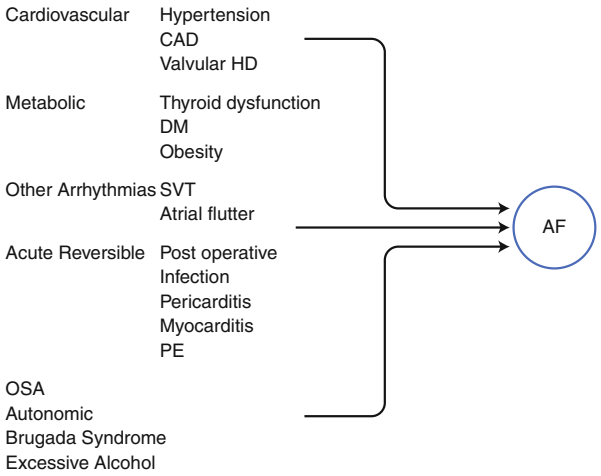

Fig. 8.1 Causes of Atrial Fibrillation. These can be divided into cardiovascular such as hypertension, coronary artery disease (*CAD*) and valvular heart disease (*HD*), metabolic, such as thyroid dysfunction, diabetes mellitus (*DM*) and obesity other arrhythmias such as SVT and atrial flutter and acute reversible causes such as post operative, infections, pericarditis, myocarditis and pulmonary embolism (*PE*). Other causes include OSA, autonomic, Brugada and excess alcohol

pursued and therefore sinus rhythm may be achieved. Permanent AF also continues for more than seven days and cannot be terminated anymore thus a rhythm control strategy has been unsuccessful or not appropriate.

Etiology

The incidence of AF is increased by other cardiovascular and metabolic conditions as well as several lifestyle factors. It may also be secondary to either acute reversible insults or to other arrhythmias.

The main cardiovascular causes of AF are shown on Fig. 8.1 and include hypertension, coronary artery disease and valvular heart disease. Metabolic causes of AF include thyroid dysfunction and diabetes mellitus while lifestyle risk factors include obesity, excessive alcohol and obstructive sleep apnea. AF is frequently seen in the acute setting in post-operative patients as well as those who have infection, or in association with pulmonary embolism, pericarditis and myocarditis. AF may also occur in association with other supraventricular arrhythmias, such as AV nodal re-entry tachycardia, AV re-entry tachycardia and atrial flutter. It is important to perform an EP study in patients who are being considered for an AF ablation and in particular young patients to ensure that there is not an underlying SVT. In patients who have undergone a successful ablation for typical atrial flutter the incidence of AF with 2.5 years post ablation is 50 % [1]. There has been some recent evidence to suggest that triggers from the pulmonary veins may also play a role in the initiation of typical atrial flutter [2]. Other less common causes of AF include autonomic, familial forms (particularly Brugada syndrome) and inflammatory.

Hypertension

The odds ratio for developing AF in association with hypertension is 1.5 for men and 1.4 for women [3]. Although this is not the highest risk for AF in an individual it is the most common cause of AF due to the high incidence of hypertension. Hypertension is often accompanied by left atrial remodeling due to pressure and volume overload as a result of a degree of left ventricular diastolic dysfunction. These changes may result in changes in the electrical properties of the myocytes in the pulmonary veins increasing the potential for them to act as triggers.

Effective treatment of hypertension in patients with AF has been shown to reduce all cause mortality (7.8 %), cardiovascular mortality (4.3 %), nonfatal myocardial infarction (5.3 %) and stroke (2.2 %), independent of blood pressure lowering effects [4]. Additionally effective treatment of hypertension has been shown to reduce the overall risk of developing AF by 28 % [5]. Data supporting this has been inconsistent however which may be a reflection of an the difficulty in optimal blood pressure control.

Coronary Artery Disease

AF is relatively common following an acute myocardial infarction (MI) occurring in approximately 15 % of patients. Early reperfusion as well as the use of beta blockers appears to have had an impact on lowering the incidence of AF post MI. AF may result from occlusion to or proximal to the sinus node artery as well as the hemodynamic changes associated with left ventricular dysfunction. It may also occur as a result of changes in autonomic tone, in particular an increase in adrenergic stimulation or as a result of pericarditis.

Of additional note some patients with AF present with chest pain, an elevated cardiac troponin and no evidence of significant obstructive coronary artery disease. It has been suggested that this may be a result of AT1 receptor mediated oxidative stress accompanied by a reduction in microvascular blood flow [6].

Valvular Heart Disease

The incidence of AF in patients with significant valvular heart disease is approximately 30 % and in patients with mitral stenosis is approximately 50 %. AF tends to be an early manifestation of mitral valve disease and tends to present later in aortic valve disease. Patients with significant mitral and aortic valve disease tend to have elevated left atrial pressure with left atrial dilatation and left atrial fibrosis which increases the possibility of re-entry circuits. The overall reduction in the incidence of rheumatic heart disease in the Western World has lead to a significant reduction in this as an overall contributor to AF.

Diabetes Mellitus

Diabetes mellitus (DM) has been shown to be associated with an increased incidence of AF and this risk increases with diabetes duration and poor glycemic control [7, 8]. DM may result in a disturbance of cardiac autonomic function, in particular an increase in sympathetic tone, which may result in the initiation of AF [9]. The cardiac autonomic dysfunction in patients with DM may also result in coronary microvascular dysfunction and diastolic dysfunction in diabetic subjects [10–12] which may increase the potential for AF. There may also be inflammatory changes responsible for both conditions. CRP and interleukin 6 have been shown to be elevated in atrial biopsies in patients with lone AF which may also be elevated in DM [13, 14].

Obesity and Obstructive Sleep Apnea (OSA)

Obesity is a significant public health concern with increasing prevalence. There is a 2.4 fold increased risk of AF in obese individuals versus those with a normal body mass index (BMI) [15]. Furthermore this risk appears to increase with increasing BMI with a 1.2 fold increase in those with a BMI of 25–30 kg/m^2 and a 2.3 fold increase in those with a BMI greater than 40 kg/m^2 [16].

There are several potential explanations for the increased risk of AF in patients who are overweight or obese. AF may occur as a direct result of obesity or in association with other risk factors, which are more commonly associated with an elevated BMI.

There is a direct association between left atrial dilatation and obesity with a 2.4 fold 10-year risk of left atrial enlargement on echocardiogram [17].

Left atrial pressure may also increase as a result of left ventricular hypertrophy and diastolic dysfunction which may occur in obesity and in particular in association with hypertension. It has also been shown that obese patients have slower left atrial conduction times and shorter effective refractory periods in the left atrium and pulmonary veins even when adjusting for confounding variables including hypertension, DM and OSA [18]. Overall these changes may result in atrial remodeling and atrial arrhythmias.

Atrial remodeling may be summarized as a heterogeneous process characterized by disruption of atrial electrical integrity. Delayed interatrial conduction reflected as a broad and biphasic P wave in the inferior leads has been shown to increase with BMI and waist circumference [19].

Increased pericardial fat occurs frequently with obesity, which may lead to a disturbance in atrial conduction. Variable expression of this adipose tissue may result in heterogeneity of atrial conduction. This has been shown to result in an increased risk of developing AF [20].

OSA may be found in up to 90 % of individuals with obesity [21]. If untreated, this is characterized by significant negative drops in intrathoracic pressure, intermittent hypercapnic hypoxia, and transient repeated wakening at the end of each episode.

These drops in intrathoracic pressure may result in alterations of the left atrial chamber dimensions which may in itself increase the risk of developing AF. Additionally, both hypercapnic hypoxia and frequent changes in sleep patterns may result in an increase in sympathetic tone. Overall these changes may result in an increase in the left atrial volume [22]. Effective treatment with CPAP in patients with OSA and no history of AF has been shown to reduce right and left atrial dimensions [23]. OSA has been shown to be independently associated with failure of catheter ablation for AF [24]. Ablation success rates are higher in patients with OSA who are treated with CPAP versus those not treated [24, 25].

Obesity and its associated conditions are potentially modifiable risk factors for AF. In general, it is currently recommended that individuals with a BMI greater than 25 with 1 associated comorbidity (diabetes, prediabetes, hypertension, dyslipidemia, elevated waist circumference) should be offered advice on dietary and lifestyle modification [25].

Aggressive risk factor modification in patients with a BMI greater than 27 and at least one other risk factor (hypertension, DM, OSA, smoking and excessive alcohol consumption) in patients awaiting catheter ablation has been shown to result in an improvement in patient's symptoms, with 30 % of patients avoiding the need for ablation [26]. In patients undergoing catheter ablation for symptomatic AF there was a significant improvement in symptoms post ablation as measured by the AF severity score [27]. AF-free survival after a single ablation procedure was 62 % for patients with risk-factor-modification and only 26 % for the control arm. After multiple ablations, AF-free survival increased to 87 % in the risk-factor-modification group versus 48 % in the control arm. Structural changes of the heart were also significantly better with left atrial volume and LV diastolic volume reduction.

Autonomic AF

An alteration in sympathetic activity may result in an increase in the potential for the initiation or maintenance of AF. This can occur either by direct effects on the action potential duration and refractory period of the cells in the pulmonary veins or left atrium or by structural changes.

An increase in adrenergic stimulation may result in an enhancement of focal automaticity which may act as a potential trigger for AF. Increased parasympathetic activation increases the action potential duration. However its contribution to AF may result from its ability to shorten the atrial effective refractory period by varying degrees throughout the left atrium, which may contribute to a heterogeneity of conduction properties [28].

Both vagally induced and adrenergic AF tend to occur in younger patients with no other obvious risk factors. Vagally-induced AF is much more common than adrenergic AF and tends to occur after a preceding sinus pause or sinus bradycardia. Vagally induced AF may be partially responsive to flecainide and disopyramide and frequently worsens with beta blockers. Adrenergic AF is often provoked by exercise

or increased emotional stress, and tends to be preceded by an increase in sinus rate. This type of AF responds well to beta-adrenoceptor blockade.

There is a suggestion that ganglionic plexi denervation may have a role in the treatment of AF. Indeed left atrial ablation may have some impact by its effects on the autonomic innervation of the heart. One of the main restrictions in ganglionic plexus denervation using an ablation catheter is the difficulty in optimal access to the nerves which are not easily ablated from the endocardium.

Familial AF

Approximately 5 % of cases of AF may have a genetic component [29]. This may be even higher in patients who develop AF at a younger age and those with no other obvious risk factors for AF. The risk of developing AF in an individual who has a parent with a history of AF is increased by a factor of 1.85 times that of the population [30]. Additionally an increased incidence of AF has been noted in long QT4, short QT and Brugada syndrome.

Several genetic mutations have been implicated in AF. A missense mutation in the KCNQ1 gene has been shown to result in an alteration of the activity of the voltage gated delayed potassium current (IKS) [31]. As well as several other mutations in the KCNQ1 gene upregulation mutations have been detected in the SHOX2, TBX3 and PITX2 genes.

Mutations have also been detected in the KCNN3 gene, which encodes calcium activated potassium channels that predominante in the atria [32].

Oral Anticoagulation

The issue of oral anticoagulation is one of the more complex issues in clinical cardiology. Most risk stratifying scores have been designed to be simple and easy to remember. Currently the most widely used risk scoring system is the CHA2DS2VASc, which is shown in Fig. 8.2. This was based on the CHADS2 score with a greater emphasis on age as well as the addition of vascular disease (prior MI or peripheral vascular disease), female gender and diabetes mellitus. It is generally recommended that oral anticoagulation should be considered in patients with a CHA2DS2VASc of greater than or equal to 2 (Class I Indication, Level of Evidence B) with either Coumadin or a direct oral anticoagulant. In patients with a CHA2DS2VASc score of greater than or equal to 1 oral anticoagulation, aspirin or no antithrombotic therapy can be considered (Class IIb Indication, Level of Evidence C). For patients with a CHA2DS2VASc of 0 no antithrombotic therapy is generally recommended. In general female gender in a patient with no other risk factor for stroke would not result in the institution of oral anticoagulation although this clearly has to be reviewed with increasing age. It should also be

Risk factor	Score	Recommendations
CCF1	1	
Hypertension2	1	0 No OAC
Age 75 years or more	2	
DM3	1	1 Consider OAC / Aspirin / nothing
Ischemic stroke / TIA / TE4	2	
Vascular disease 5	1	2 or greater OAC
Age 65-74 years	1	
Sex6	1	

1 Signs/symptoms of LV/RV/Biventricular dysfunction confirmed with objective testing
2 Resting SBP > 140 mmHg and/or DBP > 90 mmHg on 2 or more measurements or patients receiving antihypertensive medication
3 Fasting plasma glucose greater than or equal to 7.0mmol/L /126 mg/dL or treatment with oral hypoglycemic agent or insulin
4 Ischemic stroke is defined as a sudden focal neurological deficit diagnosed by a neurologist and found to be due to an ischemic orgin lasting greater than 24 hours
TIA is a sudden focal neurological deficit diagnosed by a neurologist and lasting less than 24 hours
5 Vascular disease is considered a prior MI/PVD/aortic plaque
6 Female gender with no other risk factors is not considered sufficient for commencing OAC

Fig. 8.2 Summarizing the CHA2DS2VASc Scoring system for Non-Valvular AF. *SBP* systolic blood pressure, *DBP* diastolic blood pressure, *TIA* transient ischemic attack, *TE* thromboembolism, *MI* myocardial infarction, *PVD* peripheral vascular disease

remembered that each individual risk factor does not confer an equal percentage risk for stroke.

Although CHA2DS2VASc is more sensitive for predicting low event rates in low risks patients it is only modestly effective in terms of its positive predictive value with an area under the receiver-operating characteristic curve of approximately 0.6 [33].

Additional factors which have been examined in order to help calculate the risk of stroke include the use of biomarkers as well as LAA morphology. Biomarkers such as NT-pro-BNP, von Willebrand levels, d-dimers and troponin have been studied. Although they appear to have some merit they have yet to be incorporated into the guidelines. LAA morphology appears to correlate to an extent with the risk of thrombo-embolism with a suggestion that an increase in trabeculations, number of bends and narrowness of the LAA orifice may also increase the risk of thrombus formation. Although this can be documented on TEE or CT widespread use is still not recommended for decision making regarding oral anticoagulation.

Vitamin K Antagonist

Warfarin acts by inhibiting the cyclic interconversion of vitamin K and vitamin K epoxide, thereby reducing the vitamin K-dependent clotting factors II, VII, IX and X. When compared with placebo adjusted dose warfarin maintaining an INR or 2.0–2.9 results in an absolute reduction in ischemic and hemorrhagic strokes of 2.7 % per year [34]. Warfarin has also been shown to be superior to aspirin in patients considered to be at an increased risk of stroke.

Several major limitations concerning warfarin exist. The time within the therapeutic range is often less than 75 % exposing patients to the risk of thrombo-embolism for significant periods of time. There are many interactions with other pharmacological agents as well as food and dose adjustments are frequently required. Despite this there is still a role for warfarin in clinical practice particularly in patients with valvular heart disease and AF. The non-vitamin K antagonist agents are contraindicated in the presence of valvular AF and also need to be used with extreme caution in the setting of renal impairment. There is also more clinical experience using warfarin combined with antiplatelet agents and there is also the ability to monitor the effect of the drug which may provide a reasonable indication of patient compliance. Warfarin is also relatively easily, albeit slowly, reversed with vitamin K.

Non-vitamin K Antagonist Oral Anticoagulation Therapy (OAC's)

These agents act by either directly suppressing thrombin or the conversion of prothrombin to thrombin by blocking the activated Xa factor. They have several theoretical advantages over warfarin such as a rapid onset and offset of action, reasonably predictable pharmacokinetics that do not require ongoing monitoring of anticoagulant and fewer interactions. It is important to monitor renal function particularly in patients where the baseline eGFR is below normal limits.

Direct Thrombin Inhibitors

Direct thrombin inhibitors bind to both soluble and fibrin-bound thrombin. The most commonly used in this group is the pro-drug dabigatran etexilate which was compared with warfarin in the RELY study. This prospective, randomized trial compared either 150 mg or 110 mg twice daily with warfarin (INR 2.0–3.0) for the prevention of stroke and systemic embolism in patients with non-valvular AF [35].

Dabigatran at a dose of 150 mg has been shown to be superior to warfarin with no significant difference in the primary safety endpoint of major bleeding. At a dose of 110 mg dabigatran was non-inferior to warfarin, with fewer major bleeds. The

incidence of intracranial haemorrhage and haemorrhagic stroke were lower with both doses of dabigatran.

Based on these results dabigatran etexilate has been approved by the Food and Drug Administration (FDA) at 150 mg twice daily with 75 mg twice daily in renal impairment. The European Medicines Association (EMA) has approved both the 110 mg twice daily and 150 mg twice daily in patients with non-valvular AF.

Factor Xa Inhibitors

The two major clinically available factor Xa inhibitors are rivaroxaban and apixiban.

Rivaroxaban has a plasma half life of 7–11 h with a flat dose response resulting in a once daily administration. Rivaroxaban was compared with warfarin for the prevention of stroke or systemic embolism among patients with nonvalvular AF who were at moderate-to-high risk for stroke in the Rocket AF Trial [36]. This double blind trial compared rivaroxaban 20 mg once daily (15 mg daily for those with an estimated creatinine clearance of 30–49 mL/min) with warfarin in 14,264 patients. Rivaroxaban was found to be non-inferior compared with warfarin for the primary endpoint of stroke and systemic embolism with a significant reduction in haemorrhagic stroke and intracranial haemorrhage. Rivaroxaban has a distinct advantage in being a once daily preparation. Additionally the ROCKET AF study enrolled older patients (mean age 73 years), with at least two risk factors (congestive heart failure, hypertension, stroke or TIA), higher mean values of CHADS2 score (3.5) and lower median values for therapeutic INR's compared to other trials which is more compatible with real life conditions.

Approximately one-third of active rivaroxaban is renally excreted and a dose reduction from 20 mg once daily to 15 mg once daily is recommended for patients with moderate to severe renal impairment with period monitoring of renal function. A sub-study of the ROCKET AF study showed this lower dose was safe and effective in patients with a creatinine clearance between 30 and 49 mL min^{-1}. Rivaroxaban has been approved by both the FDA and the EMA for stroke prevention in nonvalvular AF.

Apixaban has been shown to reduce the risk of stroke (predominantly through its effects on a reduction in hemorrhagic stroke) or systemic embolism, major bleeding and mortality in comparison with warfarin [37]. Additionally in patients for whom vitamin K antagonist therapy was considered unsuitable, apixaban compared with aspirin, reduced the risk of stroke or systemic embolism without a significant increase in the risk of major bleeding [38]. Apixaban has gained clinical approval with the FDA and EMA in patients with nonvalvular AF. Although the usual dose is 5 mg BiD this should be reduced to 2.5 mg BiD if 2 out of the following 3 criteria; age greater than or equal to 80 years, weight less than or equal to 60 kg or a serum creatinine greater than or equal to 133 mmol/L. The details associated with the major trials in the NOACs are summarized on Table 8.1.

Table 8.1 Showing a summary of randomized clinical trial data supporting NOAC's

Parameter	Rely	Rocket-AF	Averroes
Drug dose	Dabigatran etexilate 150 mg BID or 110 mg BID versus warfarin (INR 2.0–3.0)	Rivaroxaban 20 mg QD (15 mg QD in patients with creatinine clearance 30–49 ml/min) versus warfarin (INR 2.0–3.0)	Apixaban 5 mg BID versus Aspirin 81–315 mg OD
Study design	Randomized, open label	Randomized double-blind, double Dummy	Randomized, double-blind
Inclusion criteria	AF within 6 mths + 1 risk factor	AF within 6 mths +2 risk factors	AF within 6 mths + 1 risk factor
Number of patients	18,113	14,000	5,600
Mean age	71.5 years	73 years	70 years
Prior stroke/TIA	20 %	55 %	13.5 %
Mean CHADS2 score	2.1	3.5	2.1
Stroke and systemic embolism (percent/year)	1.71 % warfarin 1.54 % dabigatran 110 mg (p = 0.34) 1.11 % dabigatran 150 mg (p < 0.001)	2.42 % warfarin 2.12 % rivaroxaban (p = 0.117)	3.9 % aspirin 1.7 % apixaban (p < 0.001)
Major bleeding	3.57 % warfarin 2.87 % dabigatran 110 mg (p = 0.003) 3.32 % dabigatran 150 mg (p = 0.31)	3.45 % warfarin 3.6 % rivaroxaban (p = 0.576)	1.2 % aspirin 1.4 % apixaban (p = 0.33)
Intracranial haemorrhage rate (percent/year)	0.74 % warfarin 0.23 % dabigatran 110 mg (p < 0.001) 0.3 % dabigatran 150 mg (p < 0.001)	0.74 % warfarin 0.49 % rivaroxaban (p = 0.019)	0.3 % aspirin 0.4 % apixaban (p = 0.83)

HAS-BLED Score

This is a scoring system used to predict the 1 year risk of major bleeding defined as intracranial bleeding, hospitalization, blood transfusion or a drop in hemoglobin of greater than 2 g/L. The components of this scoring system are:

Hypertension: uncontrolled systolic blood pressure >160 mmHg

Abnormal renal or liver function: a serum creatinine greater than 200 mmol/L, need for long term dialysis or history of a renal transplant. Abnormal liver function is defined as an elevation of transaminases greater than 3 times the upper limit of normal or a history of chronic liver disease

Stroke

Bleeding

Labile INR: in the therapeutic range less than 60 % of the time
Elderly
Drugs or alcohol: the use of non-steroidal anti-inflammatory or antiplatelet agents

The maximum score is 9 with a score of greater than or equal to 3 indicative of a high bleeding risk where increased caution and regular review should be performed. It should not be used solely to exclude using oral anticoagulation but should be used to highlight patients at a higher risk of bleeding and should also be used to modify any controllable risk factor.

Catheter Ablation for AF

The concept of catheter ablation for the treatment of AF gained significant momentum when it was discovered that ectopic foci, which originate from sleeves of myocardium extending into the pulmonary veins may initiate AF [39]. This resulted in the concept that isolation of these foci by performing catheter ablation may reduce the likelihood of developing AF. Although the foci themselves were initially targeted this resulted in a high incidence of pulmonary vein stenosis and this has now be largely replaced with wide antral circumferential ablation (WACA). This technique has been shown to be associated with a lower incidence of recurrence of arrhythmias compared with segmental antral ablation [40]. This may be due to isolation of regions of the left atrial PV junction where micro re-entry may occur. Additionally WACA may have a greater effect on elimination of other non PV triggers in the posterior LA wall, debulk the left atrium and have a greater effect on autonomic denervation.

Pulmonary vein isolation (PVI) is currently considered the mainstream catheter approach for paroxysmal AF. It also is a very reasonable approach for the management of persistent AF with additional options to be considered. Some centers perform PVI in all patients with a history of persistent AF followed by an electrical cardioversion for the first ablation procedure. If the patient presents with further AF then either linear lesions, CFAE ablation or rotor ablation can be considered at that stage. Other centers perform more ablation for the first procedure although this may increase the potential for developing AT.

Risks of Catheter Ablation of AF

The risk of a significant complication associated with an AF ablation is approximately 2.9 % [41]. The most common complication is vascular (approximately 1 %) which is largely related to groin hematoma and occasionally femoral pseudoaneurysm formation. The risk of stroke and TIA is 0.6 %, cardiac tamponade (1 %) and clinically evident PV stenosis 0.5 %. The incidence of phrenic nerve palsy is approximately 0.4 % and although esophageal injury is common, atrio-oesophageal fistula is unusual occurring in 0.1 % of cases. The overall mortality is 0.06 %.

How to Perform a PVI

Patient Preparation

A PVI can be performed either with the patient under general anesthesia or with intravenous sedation and analgesia. There are several advantages to either strategy. General anesthesia often results in a quicker procedure with less patient discomfort and less patient movement. It may not always be available and some operators prefer sedation as there is more patient feedback during the procedure.

A TEE is performed in order to rule out a LAA thrombus particularly in patients who are in AF and have not been anticoagulated prior to the procedure. In most cases where the patient is receiving warfarin this can be continued throughout the procedure with an upper INR cut off of 3.5 above which the risk of bleeding is increased by a factor of 6 [42].

If the patient is receiving a non vitamin K antagonists OAC a decision must be made whether to stop the agent or not.

Some data suggests that uninterrupted dabigatran compared with uninterrupted warfarin is associated with an increased rick of bleeding and thrombo-embolic complications [43]. Dabigatran increases the effects of heparin often doubling the effects, an effect not seen to the same degree with rivaroxaban and apixaban [44]. It is therefore current practice to interrupt dabigatran prior to performing an AF ablation. The decision on when to hold dabigatran is dependent on the patient's renal function. In patients with normal renal function the drug may be held either the morning of the procedure or the evening prior but not for more than 24 h pre-procedure [45]. Dabigatran should be stopped earlier if renal function is reduced.

In patients with normal renal clearance, the best option may be drug suspension on the morning of the procedure, or the night before, but always <24 h before the procedure. A target ACT of greater than 350 s should be achieved during the procedure. Dabigatran can then be recommenced 3–4 h following removal of the sheaths [45]. The dosage of dabigatran following this should be based on renal function and the potentially risk of bleeding.

Recent data has shown that uninterrupted rivaroxaban therapy appears to be as efficacious as uninterrupted warfarin in preventing thrombo-embolic and bleeding complications in patients undergoing AF ablation [46]. If the decision if made to hold rivoroxaban for an AF ablation the dose on the morning of the procedure may be held. There is currently limited data regarding the use of apixaban in patients undergoing an AF ablation although it may seem reasonable to hold a dose the morning of or the evening before the procedure.

It is our practice to administer the final dose of the OAC 24 h prior to the ablation and perform a pre-procedure TEE. Heparin is then administered throughout the procedure and the OAC is recommenced 3 h following removal of the venous sheaths which are removed at the end of the case with no reversal of heparin.

If the patient is receiving a general anesthetic the TEE probe can be left in position in order to help facilitate the transseptal access and monitor for pericardial effusion.

Venous access is generally achieved via the femoral vein with two 8Fr sheaths and a 6Fr sheath. A decapolar is positioned in the coronary sinus to help with the transseptal puncture and may also be useful for mapping and pacing particularly if an AT develops during the procedure.

Two transseptal sheaths are then positioned over 0.032 wires into the superior vena cava and flushed with heparinized saline. Heparin is then administered at a dose of 100 iu/kg in order to achieve an ACT of greater than 300 s in patients who are either not on warfarin or have an INR less than 2.0 [47]. For patients who are receiving warfarin and have a therapeutic INR 75 iu/kg of heparin should be administered in order to achieve an ACT of greater than 300 s. ACT should be checked every 20 min and either further boluses or an infusion can be administered.

Transseptal Access

A posterior location in the fossa ovalis is chosen in order to facilitate access to all regions around the pulmonary veins. Although his can be performed under fluoroscopic guidance the addition of echocardiographic data is sometimes helpful particularly if the fossa is difficult to cross or is aneurysmal.

A range of sheaths and transseptal needles are available. A BRK1 needle often results in a good location and is useful in patients who have enlarged atria. If this is tenting the fossa without crossing then the flexion can be slightly reduced or a BRK or a Baylis needle can be considered. Transseptal access can generally be achieved using a combination of a PA, left lateral, RAO and LAO views. In general for PVI standard sheaths are sufficient although deflectable sheaths may help with contact and occasionally with access to superior to the right superior pulmonary vein. Deflectable sheaths may be useful for a linear lesion joining the mitral isthmus to the left inferior pulmonary vein. If a non standard sheath is to be switched to a deflectable sheath a 0.032 wire can be extended out to the left superior pulmonary vein for an over the wire switch.

Whatever choice of sheath it is very important that the side arms are flushed with heparinized saline in a closed circuit and that no air bubbles enter the system.

Anatomic Reconstruction of the Left Atrium

The anatomy of the LA is generally constructed using a multipolar circular catheter. This may merged with a pre-procedure CT. A CT may be helpful in determining the presence of aberrant pulmonary veins as well as the presence of variants such as common ostia. MRI of the LA can also be performed but is more time consuming. Either of these modalities can be merged with the electroanatomic image. CartoMerge (Biosense Webster) uses fiducial points taken from selected anatomical structures such as the pulmonary vein ostia. The image is then rotated in order to

compare the anatomic shells of both structures for comparison. If there is a difference between the two images further points can be taken on the electro anatomic map.

NavX Fusion (St Jude Medical) can also be used to integrate the electroanatomic map onto a baseline CT scan. Following acquisition of the anatomic shell this system utilizes a field scaling algorithm which adjusts for the non-linearity of the geometry taking into account the measured inter-electrode spacing for all the locations within the geometry. Four fiducial points are then taken on the CT and the electroanatomic map and secondary fusion is used to reduce mismatch between the two images [48].

Although these systems may be helpful the LA dimensions vary with rhythm status and are also dependent on the intravascular volume. There is overall no convincing data to suggest that image integration increases success or reduces complications but may reduce fluoroscopy times.

Ablation Technique

Following anatomic reconstruction of the LA a circular mapping catheter is positioned within the ostia in one of the pulmonary veins where is should record nearfield pulmonary vein potentials and farfield left atrial potentials. If a contact force catheter is being used for ablation then this is positioned in the middle of the left atrium where there is no contact and a zero is set on the catheter.

The catheter should then be positioned so that it is on the atrial side of the pulmonary vein ostia. The ostia can be difficult to precisely locate on fluoroscopy or even on an electroanatomic map and there is an overlap between left atrial myocytes extending into the pulmonary veins and venous tissue extending into the left atrium. If the demarcation is unclear the ablation catheter can be placed on the venous side of the ostia while pacing and capturing the pulmonary veins. The point at which pulmonary vein capture no longer occurs is a reasonable estimate of the ostia.

Point by point ablation is generally performed using a 3.5–4.0 mm irrigated catheter. Power is delivered at 30–35 W anterior to the pulmonary veins and 25–30 W along the posterior wall in order to limit delivery of energy to the esophagus and branches of the vagus nerve. A target temperature of less than 40 °C and irrigation at 17 ml/min are set. If contact force is used then a minimum of 10 g of force should be aimed for. The catheter is generally moved every 30–60 s.

Certain regions around the pulmonary veins may be technically more challenging than others and require different catheter manipulations. The Coumadin ridge between the left pulmonary veins and the left atrial appendage is an infolding of the lateral atrial wall is shown in Fig. 8.3. It is at its narrowest at the border of the left superior pulmonary vein measuring 2.2–6.3 mm to its broadest aspect at the boundary of the left inferior pulmonary vein measuring 6.2–12.3 mm [49]. It is at its thickest at the anterosuperior region.

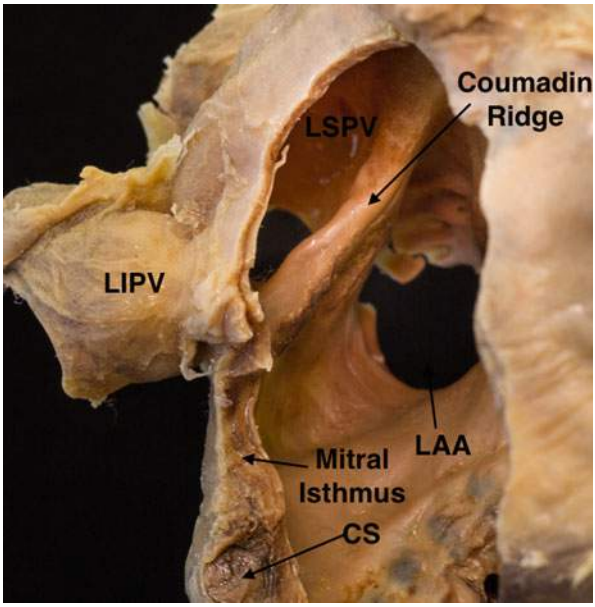

Fig. 8.3 The Coumadin ridge is seen between the left superior pulmonary vein (*LSPV*), the left inferior pulmonary vein (*LIPV*) and the left atrial appendage (*LAA*). Between the LIPV and the mitral annulus (*MA*) is the mitral. Also seen in this image is the coronary sinus (*CS*)

In order to ablate along the Coumadin ridge the ablation catheter can be withdrawn from the left superior pulmonary vein with counterclockwise rotation so that the catheter is moving anterior in the direction of the LAA. This should maximize contact with this region. Excess counterclockwise torque results in the catheter moving into the LAA and this often needs to be counteracted with clockwise rotation. Given the significant autonomic innervation of the Coumadin ridge ablation in this region commonly results in a slowing of the sinus rate.

Flexion and extension of the ablation catheter is required for ablation inferior and superior to the left sided PV's. Ablation starting on the roof superior to the left superior pulmonary vein often results in separation of local pulmonary vein signals and LAA farfield signals.

Ablation superior and inferior to the right sided PV's can be performed often with a combination of rotation with flexion and extension of the catheter. Occasionally a deflectable sheath may be useful in these regions although a bidirectional catheter used through a standard sheath is in general suitable to reach all regions. When ablation is performed inferior to the right inferior pulmonary vein in a small left atrium it is important to flex with an acute angle in order to minimize the risk of losing transseptal access.

Ablation may be required in the carina between the pulmonary veins despite WACA being performed. This may be explained by endocardial to epicardial connections in this region which may result in continued conduction. Additionally con-

nections exist between ipsilateral PV's resulting in several isthmus which may be an important consideration when performing PVI and may in part explain why segmental ablation was previously shown to have limited efficacy [50].

Pulmonary Vein Potentials and Farfield Signals

Electrograms recorded from the ostia of the pulmonary veins show an initial non circumferential lower amplitude atrial signal followed by an isoelectric period followed by sharp pulmonary vein potentials [51]. Depending on the overlap between the left atrium and the surrounding structures as well as the orientation of the mapping catheter there is a variable delay between the farfield electrogram and the pulmonary vein potentials. An example of this is shown in Fig. 8.4 in which the first component is farfield left atrial followed by an isoelectric line followed by a PVP which is a sharp high frequency signal.

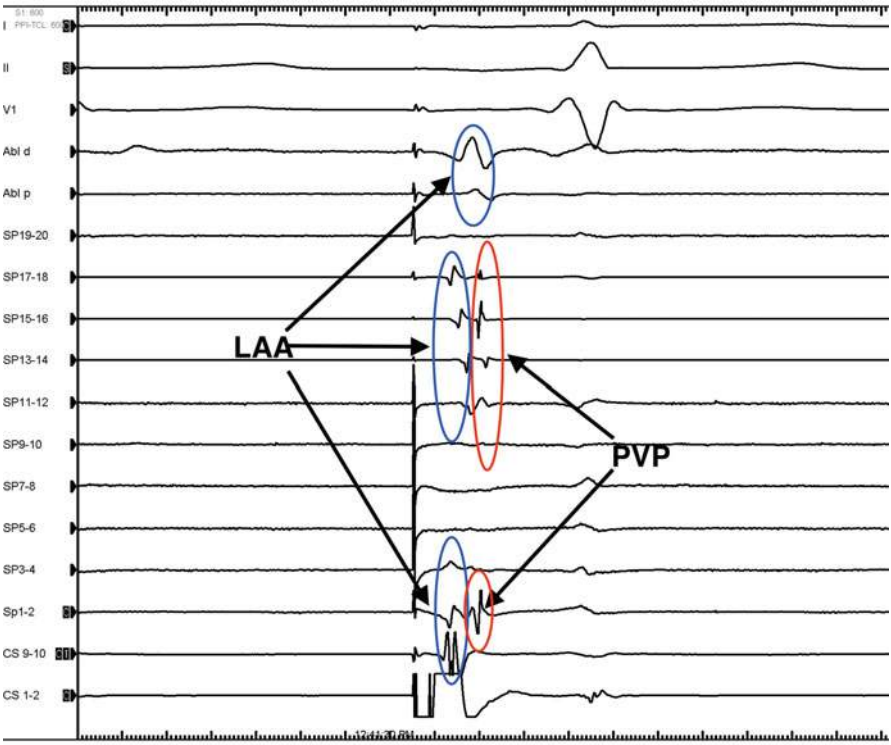

Fig. 8.4 The circular catheter (SP 1–20) is in the left superior pulmonary vein. Pacing is performed from the distal coronary sinus (CS 1–2). The first deflection is farfield from the left atrial appendage (*circled in blue*) followed by an isoelectric line followed by a sharp pulmonary vein potential (*circles in red*)

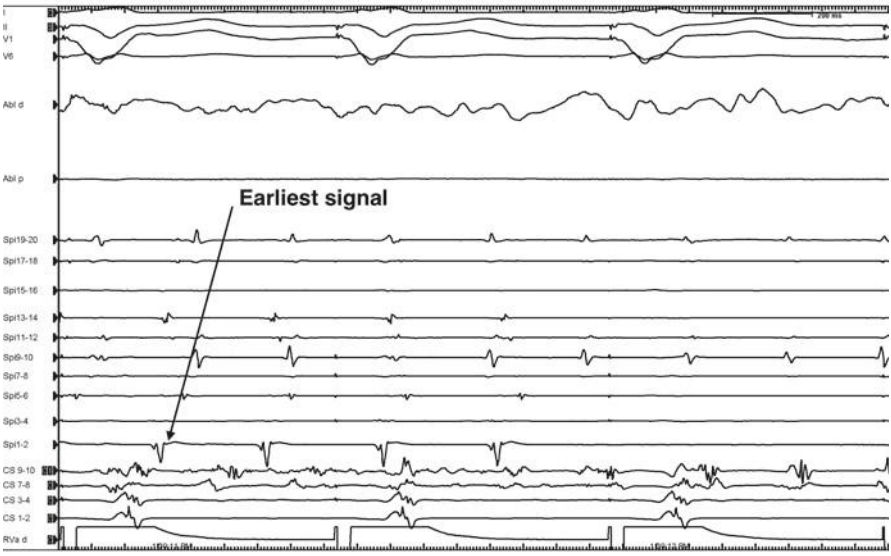

Fig. 8.5 Isolation of the LSPV. The circular catheter is positioned in the LSPV. The earliest nearfield activation is recorded on Spi poles 1–2 followed by 13–14. These poles are almost overlapping and are located along the lower junction between the LSPV and the LAA along the ridge (near to where the ablation catheter is positioned). Ablation in this region results in isolation of the vein with only LAA farfield recorded on the circular catheter. (CS 9 10 is in the proximal coronary sinus and CS 1 2 is in the distal CS). Ventricular pacing from the RV apex is performed as the patient became bradycardic during RF ablation

The LAA is anterior to the left superior pulmonary vein. As a result sharp pulmonary vein potentials can often be merged within LAA signals. In order to help differentiate CS pacing can be used to separate LAA signals from PV potentials as shown in Fig. 8.4. Additionally direct pacing may be performed from the LAA. For the left superior and inferior pulmonary veins pacing from the distal coronary sinus or left atrial appendage can be performed in order to increase the isoelectric line between the farfield and nearfield signals. Although pacing from the distal coronary sinus is reasonably simple it is somewhat dependent on the variable connections between the coronary sinus and the left atrium. Left ventricular farfield may also be recorded in the left inferior pulmonary vein.

This cannot be performed if the patient is in AF and differentiation of farfield LAA signals from local PV potentials can be somewhat more complex. An example of isolation of the LSPV during AF is shown in Fig. 8.5. In this example the circular catheter is positioned in the LSPV during ablation along the ridge between the LAA and the vein. The earliest activation is recorded on poles 13–14 where ablation is performed. This results in isolation of the vein with farfield LAA potentials being recorded on poles 9–10, 11–12 and 19–20 which are all in anterior locations. Another example of isolation of the RSPV is shown in Fig. 8.6. As ablation is performed local PVP's in the vein slow considerably and then disappear with only farfield atrial activation recorded.

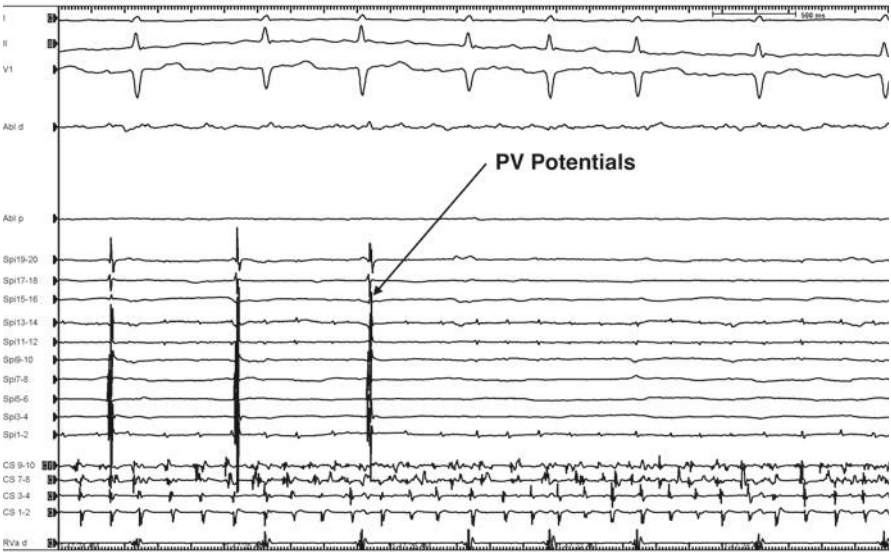

Fig. 8.6 Loss of local PV potentials during isolation of the RSPV. These signals are slowed considerably during ablation and following further ablation only farfield atrial signals are detected. The spiral (Spi) catheter is located in the RSPV (CS 9 10 is positioned in the proximal coronary sinus and CS 1 2 is located in the distal CS)

Fig. 8.7 Anatomic specimen showing a posterior view of the right superior pulmonary vein (*RSPV*) and right inferior pulmonary vein (*RIPV*). The superior vena cava (*SVC*) is anterior and close to both of these structures and farfield electrical activity from the SVC may be detected when mapping these veins

As shown in the anatomic image in Fig. 8.7 the superior vena cava is anterior to the right superior pulmonary vein. In order to differentiate superior vena cava potentials from pulmonary vein potentials the signal can be measured relative to the surface p wave. As the superior vena cava is so close to the sinus node signals will be very early if originating from the superior vena cava. If this is within 30 ms of the onset of the p wave it is likely to reflect superior vena cava activity. There is generally no significant farfield recorded in the right inferior PV. The PV potentials recorded on the circular catheter have slowed considerably during ablation. Further ablation results in loss of PV potentials with only farfield atrial signals.

Fig. 8.8 2:1 conduction from the left atrium to the left superior pulmonary vein. A potential is recorded in the vein after every second atrial electrogram. This signified continued conduction in the posterior region of the LSPV (SP 3–4) which required further ablation for isolation of the vein

Confirming Pulmonary Vein Isolation

PVI may be confirmed by proving bidirectional block with or without the administration of intravenous adenosine as well as pacing along the ablation line around the pulmonary veins. Of note, **entrance block without exit block may occur in up to 40 % of the patients** [52].

Entrance block may be observed either during normal sinus rhythm or with atrial pacing during sinus rhythm. The circular catheter is positioned in the PV antra just distal to the line of ablation. The most important principle is to distinguish between PV potentials and LA or RA signals detected as farfield on the circular catheter. Although PV potentials are sharp and of a much higher frequency than farfield atrial potentials they may be superimposed. Pacing the structure or close to the structure where the atrial signals are originating from should result in these signals becoming earlier if they are originating from that structure. For potentials coming from the LAA either the LAA can be paced directly or the distal CS if the catheter is positioned appropriately. An example of 2:1 conduction from the left atrium to the LSPV seen in Fig. 8.8 in which a potential with the vein is recorded after every second atrial electrogram. This represents slow conduction with conduction through SP 3–4 which was positioned posterior to the LSPV. Ablation in this region resulted in isolation of the vein.

In order to prove exit block the ablation catheter can be positioned in the same pulmonary vein as the circular mapping catheter. Although pacing can be performed from either the ablation catheter alone or the circular catheter alone it is often easier

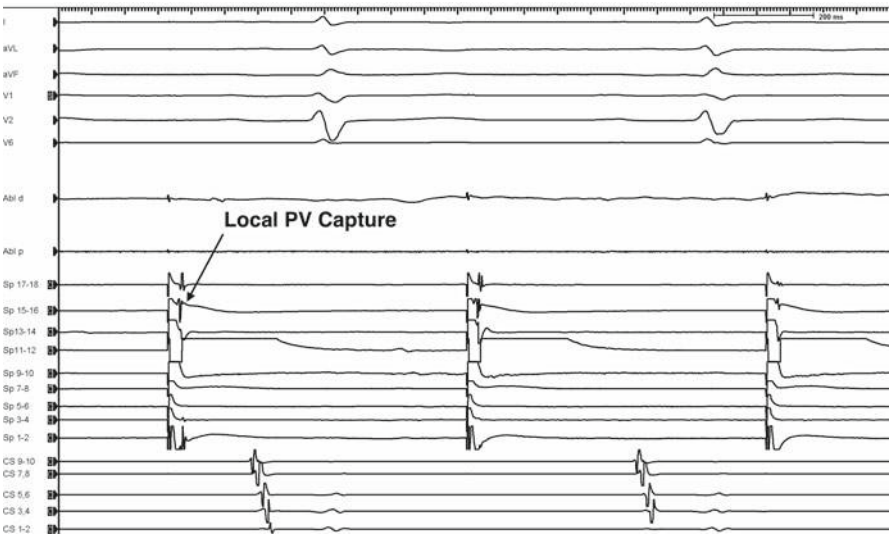

Fig. 8.9 Circular catheter (SP 1–18) in the right superior pulmonary vein with pacing from poles 15–16 showing local capture with sharp local PV potentials which do not capture the left atrium (CS 9 10 is located in the proximal coronary sinus while CS 1 2 is located in the distal coronary sinus)

to discern pulmonary vein potentials from a separate catheter which has closely spaced poles without superimposed pacing arterfact. Pacing can be performed using a decremental output until there is only pulmonary vein capture. This avoids capture of adjacent structures which may mimic intact conduction. Lack of conduction from the pulmonary veins to the left atrium proves that the ablation line is resulting in conduction block. An example of this is shown in Fig. 8.9.

Although the presence of dissociated PV potentials is a useful indicator of exit block conduction may still be present in 10 % of patients who display these [53]. An example of dissociated potentials from the RIPV is shown in Fig. 8.10. Pacing is performed from the high right atrium (HRA). Farfield atrial potentials are seen on the circular catheter with intermittent PV potentials which are not conducted to the atrium.

An additional useful technique to help prove an intact line around the pulmonary veins is to assess for unexcitability to pacing. Following ablation the catheter is positioned along the line during sinus rhythm at an output of 10 mA and a pulse width of 2 ms [54]. If lack of local capture occurs the catheter is moved a further 5 mm along the line and pacing repeated. If local capture occurred then further ablation was performed in this region and pacing performed at the same output.

The administration of intravenous adenosine appears to be of some use in assessing for dormant conduction following isolation of the PV's due to hyperpolarization of myocytes which have been acutely ablated. This can be administered after a period of monitoring post ablation and further ablation performed if there is any evidence of dormant conduction. An example of this is shown in Fig. 8.11.

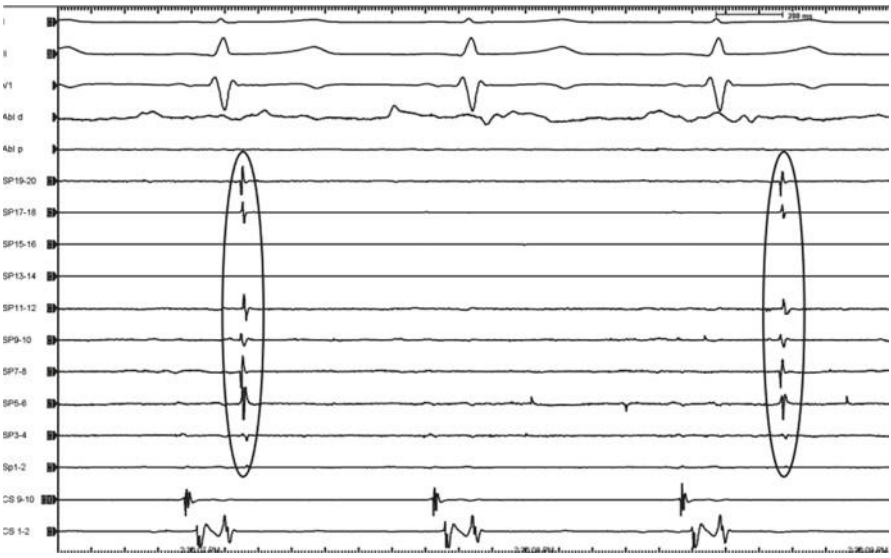

Fig. 8.10 Dissociated PV potentials (*circled*) recorded on a circular catheter (Sp 1–20) positioned in the right superior pulmonary vein (RSPV). Pulmonary vein potentials are seen which do not conduct into the left atrium. The ablation catheter is positioned in the RSPV. CS 9–10 is in the proximal CS while CS 1–2 is in the distal CS

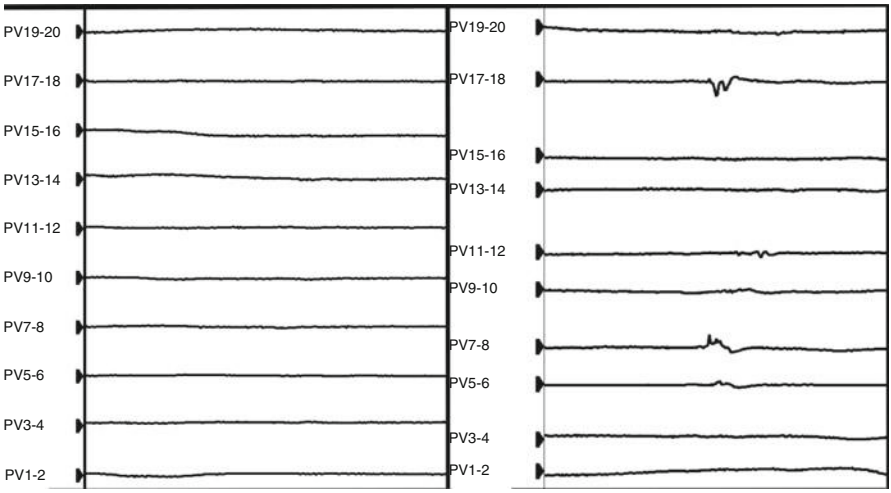

Fig. 8.11 The circular catheter (PV 1–20) is in the right superior pulmonary vein. The image on the right shows the potentials recorded following ablation and before the administration of adenosine. The pulmonary vein appears to be isolated. The image on the right is recorded following the administration of adenosine. This shows early activation in PV 7–8 followed by 5–6, 17–18, 9–10 and 11–12. This region was anterior to the right superior pulmonary vein at the level of the carina. Further ablation was delivered here and the vein was retested with adenosine and found to be isolated

Assessing for Non PV Triggers

Non pulmonary vein triggers may contribute to AF in some cases and are worth looking for particularly in redo ablations where the pulmonary veins have remained isolated. As shown in Fig. 8.12 potential locations include the superior vena cava, coronary sinus, crista terminalis, fossa ovalis, ligament of Marshall and left atrial appendage.

In order to map for non pulmonary vein triggers a multipolar catheter is positioned in the coronary sinus and another along the posterolareral right atrium extending into the superior vena cava. Intravenous isoprenaline is administered in incremental doses from 3 to 20 microgrammes per minute. If AF is not inducible decremental atrial pacing can be performed. Using the earliest sites of activation focal ablation can be performed and further triggers can then be mapped. It may be that given the increasing width of WACA that many triggers may be incorporated into the original lesions.

Cryoablation

Cryoablation utilizes a system (Arctic Front Cardiac CryoAblation, Medtronic, Inc) which pumps the refrigerant N20 into an inflatable balloon as shown in Fig. 8.13. This is positioned at the PV orifice. Contrast is injected into the PV in order to

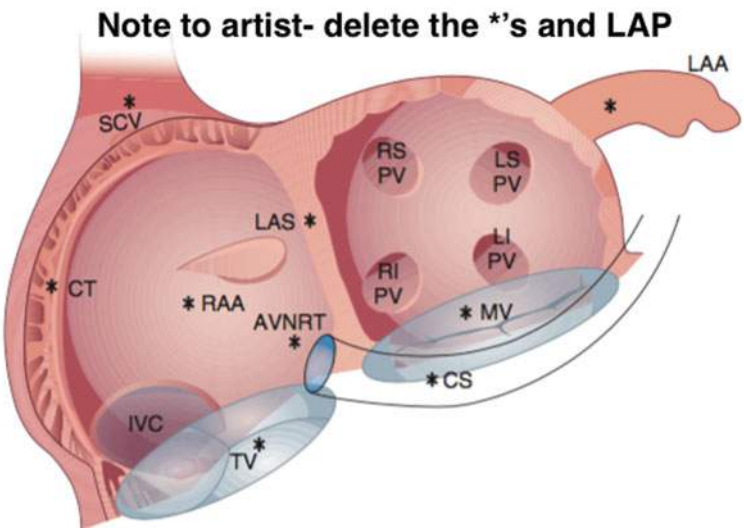

Fig. 8.12 Potential locations of non-pulmonary venous triggers (*RSPV* right superior pulmonary vein, *RIPV* right inferior pulmonary vein, *LSPV* left superior pulmonary vein, *LIPV* left inferior pulmonary vein, *MV* mitral valve, *CS* coronary sinus, *LAA* left atrial appendage, *LAS* left anterior septum, *RAA* right atrial appendage, *AVNRT* AV nodal re-entry tachycardia, *TV* tricuspid valve, *SVC* superior vena cava, *IVC* inferior vena cava)

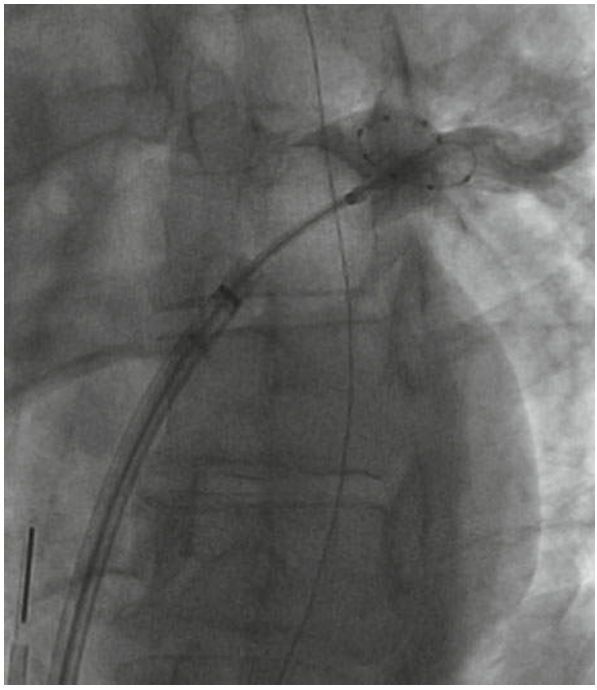

Fig. 8.13 Showing the new generation Cryoballoon used for antral pulmonary vein isolation. On this fluoroscopic image the cryoballoon is positioned in the left superior pulmonary vein (© Medtronic plc 2015)

assess for good contact and applications are generally performed over a period of 4 min. A circular catheter assesses for electrical isolation of the PV's and further applications are performed if required. This procedure generally requires a single trans septal access with a 15 Fr sheath. The balloon is advanced over a guidewire and positioned at the PV ostia. The balloon diameter is available in either 23 or 28 mm. The size can be determined on CT or ICE. Cryoablation has been shown to be non-inferior to point by point RF ablation in terms of freedom from AF and an absence of persistent complications [55]. The second generation cryoballoon has an inner mapping guidewire and an increased number of emission ports.

Hybrid Ablation of AF

Surgical ablation for AF has evolved from the Cox Maze procedure to a minimally invasive epicardial approach. These can be used to deliver RF around the PV antra as well as create a roof and floor line resulting in a posterior box lesion. Although this may be moderately effective in cases of paroxysmal AF freedom from AF for cases of persistent AF is relatively low. As a result of this a hybrid approach has been developed combining endocardial and epicardial ablation. Regions which cannot be easily reached from the epicardial approach can be ablated endocardially such as the CTI and mitral isthmus. Transmural lesions can be created and lines of

block can be assessed and any gaps completed. Although this can be performed at the same time it is often considered reasonable to delay endocardial ablation for several months in order to assess conduction block after a period of time. This may be a useful option in patients with persistent AF and dilated atria.

Ablation of Persistent AF

Ablation strategies in persistent AF are imperfect. Several techniques have been developed for ablation for persistent AF. Linear lesions may be performed until sinus rhythm is restored or until an electrical cardioversion is performed and the lines checked for conduction block. CFAE ablation may be performed in the left and right atria and rotors may be mapped either invasively or non-invasively and selectively targeted.

Linear Lesions

Following isolation of the pulmonary veins linear lesions can be performed. The most common of these involve a linear lesion along the left atrial roof joining the right superior pulmonary vein to the left superior pulmonary vein. A mitral isthmus line may also be performed although it may be difficult to achieve successful and permanent block as the wall may be relatively thick and may require epicardial ablation via the coronary sinus (at a lower power). Rather than performing linear lesions in all cases of AF, these are often performed in cases where the patient develops an atrial flutter either during the ablation or has a documented history of an atrial flutter which is then induced. In such cases the CTI is often mapped first followed by the pulmonary veins. If these are silent then entrainment in certain anatomic locations can then be performed as well as mapping of local signals. The most common locations to map are the mitral annulus and the LA roof as the majority of macro re-entry atrial flutters involve these regions. If there is a significant variability in the tachycardia cycle length (greater than 15 %) then the mechanism is more likely to represent a focal AT. In our experience both a focal AT and a macro re-entry atrial flutter may have a tachycardia cycle length less than 15 % and therefore this is not such as good discriminator.

Roof Dependent Left Atrial Flutter

In order to map roof dependent left atrial flutter the catheter is positioned anterior to the roof and then more inferiorly close to the anterior mitral annulus. This is repeated by positioning the ablation catheter along the roof in the posterior direction and then towards the coronary sinus which generally marks the general direction of the posterior mitral annulus. If the activation is in the reverse direction i.e. earlier inferior

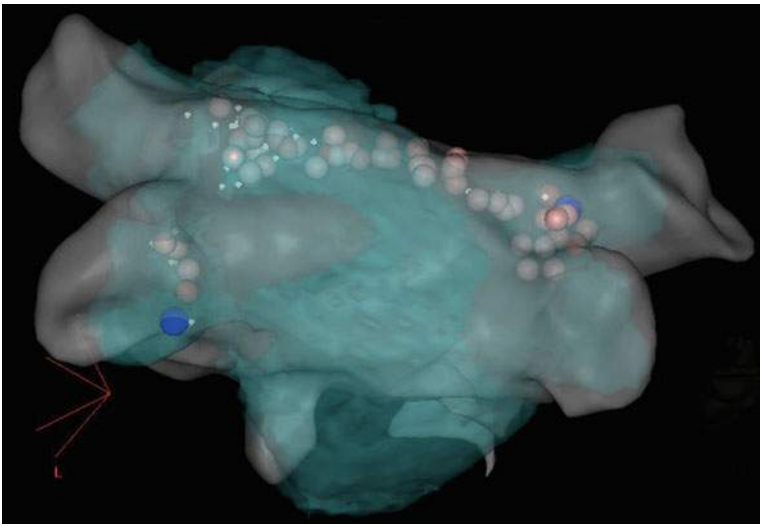

Fig. 8.14 Electroanatomic map showing a linear lesion joining the left superior pulmonary vein to the right superior pulmonary vein. This resulted in termination of the macro re-entrant atrial flutter. Further pacing demonstrated block across this line

than superior on the anterior wall and earlier superior to inferior on the posterior wall or vice versa then this is likely to be a roof dependent atrial flutter. If entrainment is performed in the anterior and posterior regions of the roof then a PPI-TCL of less than 30 ms further helps to confirm roof dependent atrial flutter. In the setting of a prior roof line or PVI with WACA mapping of fractionated potentials in the region of the roof is also helpful.

A roof line connecting the LSPV and the RSPV should be performed in the setting of a macro re-entry atrial tachycardia circulating around the PV's and involving the roof. In order to perform this the sheath is directed towards the right superior pulmonary vein while the catheter is flexed over to the left superior PV (Fig. 8.13). Using 30–35 W the catheter flexion can then be slowly released staying at each point for approximately 30–60 s. A superior and a PA view help to ensure that the line is performed along the roof rather than the posterior wall. In order to evaluate the roof line the LAA is paced during sinus rhythm. Roof line block is demonstrated by the presence of double potentials along the line during pacing as well as caudocranial activation of the posterior wall (Fig. 8.14).

Mitral Isthmus Dependent Atrial Flutter

This is a relatively common cause of post PVI atrial arrhythmias and generally occurs as a result of slow conduction inferior to the LIPV from a prior mitral isthmus ablation or PVI. In this arrhythmia CS activation is either proximal to distal or distal to proximal. It is useful to use the ablation catheter to map the anterior mitral

annulus. If CS activation is proximal to distal then anterior activation should be from lateral to septal. If the CS activation is distal to proximal then the anterior mitral annular activation should be from septal to lateral as shown in Fig. 8.15.

A posterior mitral isthmus line may be performed which connects the LIPV to the posterior mitral annulus close to the coronary sinus. A deflectable sheath is used and the ablation catheter is positioned at the ventricular side of the lateral mitral annulus with an AV ratio of either 1:1 or 2:1 [56].

During proximal CS pacing the catheter and sheath are then rotated clockwise towards the left inferior PV with delivery at 30 W for 90–120 s applied at each location. The catheter is moved whenever there is splitting of the local electrograms. The mitral isthmus varies in thickness along its length being thinner at the annular end and thicker at the medial end.

In order to prove block for a posterior mitral isthmus line pacing is performed from the CS and activation is measured in the LAA. Normally pacing from the distal CS should result in a shorter conduction time to the LAA than pacing from a less distal pole. In the event of posterior mitral isthmus block the more distal location will take longer to travel to the LAA. The presence of double potentials along the entire ablation line with coronary sinus pacing is also a useful endpoint.

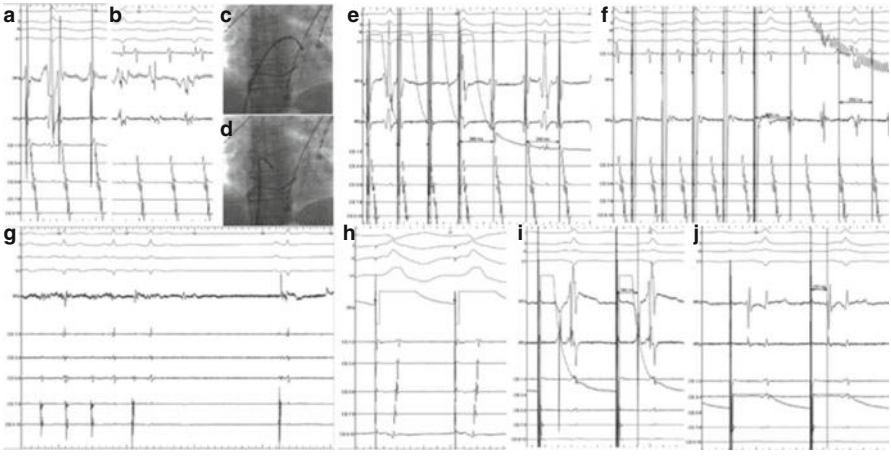

Fig. 8.15 Mitral isthmus dependent atrial flutter in a patient with a prior PVI. In panel **a**, the activation of the coronary sinus can be seen to be distal to proximal. The mapping catheter is anterolateral. As the mapping catheter is moved along the anterior wall to the septum in panel **b**, the direction of activation is clearly septal to lateral. This is compatible with perimitral flutter. Panels (**c**, **d**) demonstrate the catheter positions in panels (**a**, **b**), respectively, in an anteroposterior view. Entrainment maneuvers are performed from the distal CS (panel **e**) and septally, on the mitral annulus (panel **f**), with a return cycle length on both occasions being within 20 ms. A mitral line from the lateral mitral annulus to the left inferior pulmonary vein is performed, resulting in termination of the tachycardia (panel **g**). The completeness of the line is now checked with pacing from the line (panel **h**) demonstrating proximal to distal activation of the coronary sinus and a longer delay from close to the line (panel **i**) than distally to the line (panel **j**), confirming bidirectional block (Courtesy of Weerasooriya et al. [62], Wiley Brothers)

If block is not achieved then the line should be remapped and ablated further. In some cases ablation has to be performed at 20 W from the coronary sinus in order to block epicardial activation. An alternative approach is to perform an anterior mitral isthmus line joining the anterior mitral annulus to the LSPV.

CFAE Mapping and Ablation

CFAE's are defined as local electrograms which are fractionated with at least two components and with cycle lengths less than 120 msec recorded during AF and lasting for at least 10 s [57]. These are frequently recorded during AF within the regions of the LA close to the pulmonary vein antral regions and therefore may be ablated and electrically isolated during a pulmonary vein isolation.

In persistent atrial fibrillation CFAE's may be located anywhere within the left and right atrium with a potential propensity for the septum, inferoposterior wall of the LA and the LAA.

There are various theories as to what CFAE's actually represent with suggestions such as anchor points in rotors, regions of conduction slowing or autonomic activation. The long term results of CFAE ablation are not impressive and certainly this does not appear to represent a very effective strategy for the treatment of persistent AF.

Rotor Mapping

A rotor is defined as an unexcited core termed a phase singularity resulting in reverberations which radiate at very high velocity into the surrounding tissue [58]. Phase singularities are surrounded by different phases of the cardiac action potential and may be considered useful targets for ablation as they may be considered regions of tissue which can support rotors. They may occur on the endocardium, mid myocardium or epicardium or indeed span all layers. The theory is that following initiation of atrial fibrillation from pulmonary vein and non pulmonary vein sources rotors result in maintenance of atrial fibrillation.

Rotors differ from re-entry circuits in several ways. In a rotor the core is the active component with secondary spiral activity. The rotor core is functional and does not appear to be related to a detectable structural obstacle. Rotors are not stationary and may move over a considerable area [59]. Spiral waves also collide with each other altering the overall activation pattern. Additionally there does not appear to be a close correlation between rotors and CFAE's [59].

Some of these features actually make mapping of rotors very complex. Rotor activation is complex, can change during the mapping process and may involve different the endocardium, myocardium and epicardium. There are currently two systems which may be used for mapping rotors. These involve either invasive mapping using a multi-electrode basket catheter called the Focal Impulse and Rotor Modulation system and a non invasive multi electrode vest which is superimposed on a cardiac CT.

Focal Impulse and Rotor Modulation of Atrial Fibrillation

This system uses a 64 electrode basket with eight splines which is positioned in either the right, left or both atria as shown in Fig. 8.16. If the patient is in atrial fibrillation the unipolar electrograms are recorded and exported for analysis. If the patient is in sinus rhythm atrial fibrillation is induced with rapid atrial pacing and the signals are then recorded and analyzed after 10 min of sustained atrial fibrillation. It is extremely important that there is excellent electrode contact. The correct size of basket should be chosen and this can be difficult in large atria. Catheter orientation should be optimized on fluoroscopy and with the aid of a 3 dimensional mapping system in order to record vital areas of the left atrium including the pulmonary veins and the left atrial appendage as well as septal, roof, anterior and posterior activity.

The signals are then processed using RhythmView™ (Topera Inc.). This system is based on restitution monophasic action potential data acquired during rapid atrial pacing and atrial fibrillation. This displays the activation signals on a 2 dimensional image where the operator can then visualize potential rotors or focal sources. The image of each atria is opened so that for the right atrium the tricuspid annulus is inferior with the septal component to the right of the image and the lateral component to the left. For the left atrium the mitral annulus is at the bottom of the image

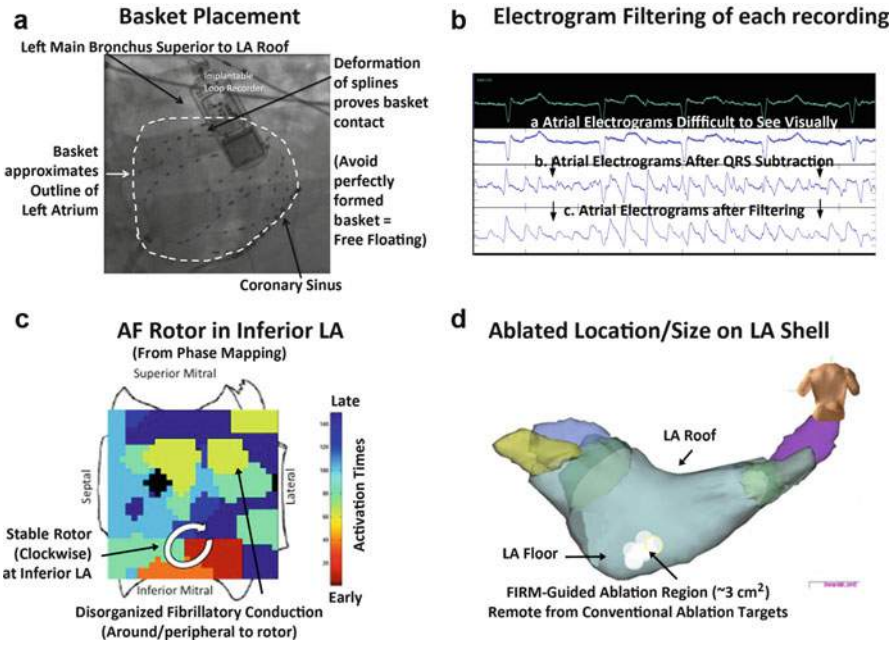

Fig. 8.16 Approach to FIRM (Focal Impulse and Rotor Mapping) guided ablation of atrial fibrillation (Courtesy of Dr Sanjiv Narayen)

and is divided. The electrodes of interest where a rotor core is felt to exist can then be referenced off an electroanatomic system and ablation can then be performed.

It has been shown that focal sources and rotors may be recorded in almost all patients with atrial fibrillation. Approximately one third of these can be recorded in the right atrium [60] and more than one half of all rotors are recorded outside of the regions where a wide area circumferential ablation would be performed [61]. Results suggest that the addition of ablation of rotors using this technique increases the success when compared with pulmonary vein isolation alone.

A. **Baskets placed in left atrium** (**shown**) and also in right atrium to map both chambers sequentially. Good positioning results in deformation of the highly compliant basket, proving electrode contact, and splines that approximate the LA roof and floor. In contrast, a spherical shape when deployed indicates an undersized basket with poor contact.
B. **Electrogram filtering** using well-established methods enables detection of sometimes difficult to visually identify atrial signals.
C. **Rotor during human AF in left atrium**, revealed by spatial phase mapping of filtered atrial electrograms, depicted as clockwise 'snapshot' (isochrone) where early and late activation meet, surrounded by fibrillatory disorganization. Phase mapping is used since activation mapping during of dynamically changing activation in AF is challenging. Intraprocedurally, diagnosis is actually made from animated 'FIRM movies' which better convey rotor precession and their dynamic interaction with the fibrillatory milieu.
D. **FIRM-guided ablation zone**, in inferior left atrium guided by map, typically of $\approx$3 cm^2 areas.

Non-invasive Multi Electrode Mapping

Using this technique a 252 electrode vest (CardioInsight, © Medtronic plc 2015) is applied to the patient during AF. This is used to record unipolar surface potentials. Anatomic data is then acquired by performing a noncontrast cardiac CT with the vest in place so that each electrode position can be calculated relative to the cardiac chambers. The system then performs a calculation in order to calculate and display electrical data on the surface of the heart from the surface unipolar electrograms. Activation sequences are then calculated by looking at the most negative dV/dT. This can then be displayed on a 3 dimensional reconstruction of the right and left atria using colors to animate various phases of depolarization and repolarization as shown in Fig. 8.16. This can be analyzed for focal sources as well as rotors. There are several advantages of this system. Since it simultaneously maps both atria and therefore can help to differentiate between active rotors and passive activation. It also does not rely on contact to record the electrograms. Given that data is acquired prior to an ablation there may be a question of changes in activation or changes related to the ablation itself.

Important Points to Remember

1. AF is classified as paroxysmal, persistent, longstanding persistent or permanent. Paroxysmal AF is defined as two or more episodes of AF each of which terminate within seven days and commonly within 24 h. Persistent AF is sustained generally for greater than seven days (or less if a cardioversion was performed in this time) and requires chemical or electrical cardioversion for termination of the arrhythmia. Longstanding persistent refers to cases in which AF has been present for more than one year and previously may have been designated as being permanent; however, an electrical cardioversion or ablation strategy is being pursued and therefore sinus rhythm may be achieved. Permanent AF also continues for more than seven days and cannot be terminated anymore thus a rhythm control strategy has been unsuccessful or not appropriate.
2. The main cardiovascular causes of AF are hypertension, coronary artery disease and valvular heart disease, metabolic causes of AF include thyroid dysfunction and diabetes mellitus while lifestyle risk factors include obesity, excessive alcohol and obstructive sleep apnea. AF is frequently seen in an acute setting in post operative patients as well as those who have infection, or in association with pulmonary embolism, pericarditis and myocarditis. AF may also occur in association with other supraventricular arrhythmias, such as AV nodal re-entry tachycardia, AV re-entry tachycardia and atrial flutter.
3. PVI is considered to be a reasonable strategy in patients with paroxysmal AF in whom medication has been ineffective, poorly tolerated or in cases of patient preference. This may be performed using a point by point technique or a ‘single shot’ device. PVI may also be useful in patients with persistent AF as a method of isolating the potential triggers.
4. Electrograms recorded from the ostia of the pulmonary veins show an initial non circumferential lower amplitude atrial signal followed by an isoelectric period followed by sharp pulmonary vein potentials. Depending on the overlap between the left atrium and the surrounding structures as well as the orientation of the mapping catheter there is a variable delay between the farfield electrogram and the pulmonary vein potentials. For the LSPV and to a lesser degree the LIPV farfield electrograms from the LAA may be recorded. These can be separated from the PV potentials by pacing from the LAA or the distal CS. For the RSPV farfield electrograms may be recorded from the SVC. If the signal is within 30 msec of the onset of the p wave then these are likely to represent SVC farfield.
5. Entrance block may be observed either during normal sinus rhythm or with atrial pacing during sinus rhythm. The circular catheter is positioned in the PV antra just distal to the line of ablation.
6. In order to prove exit block the ablation catheter can be positioned in the same pulmonary vein as the circular mapping catheter. Although pacing

can be performed from either the ablation catheter alone or the circular catheter alone it is often easier to discern pulmonary vein potentials from a separate catheter which has closely spaced poles without superimposed pacing arterfact.

7. An additional useful technique to help prove an intact line around the pulmonary veins is to assess for unexcitability to pacing. Following ablation the catheter is positioned along the line during sinus rhythm at an output of 10 mA and a pulse width of 2 ms. If lack of local capture occurs the catheter is moved a further 5 mm along the line and pacing repeated. If local capture occurred then further ablation was performed in this region and pacing performed at the same output.
8. In some cases non pulmonary vein triggers may contribute to AF. Potential locations include the superior vena cava, coronary sinus, crista terminalis, fossa ovalis, ligament of Marshall and left atrial appendage.
9. Post PVI atrial arrhythmias may involve the CTI, gaps around the PV's, the mitral annulus or the LA roof. Activation mapping using the ablation catheter relative to a stable CS electrogram may help to distinguish these.
10. Newer mapping techniques including the potential mapping of rotors may help to further understand the mechanism for AF.

Chapter 9
Ventricular Tachycardia

Benedict M. Glover and Pedro Brugada

Abstract Ventricular tachycardia is defined as an arrhythmia which originates from the ventricles consisting of at least three or more consecutive beats at a rate of greater than 100/min and independent of AV or atrial conduction. If this terminates spontaneously within less than 30 s it is defined as non-sustained. If it lasts greater than 30 s or requires treatment for termination it is defined as sustained. Most commonly VT is associated with structural heart disease such as scar related re-entry in patients who have had a prior MI. Occasionally it may be associated with a structurally normal heart and is termed idiopathic. This is most commonly seen in the right ventricular outflow tract, coronary cusps, coronary veins or around the valve annuli.

ECG Criteria

One of the most important issues is to record an ECG during tachycardia in order to help make a diagnosis as to whether the arrhythmia is ventricular or supraventricular and if ventricular where the exit site may be located. As shown in Fig. 9.1 several criteria exist in order to help make this differentiation.

The Brugada criteria uses a straightforward and stepwise approach. This was developed by examining 348 cases of VT and comparing these with 170 cases of SVT with abberancy [1]. No patients were receiving anti-arrhythmic drugs. The first step looks at the absence of an RS in all of the precordial leads. If this is the case

then VT is diagnosed. If not then the longest RS interval is examined and if greater than 100 ms VT is diagnosed. If not the presence of AV dissociation is looked for. As VA conduction may occur in almost half of all cases of VT it is important not to confuse 1:1 VA conduction with a supraventricular arrhythmia with 1:1 A:V conduction or 2:1 VA conduction during VT with AV dissociation.

If this is not seen then the classical Wellens criteria for VT in leads V1 or V2 as well as V6 are looked for [2]. These include a QR, R or RSr' in V1 or V2 with an RS less than 1 in V6 or a QS in V6 in a RBBB morphology or an R in V1 greater than 30 ms with notching of the S wave and an onset of QRS to S wave of greater than 70 ms in V1 or V2 with a Q wave in V6 in a LBBB morphology.

Another interesting algorithm has also been developed in which inly lead aVR is analysed [3]. As shown in Fig. 9.1 the presence of an initial R-wave, the width of an initial r- or q-wave greater than 40 ms, the presence of notching on the initial downstroke of a predominantly negative QRS complex and a V_i/V_t less than or equal to 1 are more indicative of VT.

Scar Related VT

Macro re-entry scar related monomorphic re-entry VT requiring treatment is a common indication for catheter ablation. Although this is most commonly the result of coronary artery disease other potential causes include infiltrative conditions and

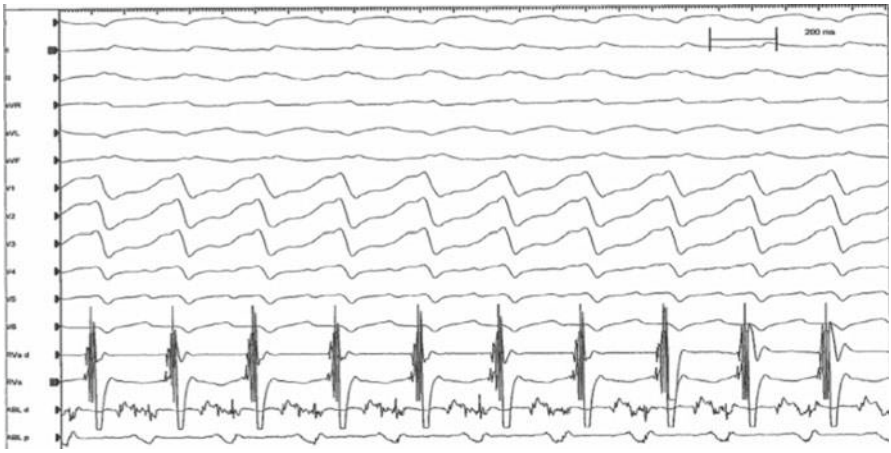

Fig. 9.2 Mapping during scar related re-entry VT showing long fractionated signals on the distal ablation catheter (ABL d) during diastole most likely indicative of a critical isthmus. Ablation in this region resulted in termination of the tachycardia with no further inducible tachycardia

dilated cardiomyopathy. As anti-arrhythmic drugs are often only moderately effective and often have significant side effects catheter ablation represents a reasonable alternative. Of course the potential complications of catheter ablation should also be considered. These include vascular injury, thrombo-embolism, hemodynamic instability and compromise, damage to the conduction system and cardiac tamponade.

Mechanism

Most scar related VT is a macro re-entry circuit. This is composed of an area of slow conduction with functional unidirectional conduction block as well as a structural barrier which is generally scar. Like all re-entry circuits the tachycardia can be entrained and reset if pacing is performed close to the circuit at a cycle length slightly shorter than the tachycardia cycle length with a closely matched post pacing interval minus tachycardia cycle length. There is generally an isthmus which is characterized by electrical activity during diastole. This is often the region which is targeted for catheter ablation. Pacing from this location results in a long stimulation to onset of QRS with a good pace map at the exit site. It is the exit site which determines the QRS morphology. Following this the waveform either propagates around the outer loop of the scar or an inner loop within the scar (Fig. 9.2).

Mapping and Ablation of Scar Related VT

In general it is reasonable to induce VT at the start of the procedure in order to have some procedural endpoint following ablation. Performing activation mapping and

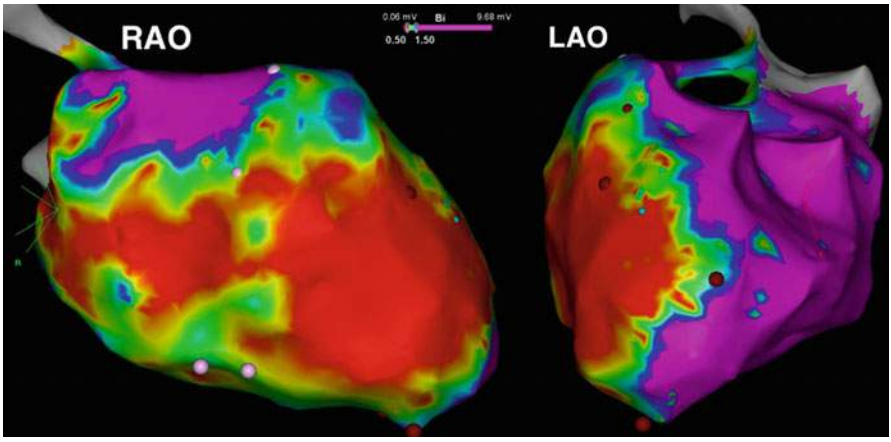

Fig. 9.3 Substrate mapping in a patient with monomorphic ischemic VT. Scar is seen in the LV septum, anterior wall and apex with heterogeneous tissue around this. This is clearly seen in the RAO image on the left and LAO image on the right

ablation of VT can result in significant hemodynamic compromise and may have adverse effects in itself. It is therefore our practice to map the substrate and target fractionated, low amplitude or delayed electrograms. In general **scar is defined as a bipolar voltage less than 1.5 mV and dense scar is a voltage less than 0.5 mV**. As shown in Fig. 9.3 scar is shown as red along the LV septum, anterior wall and apex with a region of heterogeneous tissue around this colored yellow, green and blue and higher voltage areas are seen in pink.

The targeting of **local abnormal ventricular activities** (**LAVA**) which represent poorly coupled fibers surrounded by appears to be an effective strategy [4].

The classical features of LAVA during sinus rhythm are:

- High frequency often double (or more) potentials separated by either a low amplitude baseline
- Separate from and often (but not always) following ventricular far-field
- May require pacing at the site in order to distinguish LAVA from ventricular farfield.

As well as exposing LAVA, which may be within the farfield, ventricular pacing at different outputs may result in different morphologies which means that the pacing substrate is complex. This is shown in Fig. 9.4.

The interesting concept is that although later potentials do tend to be significant and generally should be targeted the timing of these potential relative to the QRS is not just dependent on local conduction but on the anatomic location being earlier closer to the endocardial septum and latest being closer to the posterobasal epicardium which is activated at least 30 ms after [5].

It is therefore a reasonable strategy to perform pacing in order to separate out local fractionated potentials from farfield ventricular activation.

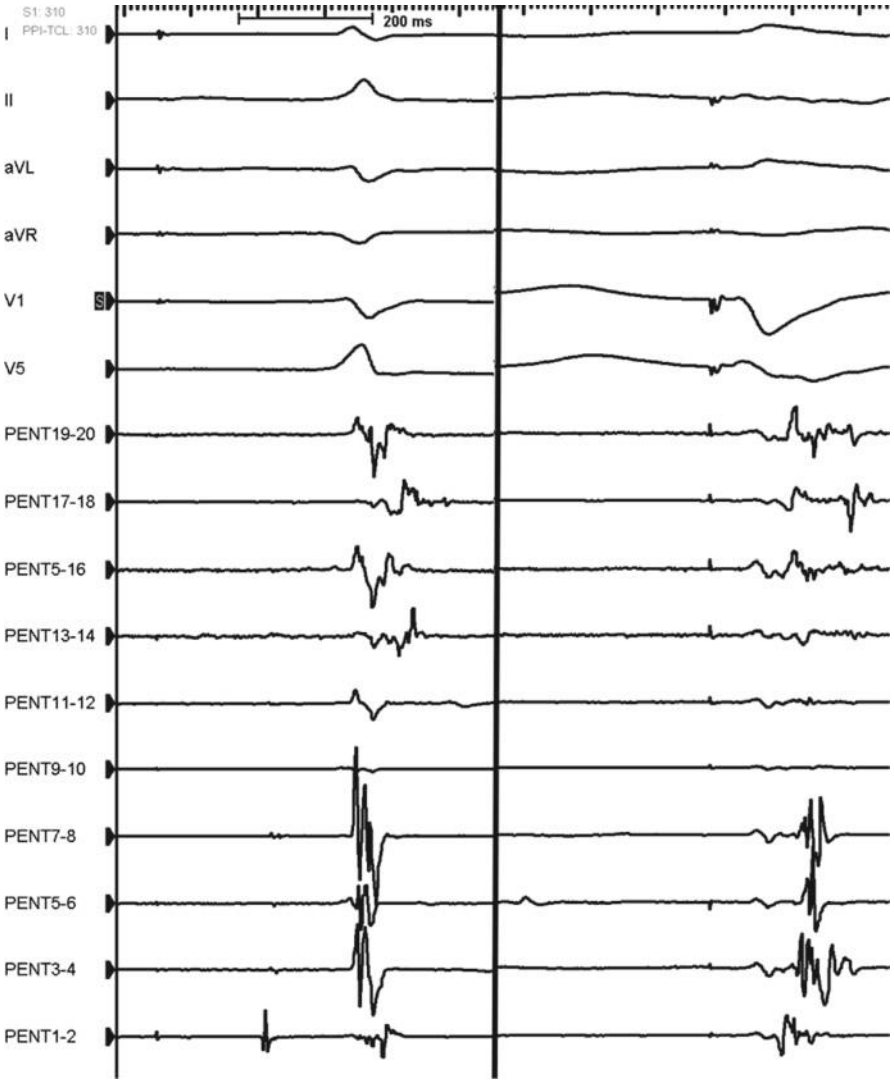

Fig. 9.4 LAVA potentials exposed during pacing from the RV apex (*circled on the right*). The pentarray catheter (PENT 1–20) is positioned in the inferior wall of the left ventricle. The first beat on the left occurs following an atrial paced beat in which fractionation is noted in PENT 13–20. On the right pacing is performed from a catheter in the RV apex which expose higher frequency split potentials in PENT 15–20 and 3–4 which were targeted for ablation

Pace mapping particularly along the critical isthmus is also a very helpful strategy. A long stimulus to QRS with a good pace map is often a reasonable sign of being close to the isthmus. In cases of septal VT we perform this on both the right and left septum. This is shown in Fig. 9.5 in which the patient has extensive scar along the LV septum, anterior wall, inferior wall and apex. A pace map on the RV

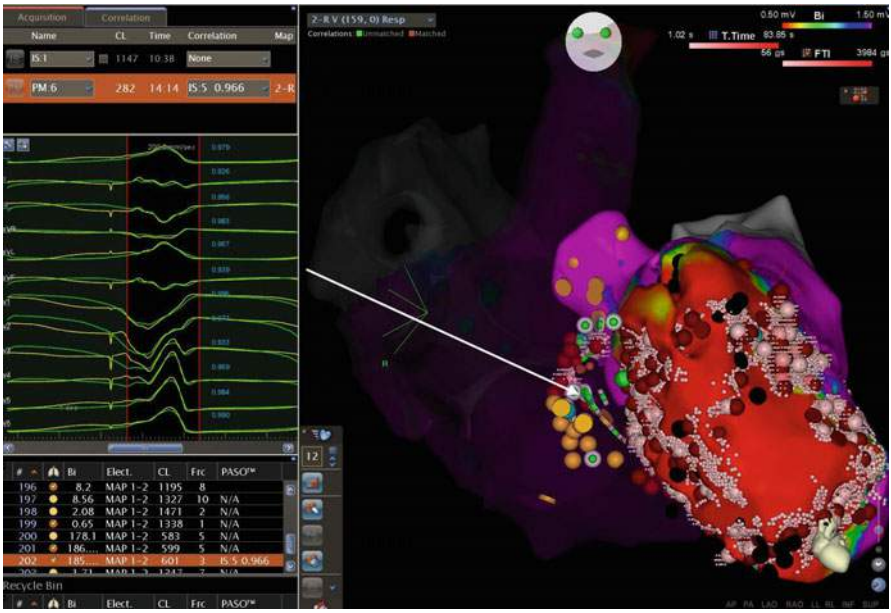

Fig. 9.5 Substrate map showing extensive scarring of the left ventricle involving the septum, anterior wall, inferior wall and apex. VT could be easily induced and terminated with ablation at 50 W along the septum (exact point *green dot*). Despite this VT could be re-initiated and therefore pace mapping was performed on both sides of the septum. The pace map shows a very good match with the clinical VT on the right side of the septum. Despite the appearance of relatively normal signals ablation was performed in this region with no further inducible tachycardia. The *arrow points* to the area with the best pace map and indicates that the exit site was likely on the right side and that ablation was required on both sides of the septum. (*Yellow dots* were regions with less good pace map matches and *black dots* were LAVA potentials which were also targeted)

septum in which the voltages were normal revealed an excellent pace map as shown. Ablation was therefore performed on both sides of the septum which successfully targeted the circuit which was likely deep septal.

If tolerated and a distinct region has been mapped such as the isthmus then VT can be induced and the signals examined during tachycardia or ablation can be performed looking for tachycardia termination. Additionally if the arrhythmia is tolerated entrainment can be performed in order to assess the location of the catheter relative to the circuit.

At the end of the procedure further testing can be performed in order to examine for tachycardia induction.

Epicardial Access and Ablation

Scar related monomorphic VT circuits may involve the endocardium, mid myocardium and epicardium. This is more commonly but not exclusively seen in non-ischemic VT. Certain cases may require epicardial access in order to successfully

target the critical components of the circuit. This may be determined according to the underlying substrate, by using imaging which may help visualize scar distribution, in cases where ablation was unsuccessful from the endocardium and in cases where the ECG may exhibit certain characteristics.

ECG Characteristics Suggestive of Epicardial Involvement

In general the QRS during VT originating from or involving the epicardium results in a significantly wider QRS due to the greater distance from the His Purkinje system. For epicardial VT with a RBBB morphology thought to have an exit site in the region of the left ventricle several parameters can be measured which may suggest epicardial involvement.

These include the following parameters [6]:

1. **The onset of the QRS to a pseudo-delta wave of greater than 34 ms**. A pseudo-delta wave is defined as an early rapid deflection on the upstroke of the QRS complex.
2. **An intrinsicoid deflection time of greater than 85 ms**. The intrinsicoid deflection time is the time from the onset of the QRS to the peak of the R wave measured in V2.
3. **The RS complex duration** defined as the earliest ventricular activation to the nadir of the first S wave in any precordial lead of **greater than or equal to 121 ms**.

For VT originating from the epicardial surface of the RV these parameters do not appear to be helpful [7].

The presence of a Q wave or a QS in the local site of activation provides a more useful indicator. Therefore an inferior origin tends to have a Q or QS in leads II, III and aVF. None of these parameters are useful in determining whether an outflow tract tachycardia is endocardial or epicardial. An example of an ECG in a patient with VT with an epicardial focus involving the LV inferior wall is shown in Fig. 9.6.

Epicardial VT Ablation

Although this procedure can be performed with sedation it is generally uncomfortable for the patient and general anesthesia should be considered. A sterile field is prepared inferior to the sternum and fluoroscopy with or without the addition of echo can be used for imaging.

Epicardial Access

A 17 Guage Tuohy needle is introduced at a 45° angle initially until it has passed through the diaphragm and then a slightly steeper angle. The direction of the needle can be visualized in the RAO view aiming towards the medial one third of the RV

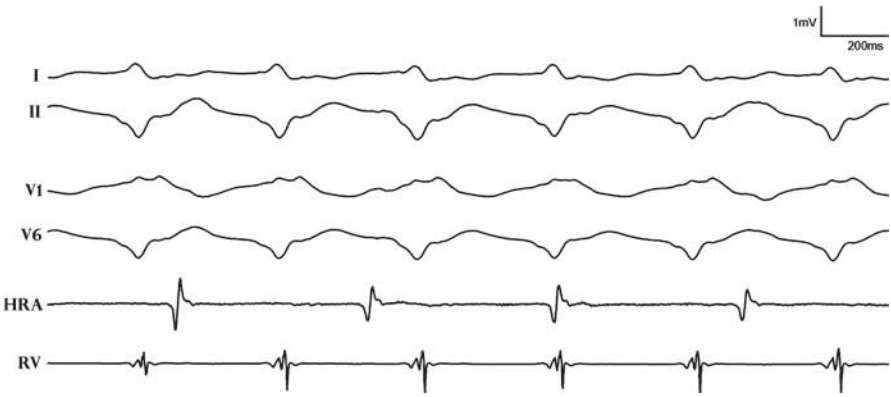

Fig. 9.6 ECG of VT originating located in the epicardial surface of the LV inferior region. V1 and V6 are indicative of a left ventricular origin while lead I and II indicate an inferior origin. The QRS is broad with a pseudodelta wave seen on lead V1. There is clear dissociation seen between the RV and RA activation

(where there are no major coronary vessels) while the depth is most easily seen in a left lateral projection.

As the tip of the needle enters the epicardial space a sensation of a 'give' is felt followed by a cardiac pulsation. Although contrast can be injected this should be minimized as it often then obscures the view. A more straightforward approach is to advance a long wire into the pericardial space. If this is truly in the pericardial space it should not follow the course of any cardiac chamber. If this is in the RV it will tend to pass towards the RVOT and into the pulmonary truck often with significant ectopy. Another option is to record the pressure from the needle which will change from a flat line as the needle is advanced through tissue to a sudden negative pressure as the tip of the needle passes into the pericardial space. Entering the right ventricle will demonstrate an RV pressure waveform. In general as long as only the needle tip and wire enter the ventricle this should not result in a major problem and a fresh attempt can be made with close hemodynamic monitoring.

As soon as it is confirmed that the needle and wire are in the epicardium then a sheath and dilator can be introduced. In general a short deflectable sheath can be used. We also tend to introduce a second wire through the sheath in case access is lost.

It is important that a catheter is left in the sheath and if removed that it is replaced with a wire in order to avoid laceration of the ventricular wall with the tip of the sheath.

The relevant anatomy pertaining to epicardial access is shown on anatomical image and the CT image in Fig. 9.7.

In approximately 10 % of patients epicardial access is not possible. This is particularly common in patients who have had prior cardiac surgery as well as some patients with a prior history of pericarditis. In these cases a surgical window can sometimes be made.

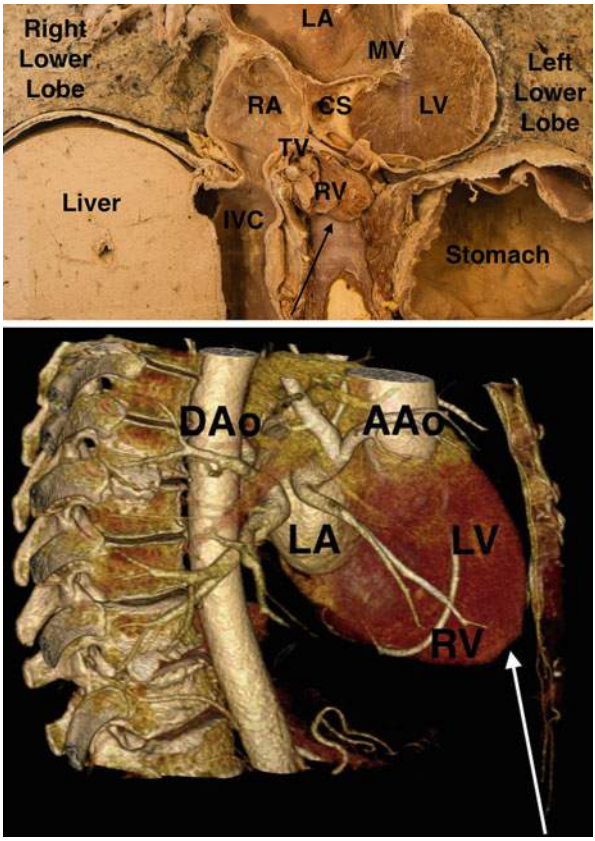

Fig. 9.7 Anatomical image showing the relevant anatomy from an anterior coronal view in epicardial access (*top image*) and a lateral sagittal view shown on a CT (*bottom image*). The *arrow* in the *top image* shows the direction in which the needle should be advanced towards the middle one third of the RV. The angulation of this is seen in the CT image below this in which the arrow shows the course of the needle (*LA* left atrium, *RA* right atrium, *TV* tricuspid valve, *MV* mitral valve, *CS* coronary sinus, *IVC* inferior vena cava, *AAo* ascending aorta, *DAo* descending aorta)

Epicardial Mapping and Ablation

An irrigated catheter is used for mapping and ablation. The general principles of mapping are the same as for endocardial mapping. The main issue which may arise, is the differentiation of scar from epicardial fat. In generally fat greater than 5 mm results in a reduction in the amplitude of the local electrogram. The degree of fractionation is helpful and is generally reasonably specific for local scar rather than fat. If a region of low amplitude signals follows the distribution of a coronary vessel then it is likely to represent epicardial fat. An example of a voltage map recorded on the epicardium and showing scar along the inferior wall of the LV is shown in Fig. 9.8 along with the region of ablation performed.

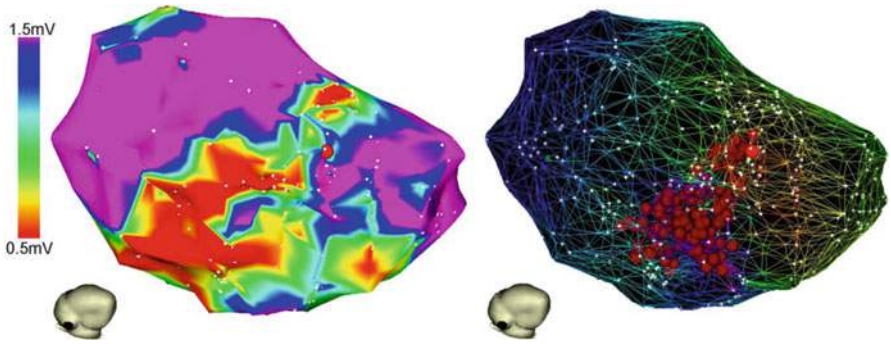

Fig. 9.8 Voltage Map of VT along the epicardial surface of the LV inferior wall. *On the image on the left red* represents dense scar surrounded by heterogeneous zones and normal voltages are shown in *pink*. The *image on the right* shows the points recorded with ablation shown as *red dots* along the critical isthmus

The fact that ablation catheters deliver circumferential radiofrequency energy means that there is always a degree of damage to surrounding structure. This is generally the pericardium and pleura which accommodate this with no major problems. The main structures to be cautious of when delivering RF to the epicardial surface are the coronary arteries and the phrenic nerves. In general either a CT is merged at the start of the procedure with the locations of the coronary arteries or a coronary angiogram is performed prior to ablation. A **minimum distance of 5 mm** should be maintained between the site of ablation and the coronary artery in order to prevent coronary artery spasm or acute thrombosis.

As there is no flow in the pericardium irrigation is used at a rate of 10 ml/min. This should be aspirated from the side arm of the sheath to prevent cardiac tamponade. RF can be delivered at a power ranging from 25 to 50 W.

Epicardial Ablation: The Difficult Case

The difficulties in epicardial mapping and ablation relate to either general issues relating to mapping which are similar to those of endocardial ablations and additional technical issues. One of the first issues is that of gaining access with minimal complications. Maintaining a relatively shallow angle while beneath the diaphragm minimizes the risk of hepatic laceration and subdiaphragmatic injury. Perforation of a subdiaphragmatic vessel should be suspected in a patient with significant hypotension and no evidence of a pericardial effusion.

Another technical issue is that of phrenic nerve proximity to a region where ablation is required. In general the phrenic nerve can be pushed away from the ablation catheter by injecting air through the pericardial sheath. This should be aspirated immediately if defibrillation is required and after ablation has been performed.

Although some centers use local non steroidal drugs in the pericardial space post procedure we tend to manage the majority of cases with simple analgesia.

Idiopathic VT

Bundle Branch Re-entry

Under normal circumstances antegrade conduction through the His Purkinje network is relatively rapid. The fact that the tissue remains refractory for more prolonged periods of time therefore generally prevents re-entry from occurring between the right and the left bundle branches. In cases where conduction is slowed or transiently blocked in either the antegrade or retrograde directions re-entry may occur. As shown in Fig. 9.9 this may result in antegrade conduction down the right bundle with retrograde conduction up the left bundle resulting in a left bundle branch block morphology during VT. The reverse may also occur with antegrade conduction down the left bundle and retrograde conduction up the right bundle resulting in a right bundle branch block morphology during VT.

EP Study and Ablation for Bundle Branch Re-entry VT

In patients with bundle branch re-entry the baseline ECG during normal sinus rhythm often shows first degree AV block with some variant of intraventricular conduction delay or an incomplete bundle branch block.

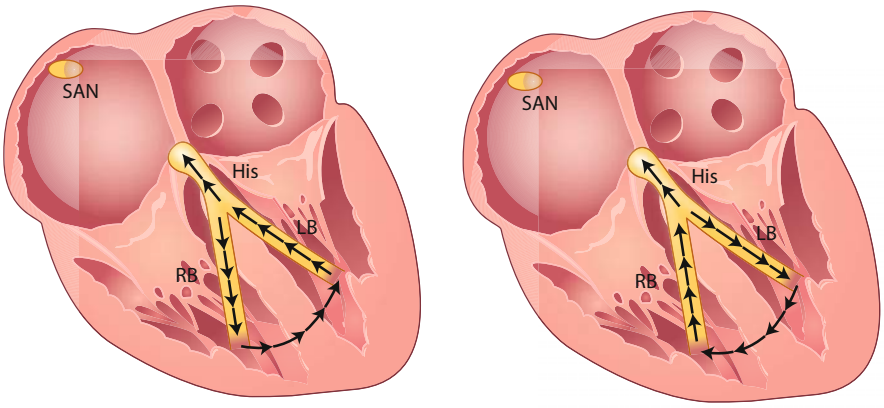

Fig. 9.9 Showing the potential circuits involved in BBR. *Top image* shows the more common scenario where antegrade conduction occurs along the right bundle and retrogradely along the left bundle and below the less common antegrade conduction along the right bundle with retrograde conduction along the right bundle

The baseline EP study demonstrates a **prolonged HV interval during sinus rhythm of greater than 60 ms** [8]. Tachycardia may be induced with either atrial or ventricular pacing. The morphology is more commonly a LBBB than a RBBB. The diagnosis is generally made by the presence of a **His signal before every QRS** with a HV interval slightly shorter than during sinus rhythm. The His signal is generally followed by the right bundle potential or less commonly a left bundle potential depending on the direction of the circuit. As these are all vital components in the circuit a change in either the H-H, RB-RB or LB-LB intervals prolongs the tachycardia cycle length. Entrainment may be possible by pacing from the right ventricular apex. A difference of less than 30 ms is suggestive of bundle branch re-entry [9].

In general ablation of the right bundle branch is performed. In order to map this the His is located and a more distal location with a right bundle electrogram and no atrial signal is chosen along the anterobasal region.

Fascicular Re-entry VT

Fascicular re-entry VT is sometimes referred to as either verapamil sensitive or Belhassen VT. Whereas in Bundle Branch Re-entry VT the His activation occurs before left bundle activation in fascicular re-entry His activation tends to occur after left bundle activation and with a much shorter HV interval during tachycardia. The QRS in fascicular VT although prolonged, is generally less than 140 ms and therefore is not as prolonged as many other types of VT. Upper septal re-entry tends to be narrower and may even be confused with SVT. Three different types of fascicular VT exist.

The most common type is **left posterior fascicular** in which the antegrade component to the circuit involves slowly conducting decremental verapamil sensitive Purkinje fibers extending from the base of the interventricular septum towards the LV apex. The retrograde circuit then propagates along the posterior fascicle with an exit site in the inferoposterior septum resulting in a **RBBB morphology with a superior directed axis**.

Less commonly is **left anterior fascicular** in which the retrograde activation occurs along the anterior fascicle with an exit along the anterolateral wall of the LV resulting in a **RBBB** morphology QRS during tachycardia with an inferior directed axis.

In **upper septal VT** the left posterior and left anterior fascicles both act as the antegrade limbs resulting in a relatively narrow QRS often with a **RBBB** morphology although occasionally there is a LBBB pattern with an inferior or normal axis. Diagrammatic representation of these is shown in Fig. 9.10.

EP Study and Ablation for Fascicular VT

EP evaluation and catheter ablation may be performed successfully in the majority of patients. Given that the circuit is located in the left ventricle access can be achieved either retogradely across the aortic valve or through a transseptal approach.

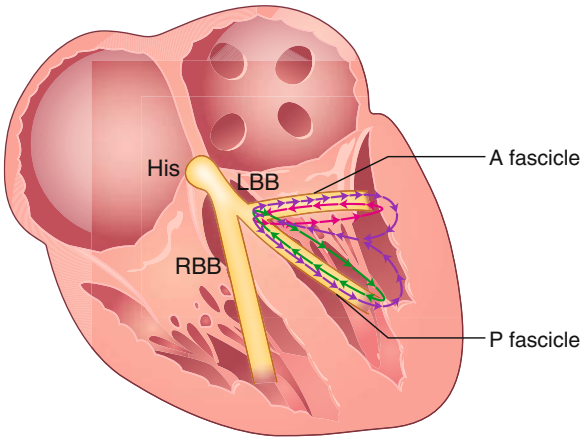

Fig. 9.10 Demonstrating the circuits involved in fascicular VT utilizing the posterior fascicle as the retrograde limb (*green*) and the anterior fascicle as the retrograde limb (*pink*) as well as the uncommon upper septal fascicular re-entry (*purple*)

The risks are therefore similar to those for all left ventricular ablations with the additional potential risk of the development of LBBB and AV block.

One of the interesting and diagnostic features of this type of VT is that it can be induced and entrained by performing atrial pacing. If pacing is insufficient for the induction of VT then isoprenaline can often be helpful.

During normal sinus rhythm and during tachycardia a sharp high frequency Purkinje potential can be recorded prior to the onset of the QRS which represents depolarization of the fascicle. During sinus rhythm a lower frequency potential may be recorded after the QRS which is known as a **pre-purkinje potential**. This term is used for this potential as during tachycardia it represents activation of the verapamil sensitive antegrade limb of the circuit and therefore occurs before the purkinje potential. As the mapping catheter is moved further from the base of the interventricular septum towards the LV apex the pre-purkinje potential becomes later. The area of slow conduction tends to occur at the junction of the fascicle and the antegrade limb where the purkinje potential is at its earliest and the pre-purkinje potential is at its latest.

Ablation is generally performed during tachycardia as termination with ablation with no further initiation is a reasonable endpoint. A region close to the exit site can be targeted approximately one third from the LV apex where the **purkinje potential precedes the QRS by approximately 20 ms**. The pre-purkinje potential tends to occur after the QRS in this region. An alternative approach where the earliest pre-purkinje potential can be targeted until VT is terminated and in which case the potential then becomes late. This appears to be associated with a slightly higher risk of AV block or LBBB.

If VT cannot be induced nor sustained and the suspicion is that of a left posterior fascicular VT then a linear lesion can be made 1 cm proximal to the exit site. The exit site can be identified by careful pace mapping. If the linear lesion is successful the purkinje potential jumps from before to after the QRS complex.

The Difficult Case

Several issues may make ablation of this arrhythmia difficult. In general from a practical perspective the two major issues are difficulty with initiation of the tachycardia and ensuring that the correct diagnosis has been made.

Although atrial and ventricular pacing should initiate the tachycardia if this is not possible the administration of intravenous isoprenaline may be helpful.

In cases where ablation appears to be unsuccessful it is important to review the diagnosis. It is possible to have a focal arrhythmia originating from the purkinje network which also results in a RBBB morphology QRS with either a superior or inferior directed axis. Being focal it tends not to be initiated or entrained from pacing in the atrium or ventricles. In mapping this unusual VT the earliest site of activation should be targeted. Another possibility is that of mitral annular VT which may have a RBBB morphology with a superior axis.

Given the relatively narrow QRS and the fact that initiation may occur with atrial pacing, fascicular VT may also be confused with SVT. This is most easily differentiated by the presence of AV dissociation.

Outflow Tract VT

The most common locations for premature ventricular complex's (PVC's) are within the right and left ventricular outflow tracts. Isolated PVC's in the setting of normal left ventricular function are generally of minimal significance. Indications for ablation include PVC induced left ventricular dysfunction or significant symptoms where pharmacological therapy is ineffective or not tolerated. Non-sustained and sustained focal VT may also originate from the outflow tracts and like PVC's is more commonly found on the right ventricular outflow tract (RVOT) compared with the left ventricular outflow tract (LVOT). Although RVOT extrasystoles are more common in females there is an approximate equal gender distribution in LVOT extrasystoles.

Outflow tract tachycardia generally occur more commonly at rest than with exercise and are often suppressed with an increase in the sinus rate. A proportion of cases are exercise induced occurring either at peak exercise or during the recovery phase.

Anatomy and ECG Features

The RVOT runs from the superior aspect of the tricuspid annulus at the inferior aspect to the pulmonary valve at the superior end. The LVOT includes the coronary cusps superior to the aortic valve and extends inferiorly to the aortomitral continuity and the superior aspect of the mitral annulus. The majority of foci in both outflow tracts tend to be relatively close to the annulus of either valve which may result in anisotropy and arrhythmogenesis.

Given that both the right and left ventricular outflow tracts are superior structures the ventricular activation tends to be from superior to inferior resulting in a positive QRS axis in leads II, III and aVF and negative in aVR and aVL.

The differentiation between tachycardia's originating from the right versus the left ventricular outflow tracts based on the ECG can occasionally be more complex. The majority of outflow tract tachycardia's originate from the superior and anterior septal RVOT making it difficult at times to know if these are originating from the left or the right side. In approximately 15 % of cases the origin is the LVOT. Occasionally the origin may be the right ventricular infundibulum, superior to the pulmonary valve, the aortomitral continuity or with close to the anterior interventricular vein.

As shown on the CT image in Fig. 9.11 the right ventricular outflow tract is anterior to the left ventricular outflow tract and as it becomes more superior moves to the left of the LVOT so that the pulmonary valve is actually left of the aortic valve. As a result of this basic fact, ventricular activation from the RVOT generally spreads from anterior to posterior. This results in a negative QRS in V1 with a LBBB type pattern on the ECG. If the precordial transition occurs at lead V4 or later then the origin is almost certainly RVOT.

The difficulty arises when the precordial transition occurs at or close to V3 and where there may be a predominantly negative QRS in the early precordial leads with an R wave. A small R wave may be present in posterior and superior RVOT foci as

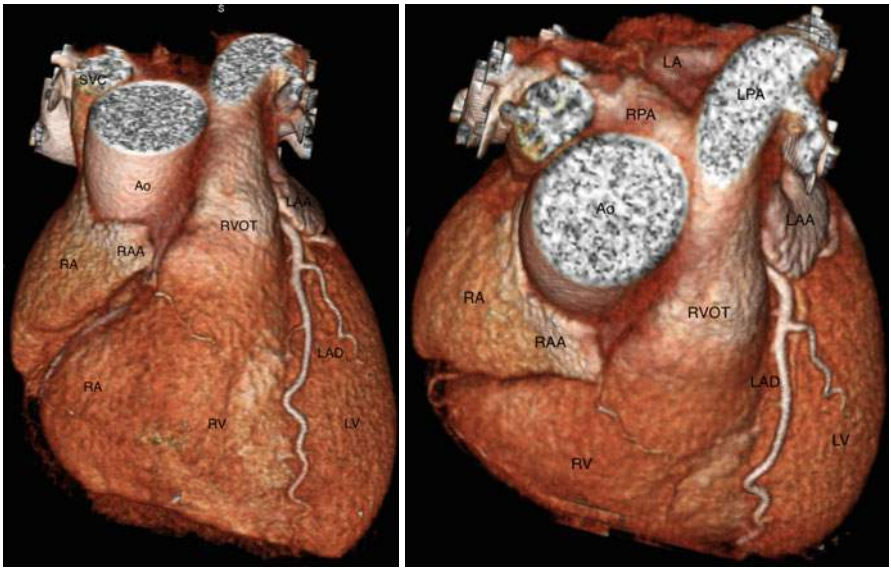

Fig. 9.11 CT Image showing the Relationship of the RVOT and LVOT. The figure on the *top* shows an anterior view in which the RVOT is anterior and to the left of the LVOT. The image at the *bottom* shows a superior view (*Ao* aorta, *RA* right atrium, *RAA* right atrial appendage, *RV* right ventricle, *LAA* left atrial appendage, *SVC* superior vena cava, *LV* left ventricle, *LAD* left anterior descending artery, *LPA* left pulmonary artery, *RPA* right pulmonary artery)

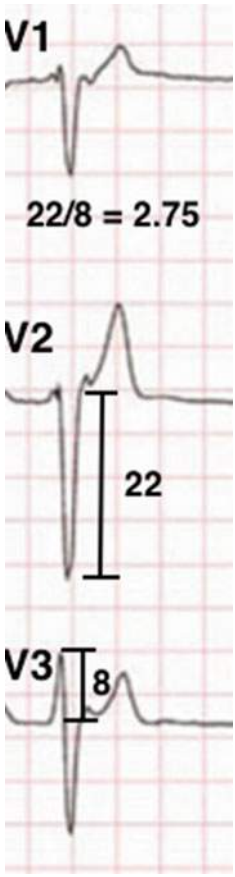

Fig. 9.12 Measurement and calculation of the V2S/V3R ratio for an outflow tract PVC. The S wave in lead V2 is 22, while the R wave is 8 resulting in a V2S/V3R of 2.75 which is indicative of an RVOT origin

well as the anterior LVOT where it tends to be slightly higher in amplitude. In order to help estimate the location several algorithms have been developed.

The V2S/V3R Index is useful in helping to differentiate between a RVOT and LVOT origin in outflow tract PVC's with a LBBB type morphology [10]. As shown in Fig. 9.12 using this simple calculation the amplitude of the S wave in lead V2 is divided by the amplitude of the R wave in lead V3. A value of less than or equal to 1.5 has been shown to be suggestive of a LVOT origin while a value greater than 1.5 represents a likely RVOT origin.

Having ascertained whether the origin is located in either the RVOT or LVOT further ECG analysis can be performed to help estimate the specific location within the specific outflow tract.

As demonstrated in Fig. 9.13 a lateral lead such as Lead I may be useful in further ascertaining the origin of an outflow tract tachycardia. In an RVOT tachycardia a negative QRS in lead I is more indicative of a more superior origin close to or above the pulmonary valve. A positive QRS in lead I indicates a more rightward inferior structure such as the RVOT freewall. Septal and anterior origins often are biphasic in lead I.

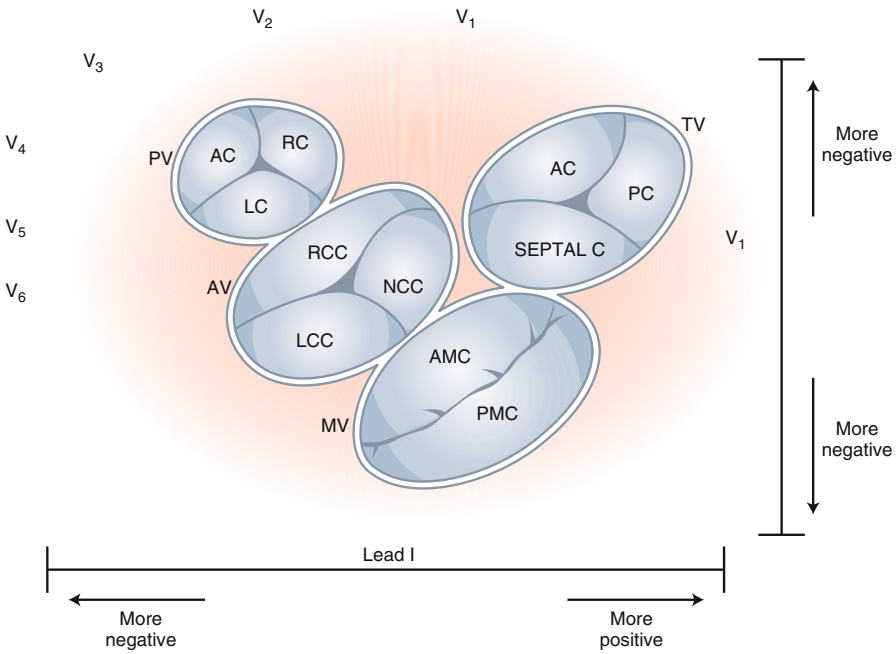

Fig. 9.13 Showing the anatomic relationship of the precordial lead V1 and lead I to the outflow tracts (*PV* pulmonary valve, *AC* anterior cusp, *RC* right cusp, *LC* left cusp, *AV* aortic valve, *RCC* right coronary cusp, *LCC* left coronary cusp, *NCC* non coronary cusp, *MV* mitral valve, *AMC* anterior mitral cusp, *PMC* posterior mitral cusp, *TV* tricuspid valve, *AC* anterior cusp, *PC* posterior cusp, *Septal C* septal cusp)

One further important point to examine on the ECG in more detail is leads aVR and aVL. These are almost always negative for all outflow tract tachycardias. However if aVL is isoelectric or positive the inferior portion of the RVOT close to the Bundle of His and right bundle should be considered.

Outflow Tract Tachycardia: EP Study and Ablation

Indications

The two main indications for the ablation of outflow tract tachycardias are either symptoms which cannot be effectively treated with pharmacological agents or frequent arrhythmias resulting in left ventricular dysfunction. For minimal symptoms often no treatment is required. Pharmacological therapy is often of moderate efficacy if symptoms persist and includes beta blockers, flecainide and calcium channel blockers. Acute termination can be performed with the administration of intravenous adenosine which acts by blocking the beta adrenergic activation of intracellular calcium [11].

Risks

The most common risks of ablation of the outflow tracts are vascular complications in the groin. This is more likely for arrhythmias on the left side which generally require arterial access. For left sided ablations heparin should be administered during the procedure in order to minimize the small risk of thrombo-embolism. Coronary artery damage in the mapping and ablation of aortic cusp tachycardias is a potential risk and therefore it is generally recommended that the coronary arteries are visualized prior to delivering ablation by performing a coronary angiogram. This should also be performed prior to ablation in the cardiac veins which generally run beside the coronary arteries.

On the right side the risks depend on the location of ablation. If the focus is inferior and septal then damage to the His is a possibility. For ablations in the more superior posterior RVOT it must be remembered that the left main coronary artery is often only 5 mm from the site of the ablation catheter [12].

Tamponade is a possibility in either outflow tract however the RVOT is relatively thin in many regions and care must be taken not to use excess power or force.

Procedure

Initiation and Catheter Positioning

In general, if possible all anti arrhythmic drugs should be discontinued for at least 5 half lives prior to the procedure. A single catheter can be used to map and ablate or else a reference catheter can be positioned in either the RV apex or the outflow tract which may help in mapping the level of the focus. For RVOT tachycardia's this is advanced into the right ventricle and then clockwise rotated in order to access the outflow tract. A curl in the tip of the catheter often makes advancement less traumatic with a lower chance of right ventricular outflow tract perforation.

In order to access the LVOT the catheter is generally advanced via the femoral artery with a curve placed on the catheter as it is advanced around the aortic arch. Occasionally trans-septal access can be performed if additional stability is required. The epicardium can often be mapped in this location from the coronary veins.

It is important to try to induce the arrhythmia at the start of the procedure in order to examine the activation sequence of the arrhythmia and map for the earliest and most interesting sites. Activation mapping of outflow tract tachycardias has been shown to result in higher success compared with pace mapping. In general intravenous sedation should be minimized. If there is difficulty with spontaneous initiation of the arrhythmia rapid atrial pacing can be performed provided AV conduction is intact, otherwise ventricular pacing can be carried out. By increasing the ventricular rate this may initiate some outflow tract arrhythmias. If this is unsuccessful isoprenaline or epinephrine can be infused.

Mapping

Activation mapping is superior to pace mapping. It is important to use both the bipolar electrogram looking for early signals relative to the onset of the QRS complex and a unipolar signal which should show only a QS wave with no R wave during ectopy. The earlier the signal the better and success is generally noted when the onset of the local electrogram is at least 10 ms ahead of the onset of the QRS. It is unusual for this to be much earlier than 60 ms ahead of the surface QRS. Following the determination of an early site it is useful to pacemap using the minimal output in order to compare with the morphology of the intrinsic beat. A good pacemap is an additional useful parameter prior to delivery of ablation.

Ablation

Following the mapping of an early region of activation and a good pacemap ablation can be performed in either of the outflow tracts. In general a 4 mm tip catheter is used. For the RVOT if a non irrigated catheter is used then the power is generally set at 40 W with a target temperature of 55 C for a period of 60 s. If an irrigated catheter is used power can be set at 30 W in the RVOT up to a maximum of 35 W.

In the LVOT ablation is typical performed using an irrigated catheter with a power of 25–30 W. Care must be taken in the left and right coronary cusps to ensure that ablation is performed at least 8 mm from the coronary ostia. Of note when mapping the coronary cusps it may be difficult to pacemap and high outputs may be required making this relatively unreliable. Activation mapping in this region is more reliable. During ectopy from this region the electrogram is often biphasic and the earliest component of the first signal should be recorded as the earliest activation. If ablation is performed in the cardiac venous system then power is generally limited to 20–25 W using an irrigated catheter. The issues in these regions may include the possibility of coronary artery damage and a minimum distance of 1 cm should be kept from the coronary artery to the ablation catheter as well as the possibility of impedance rises due to poor flow.

During the delivery of RF in a successful region there is often an episode of non sustained VT or frequent unifocal ventricular ectopy in the first 10–15 s followed by normal rhythm for the remainder of the ablation. The presence of ST segment elevation in the unipolar electrogram is generally a good sign of local tissue injury.

Endpoints and Success

In general it is reasonable to monitor the patient for 30 min following ablation. If there is a recurrence of ectopy with the same morphology then further mapping and ablation should be performed. It is possible that the exit site of an ectopic foci may be shifted by ablation and therefore all the leads on the ECG should be examined in order to ensure this. If pharmacological agents were required fro initiation of the ectopy at baseline then these should be administered following ablation.

The overall acute success for catheter ablation for outflow tract tachycardia is approximately 90 %. Following the procedure ectopy may recur even after 1 year. The two predictors of recurrence are less early local signals targeted for ablation as well as pace mapping being used as the mapping strategy [13].

The Difficult Case

Lack of Spontaneous Ectopy

One of the most common arises from the inability to induce the tachycardia at the start of the case. All anti-arrhythmic agents and beta blockers should be ideally stopped for 5 half lives prior to the procedure. Intravenous sedation should be minimized and if there is no spontaneous ectopy rapid atrial or ventricular pacing can be performed or isoprenaline or epinephrine can be infused at the start of the case. These agents should ideally be stopped during ablation in the RVOT as they may result in hypercontractility of this region which may in theory increase the risk of perforation. If there are very infrequent episodes of ectopy then careful pacemapping can be performed using the minimum output to result in local capture with time spent ensuring that the morphology matches the spontaneous beat very closely.

Lack of Early Sites

If there are no focal regions of early activation but rather a general area either on time with or slightly ahead of the onset of the QRS then the other outflow tract should be mapped. If there are still no particularly early sites then it is useful to map the cardiac venous system.

Continuation of the Arrhythmia Despite Ablation

There are several potential reasons for this. The most likely is that the exact focus has not be accurately mapped and ablated. It is also possible that contact with the catheter is poor and it is useful to flex the catheter in order to alter the angle on the endocardial surface. If the focus is slightly deeper it is possible that the endocardial exit site has shifted with a subtle change in the QRS morphology on the 12 lead ECG. It is also possible that an entirely different PVC is present and a decision must be made as to whether this is significant enough to required further mapping and ablation in another region.

Inability to Deliver Ablation in the Cardiac Venous System

This is not uncommon. The most likely reason for not being able to deliver RF in the cardiac venous system is the proximity to the coronary arteries. It is sometimes possible to perform the ablation in a site which is slightly further from the earliest activation and still achieve success.

Another potential problem with ablation in the cardiac venous system is a significant rise in impedance due to low flow with an inability to deliver sufficient power. This can be overcome by moving the catheter to a slightly different location or different angle as well as increasing the rate of infusion of the irrigation through the ablation catheter.

Mitral Annular VT

This is a less common location for ectopy when compared with the outflow tracts. The ECG typically shows a RBBB pattern with very early precordial transition with in V1 or between V1 and V2 an a positive concordance in the precordial leads due to the relative posterior locations of the mitral annulus relative to the ECG lead positions. For anterolateral origins leads II, III and aVF tend to be positive and leads I and aVL tend to be negative. For posterior or posteroseptal foci leads II, III and aVF tend to be negative and positive in leads I and aVL. More septal origins tend to be narrower than LV free wall locations. Mapping and ablation of a mitral annular PVC is shown in Fig. 9.14.

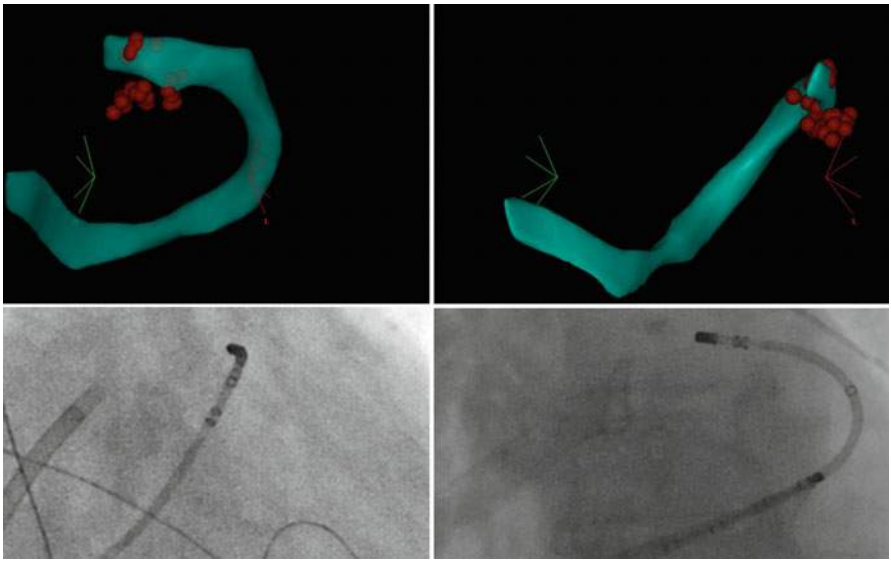

Fig. 9.14 Ablation of a mitral annular PVC resulting in LV dysfunction. This was mapped to the anterior mitral annulus however ablation in this region did not result in termination of ectopy. The ablation catheter was then positioned in the anterior cardiac vein where ablation was successful in terminating ectopy. The successful site of epicardial ablation is shown in the electroanatomic maps on the top of the image (LAO on the *left* and RAO on the *right*) and fluoroscopically (LAO on the *left* and RAO on the *right*). Pace mapping was also used to help confirm the location prior to ablation. These images are shown at the bottom of the figure in which the epicardial map was much closer in morphology to the intrinsic beat when compared with a similar endocardial location

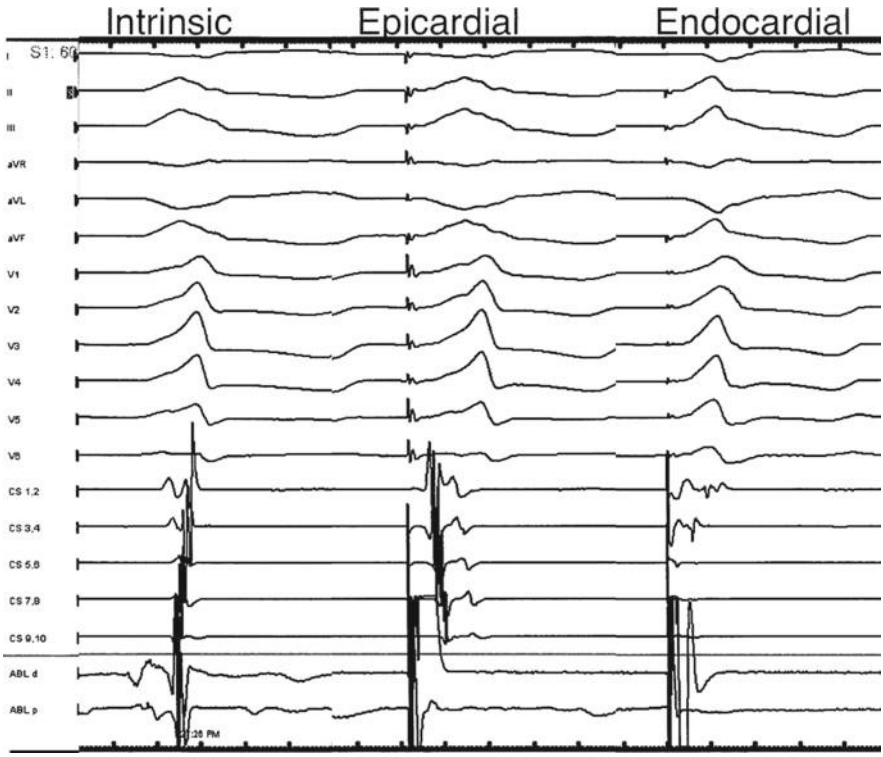

Fig. 9.14 (continued)

Important Points

1. Ventricular tachycardia is defined as an arrhythmia which originates from the ventricles consisting of at least three of more consecutive beats at a rate of greater than 100/min and independent of AV or atrial conduction.
2. The majority of scar related VT is composed of an area of slow conduction with functional unidirectional conduction block as well as a structural barrier which is generally scar.
3. The isthmus is characterized by electrical activity during diastole and is generally the focus for ablation.
4. Scar is defined as a bipolar voltage less than 1.5 mV and dense scar is a voltage less than 0.5 mV.
5. The classical features of LAVA during sinus rhythm are:

   High frequency often double or more potentials separated by either a low amplitude baseline
   Separate from and often but not always after ventricular far-field
   May require pacing at the site in order to distinguish LAVA from ventricular farfield.

6. VT with a RBBB morphology may have an epicardial component if the following features are present:

   The onset of the QRS to a pseudo-delta wave of greater than 34 msec. A pseudo-delta wave is defined as an early rapid deflection on the upstroke of the QRS complex.
   An intrinsicoid deflection time of greater than 85 msec. The intrinsicoid deflection time is the time from the onset of the QRS to the peak of the R wave measured in V2.
   The RS complex duration defined as the earliest ventricular activation to the nadir of the first S wave in any precordial lead of greater than or equal to 121 msec.
   The presence of a Q wave or a QS in the local site of activation provides a more useful indicator. Therefore an inferior origin tends to have a Q or QS in leads II, III and aVF.

7. For VT originating from the epicardial surface of the RV these parameters do not appear to be helpful.
8. Bundle branch re-entry may occur in cases where conduction is slowed or transiently blocked in either the antegrade or retrograde directions re-entry may resulting in a LBBB morphology or less commonly a RBBB morphology.
9. Fascicular re-entry may occur with antegrade or retrograde conduction in the anterior fascicle of the left bundle an conduction in the opposite direction in the posterior fascicle. Either of these activation sequences results in a right bundle branch block type morphology during VT with a superior directed axis.
10. Outflow Tract ectopy is common and may occur in either the RVOT or less commonly the LVOT. Given that both the right and left ventricular outflow tracts are superior structures the ventricular activation tends to be from superior to inferior resulting in a positive QRS axis in leads II, III and aVF and negative in aVR and aVL.
11. Ventricular activation from the RVOT generally spreads from anterior to posterior. This results in a negative QRS in V1 with a LBBB type pattern on the ECG. If the precordial transition occurs at lead V4 or later then the origin is almost certainly RVOT.
12. If the precordial transition occurs at or close to V3 and where there may be a predominantly negative QRS in the early precordial leads with an R wave. A small R wave may be present in posterior and superior RVOT foci as well as the anterior LVOT where it tends to be slightly higher in amplitude. In order to help estimate the location several algorithms have been developed.
13. The V2S/V3R Index is useful in helping to differentiate between a RVOT and LVOT origin in outflow tract PVC's with a LBBB type morphology. A value of less than or equal to 1.5 has been shown to be suggestive of a LVOT origin while a value greater than 1.5 represents a likely RVOT origin.

14. Lead I may be useful in further ascertaining the origin of an outflow tract tachycardia. In an RVOT tachycardia a negative QRS in lead I is more indicative of a more superior origin close to or above the pulmonary valve. A positive QRS in lead I indicates a more rightward inferior structure such as the RVOT freewall. Septal and anterior origins often are biphasic in lead I.
15. If aVL is isoelectric or positive the inferior portion of the RVOT close to the Bundle of His and right bundle should be considered.
16. The mitral annulus This is a less common location for ectopy when compared with the outflow tracts. The ECG typically shows a RBBB pattern with very early precordial transition with in V1 or between V1 and V2 an a positive concordance in the precordial leads due to the relative posterior locations of the mitral annulus relative to the ECG lead positions. For anterolateral origins leads II, III and aVF tend to be positive and leads I and aVL tend to be negative. For posterior or posteroseptal foci leads II, III and aVF tend to be negative and positive in leads I and aVL. More septal origins tend to be narrower than LV free wall locations.

Mitral annular PVC's can be ablated with a success as high as that of outflow tract tachycardia [14]. Mapping can be performed using either a transseptal or retrograde approach. It is also worth mapping within the coronary sinus as the focus may be epicardial.

Chapter 10
Anti-arrhythmic Drugs

Benedict M. Glover and Paul Dorian

Abstract Anti-arrhythmic drugs (AAD's) alter the electrical properties of the heart principally by either prolonging the cardiac action potential, decreasing conduction velocity, reducing focal automaticity or a combination of these effects. Despite the fact that a large number of AAD's were initially developed for ventricular arrhythmias the most common current indication is actually AF.

Although the majority of these drugs act relatively specifically on certain receptors the overall general distribution of these receptors throughout the ventricular and atrial myocardium may result in unwanted effects such as Torsades de Pointes (TdP) predominantly with class IA and class III drugs, prolongation of AV conduction, QRS widening and monomorphic VT with class IC drugs.

A meta-analysis of 44 trials involving 11,322 patients showed that all AAD's were associated with an increased risk of proarrhythmia with the exception of amiodarone and propafenone (Lafuente-Lafuente et al. Arch Intern Med 166:719–28, 2006). Although amiodarone is a very useful agent in the treatment of both atrial and ventricular arrhythmias its use is often limited as a result of its potential long term non-cardiac side effects which limit its use (Rothenberg et al. Heart Dis Stroke 3:19–23, 1994).

More recently, "atrial selective" AAD's have been developed which may have improved efficacy with better side effect profile. Additionally some drugs (such as renin-angiotensin aldosterone inhibitors and anti-inflammatory agents) may affect the underlying substrate and be indirectly antiarrhythmic.

Table 10.1 Classification of current anti-arrhythmic drugs as well as inotropic effects on the ventricle and potential pro-arrhythmic effects

Class	Examples	Mechanism	Inotropic effect	Pro-arrhythmia
Ia	Procainamide Quinidine	Inhibition of intermediate Na^+ channel	Negative	QRS widening and VT
Ib	Lidocaine Mexilitine	Inhibition of fast Na^+ channel	Negative	VT
Ic	Flecainide, propafenone	Inhibition of slow Na^+ channel	Negative	1:1 AV conduction
II	B blockers	B Adrenoceptor blockade	Negative	Bradycardia
III	Amiodarone Sotalol	K^+ channel blockade	Neutral	Sotaolol: bradycardia, ↑QT, torsades
IV	Ca channel blockers	Ca^{2+} channel blockade	Negative	Bradycardia

Mechanisms of Action: An Overview

Although the majority of AAD's have multiple effects on either the AP directly or by autonomic modulation, their actions can generally be classified into groups according to the predominant mechanism or resulting electrophysiological effect. This classification is called the Vaughan Williams system which was subsequently modified by Singh and Harrison (Table 10.1). It should be remembered that most AAD's have properties belonging to more than one group.

Drugs with Class I action act by blocking the fast sodium channels that are responsible for phase 0 of the AP thus affecting its slope and amplitude. These drugs are subdivided according to the rate of binding and dissociation from the sodium channel. Class IB mechanism of action is associated with the most rapid onset of action and dissociation, IA has intermediate activities and IC the slowest (Fig. 10.1).

These differences result in clinically relevant differences as a function of heart rate- drugs with slowest rates of binding and unbinding have "rate dependent properties" and the effect increases at high heart rates, not seen with the class 1b mechanism of action. As well as their effects on the slope of rapid depolarization, class I agents also have different effects on the repolarization (and APD) and thus refractory periods. Class IA property is generally associated with an increase, Class IB with a shortening (invitro) and Class IC have no effect on the APD.

Class II mechanism of action is the property of blocking beta adrenergic receptors. The primary consequence is to antagonize the effect of circulating, neurally or locally released catecholamines, with effects on all cardiac tissues and to prolong the phase 2 and 3 (after chronic use) of the AP and thus lengthen the effective refractory period.

Class III agents such as sotalol and amiodarone prolong the APD principally by inhibition of the potassium channels.

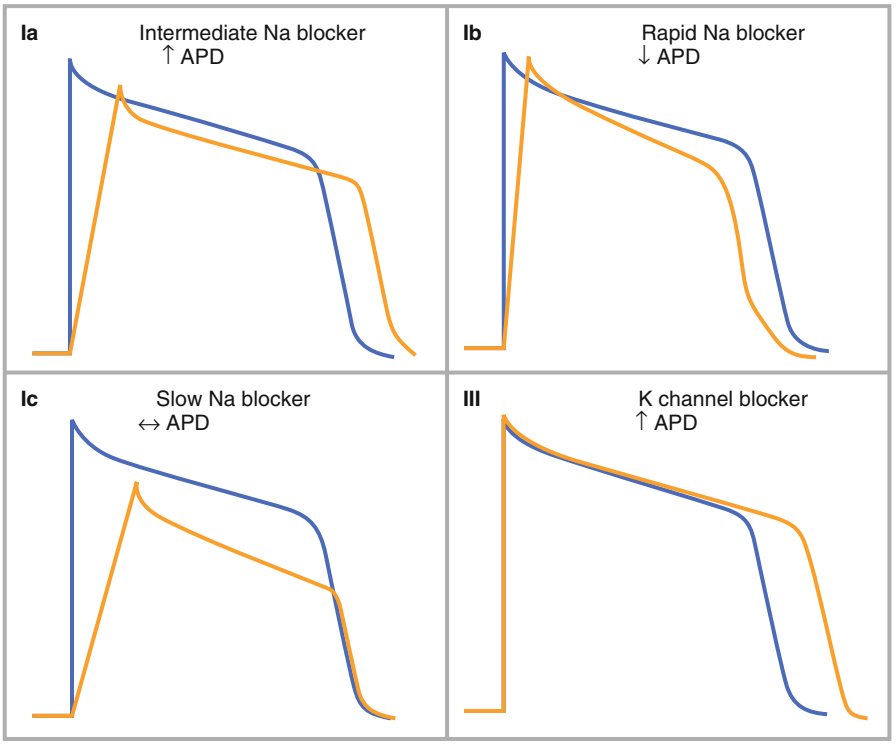

Fig. 10.1 Schematic of the effects of Class Ia, Ib, Ic and Class III AAD's on the cardiac AP

Class IV action inhibits the slow calcium current and therefore depress phase II and III of the AP in certain tissues primarily the SN and AV nodes.

Class IA Antiarrhythmics

Procainamide is conjugated to the active metabolite N-acetylprocainamide at a rate determined by whether the patient is a rapid acetylator [3, 4]. Although it was previously used for the treatment of atrial and ventricular arrhythmias its use is now largely reserved for the treatment of VT. It is also used for the acute management of haemodynamically stable pre-excited AF in the WPW syndrome (Class IIb indication) [5]. Proarrhythmia occurs in up to 9 % of cases [6] and like all class IA drugs its use has been severely restricted due to the associated risk of TdP particularly in patient with bradycardia and left ventricular hypertrophy (LVH) [7]. In general terms the risk of TdP for all class IA and some class III AAD's include a long baseline QT interval, a family history of Td, female gender, bradycardia, renal impairment (for renally excreted drugs) and a low potassium or magnesium [8].

Procainamide can also increase the ventricular rate in patients with uncontrolled AF or flutter (Class IA effect). This occurs as a result of slowing the fibrillation or flutter rate as well as increasing the likelihood that a given impulse will pass through the AV node due to the direct vagolytic action of procainamide. Thus, conduction through the AV node must be slowed and the ventricular response controlled before therapy with procainamide is initiated in these disorders. Nearly all patients will develop a positive antinuclear antibody, with a lupus-like syndrome in approximately one-third of patients taking the drug for more than one year [9]. Severe neutropaenia has been reported with long term use of oral procainamide [10]. There is limited evidence to suggest that procainamide is comparable to or superior to lidocaine in terminating monomorphic VT [11]. It is also commonly used for pharmacological testing in Brugada risk stratification.

Quinidine has similar properties and side effects to procainamide but owing to its additional effect on the the transient outward current there has been a some limited interest in this drug in patients with Brugada syndrome. Although there is some evidence to support a degree of efficacy in maintaining sinus rhythm following an electrical cardioversion for AF [12] it carries significant pro-arrhythmic side effects with an increased associated mortality [13]. The incidence of TdP reported with quinidine use varies from 0.5 to 8 % [14] and like all class IA drugs the QT prolongation tends to occur early and therefore it is recommended that it should be initiated in the hospital under continuous ECG monitoring [15]. Modest QT prolongation is relatively common while excessive prolongation is unusual and generally indicates toxicity. Like all AAD's in this group it is contraindicated in the presence of structural heart disease and LVH and is not a first-line agent for the long-term management of any atrial arrhythmia. One of the more common reasons for discontinuation of the drug is gastrointestinal side effects such as nausea, reduced appetite, an abnormal bitter taste and abdominal discomfort are relatively common occurring in approximately one third of patients.

Although the use of quinidine in cases of asymptomatic Brugada syndrome [16, 17] seems counterintuitive given that other sodium channel blockers are used for provocation; it is thought that the potential beneficial effect may be due to blockade of the transient outward current Ito thus preventing phase II reentry and VF [18]. Discontinuation of quinidine therapy due to predominantly gastrointestinal side effects may occur in approximately one third of patients. A registry of patients with asymptomatic Brugada is currently looking at the effects of quinidine in this population. Overall quinidine is generally not readily available throughout the world except in exceptional circumstances.

Disopyramide has marked anticholinergic effects and thus in theory may prove useful in vagally mediated AF [5]. The evidence for disopyramide in AF however is very weak involving a small study involving 90 patients following a successful electrical cardioversion from AF to sinus rhythm [19]. Following 1 month 70 % of patients receiving disopyramide were in sinus rhythm versus 39 % in the placebo group. It is considered a second or third line agent for suppression of atrial and ventricular arrhythmias and conversion of AF to normal sinus rhythm. Due to its negative inotropic effect it has been used in the treatment of hypertrophic cardiomyopathy

in order to reduce the outflow tract gradient and improve symptoms [20]. Other than the proarrhythmic and negative inotropic effects characteristic to this group the other main adverse effects are related to its anticholinergic effects, including urinary retention, blurred vision, constipation and dry mouth. This drug is therefore rarely used clinically.

Class IB Antiarrhythmics

The two main drugs in IB are lidocaine and mexiletine both of which act predominantly on the ventricular myocardium.

Lidocaine is a short acting intravenous antiarrhythmic which has been used extensively for the management and prophylaxis of ventricular arrhythmias. The initial clinical data for the use of lidocaine was in its ability to suppress PVC's and prevent VF after an acute myocardial infarction [21]. However this practice stopped after data showed an associated increased mortality most likely related to bradyarrhythmias and hypotension [22]. Although one trial has shown an increased prehospital survival with lidocaine [23] other randomised trial comparing lidocaine with amiodarone have shown amiodarone to be superior in terms of return of spontaneous circulation [24] as well as a lower rate of asystole [25]. As a result of this the ALS (UK) guidelines recommend the use of lidocaine only as an alternative if amiodarone is not available.

Mexiletine is structurally similar to lidocaine but has a much higher oral bioavailability and thus is available in an oral preparation. Its main activity occurs in the His Purkinje and ventricular myocardium with minimal effects on the sinus node, atrium and AV node [26, 27]. The most frequent side effects are related to GI disturbances and CNS toxicity. Cardiovascular side effects include hypotension, sinus bradycardia, and worsening of ventricular arrhythmias in 10–15 % of cases [27]. Use of mexiletine has been reported to be associated with an increased mortality [28] but may be used in patients who cannot tolerate amiodarone.

Class IC Action AAD's

The class IC drugs flecainide and propafenone have the slowest onset of action in sodium inhibition and have no effect on action potential duration.

Both flecainide and propafenone have been shown to be relatively similar in terms of efficacy in the management of symptomatic paroxysmal AF in two randomized control trials [29, 30]. Additionally in cases of recent onset AF flecainide has been shown to be effective in termination of the arrhythmia in 90 % of cases [31]. Oral flecainide has been shown to be as effective as the intravenous preparation for acute chemical cardioversion although obviously with a slower onset of action [32].

This fact combined with the large degree of use dependence has lead to the regimen called 'pill in the pocket' in which patients with symptomatic paroxysmal AF self administer a single oral dose of flecainide (generally with a beta blocker) for chemical cardioversion. Although this has been shown to be effective in 94 % of cases with no significant adverse effects, patients in this group were very carefully selected and this strategy is not ideal for many patients with paroxysmal AF [33]. In general if this strategy is to be used patients are usually tested with the identical regimen in hospital to assess for side effects and potential arrhythmias. Despite this 5 % of patients still experience problems such as presyncope, syncope and sinus arrest [34].

Despite the efficacy of class IC drugs their use has been largely limited by safety concerns. They may occasionally convert AF to atrial flutter with 1:1 AV conduction and thus a paradoxical increase in ventricular response rate. This tachycardia occasionally looks like VT particularly when there is QRS widening (also due to the drug) and since they have minimal effects on AV conduction it is recommended that they be used in the presence of an AV nodal blocker such as a beta blocker. However the major concerns regarding these drugs arose from a series of trials showing an increase in cardiovascular mortality in patients with ventricular arrhythmias in the setting of coronary artery disease and other structural heart disease The Cardiac Arrhythmia Suppression Trial (CAST) compared flecainide, encainide, moricine and placebo for the suppression of PVC's in post MI patients [35]. The trial which enrolled 1498 patients was prematurely terminated after showing an increased mortality in patients receiving flecainide and encainide (subsequently withdrawn) primarily due to arrhythmias.

Although propafenone may have a relatively better side effect profile given its additional beta adrenergic blocking effects the Cardiac Arrest Survival in Hamburg (CASH) study, in which 349 survivors of cardiac arrest due to documented VT were randomised to either an ICD, amiodarone, propafenone or metoprolol, showed a significant increase in mortality in patients receiving propafenone [36].

For these reasons, these drugs are contraindicated in the setting of prior myocardial infarction or a history of VT, and relatively contraindicated in the setting of structural heart disease.

Class II Antiarrhythmics

These drugs act by inhibiting sympathetic activity, primarily through beta-adrenergic blockade. This class is subdivided based on the specific adrenergic blockade profile, and associated properties. Propranolol is a first-generation non-selective beta-blocker with equal affinity for the β1 and β2 receptors. At high doses, propranolol may also block sodium channels. Propranolol, although useful in reducing ventricular rate in AF has not been shown to be useful as an atrial anti-arrhythmic' [37].

Metoprolol and bisoprolol are second-generation beta-blockers, which preferentially inhibit β2 receptors and may have more useful atrial antiarrhythmic effects

than propranolol. Bisoprolol has been shown to be similar to sotalol in maintenance of sinus rhythm at 12 months following an electrical cardioversion [38]. Metoprolol, has also been shown to be superior to placebo in maintenance of sinus rhythm as well as a slower ventricular rate during a recurrence [39].

Beta adrenergic blockers have been shown to reduce mortality, likely largely to a reduction in arrhythmic death in most cases, in patients with long QT syndrome [40], survivors of cardiac arrest [41], post myocardial infarction [42] and in patients with impaired LV systolic function [43].

Class III

Class III action AAD's block the potassium channels, thereby prolonging repolarization, the APD, and the refractory period. These changes are manifested on the surface ECG by prolongation of the QT interval. This group includes sotalol, amiodarone, dofetilide, vernakalant and ibutilide.

Sotalol consists of 2 isomers called D and L each of which contribute to the anti-arrhythmic properties. The D isomer blocks the rapid component of the delayed rectifier potassium current (IKr channel) during phase 3 of the AP and thus prolongs the AP duration. The L isomer also prolongs the cardiac AP as well as having a degree of Beta Adrenergic blocking activity. Although a preparation of the D isomer has been developed it has been shown to be associated with an increase in the risk of mortality in patients with impaired LV function and a recent MI or heart failure with a history of prior MI [44]. Therefore that the beta adrenergic blocking effects may also confer an advantage.

Sotalol has been shown to be effective in maintaining sinus rhythm and reducing the incidence of episodes of AF, although not as effectively as amiodarone. The CTAF study randomised patients with a history of AF to sotalol, amiodarone or propafenone [45]. After a mean follow-up of 16 months similar percentages of patients receiving sotalol and propafenone had a recurrence of AF while significantly fewer receiving amiodarone had an AF recurrence.

In clinical practice sotalol is generally used for the control of paroxysmal AF as second or third line agent after flec/propafenone and amiodarone. It has also been shown to reduce the recurrence of sustained ventricular arrhythmias [46, 47] but less than amio (OPTIC study) and can also be considered after amiodarone in terms of reducing ICD discharges.

The most significant risk associated with sotalol is the risk of TdP particularly at slower heart rates. The actual risk of TdP has been reported as approximately 2.5 % at a median follow up of 164 days [48]. This risk is increased in females, patients with a history of heart failure, patients with renal impairment and at high doses of sotalol (greater than 320 mg per day) [48].

Amiodarone was first used as an anti-anginal drug in the 1960s, and its anti-arrhythmic properties were first reported in 1970. The predominant mode of action is class III by blocking the IKr and IKs channels. This results in a reduction in

dispersion of refractoriness, re-entry and proarrhythmia and overall a prolongation of myocardial repolarization homogeneously. Additionally it also blocks sodium channels (Class I effects) and thus reduces conduction velocity, has non selective beta adrenergic blocking effects (Class II) and inhibits the L type calcium channel (Class IV). It causes use dependent potassium channel blockade meaning that as the heart rate increases the refractory period increases incrementally [49].

The onset and mode of action depends on the type of administration. If given intravenously the onset of action is several hours and there is minimal AP prolongation except in the AV node. The oral preparation takes several days and the overall effects are more pronounced after chronic usage.

Amiodarone has been shown to be the most efficacious AAD in the treatment of both AF and VT. The Canadian Trial of AF in which patients with at least one episode of AF were randomized to various antiarrhythmic medications showed that 35 % of patients randomized to amiodarone had a recurrence of AF versus 63 % of patients randomized to either sotalol or propafenone [44]. There was no significant difference in the maintenance of sinus rhythm between those who received either sotalol or propafenone. Given its multichannel effects and minimal negative inotropic effects it is considered relatively safe in patients with impaired LV function and is recommended as first line therapy for the treatment of ventricular arrhythmias unless there is a contraindication [22]. Although amiodarone prolongs the QT interval the risk of torsades de pointes VT is less than 1 % [50].

The most common and significant side effects which limit the longterm use of amiodarone are generally non cardiac and adverse effects have been reported to be as high as 15 % within the first year of treatment and 50 % during long term therapy [50]. It is therefore important that the patient is monitored for side effects as shown in Fig. 10.2.

Amiodarone induced hypothyroidism is more common than thyrotoxicosis. Within the first 3 months of therapy there is an increase in thyroid stimulating hormone (TSH), free T4 and a reduction in free T3. TSH then normalises while T4 and T3 may remain abnormal. The importance of this is that it is generally not useful to check thyroid function within the first 3 months and following this the most useful measure is TSH [50]. Amiodarone induced thyrotoxicosis is less predictable and can occur relatively suddenly at any time during treatment. It can be due either to aggravation of pre-existing thyroid disease or thyroiditis, although often it is difficult to distinguish between these. It is generally recommended that all patients being commenced on long term amiodarone therapy should have baseline TFT's which should be rechecked after 3 months to establish a new baseline and then every 6 months or sooner if clinically indicated [50].

Lung toxicity has been reported as occurring in up to 2 % of patients [50]. Risk factors for pulmonary fibrosis are a prior history of lung disease and a daily dose of amiodarone greater than 400 mg per day [51]. It may present anytime from 1 week following initiation of the drug and is relatively unpredictable and therefore although pulmonary function tests are frequently performed they of limited value.

These and other non cardiac side effects of amiodarone have subsequently lead to the development of the noniodinated benzofuran derivative dronedarone.

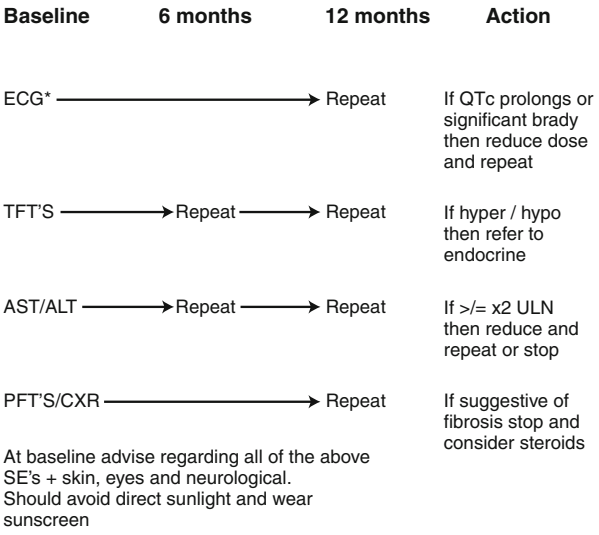

Fig. 10.2 Suggested monitoring for the side effects of long term amiodarone (* Evidence of QTc prolongation, sinus node or AV node conduction abnormalities should prompt close monitoring)

The dose of dronedarone was established in the Dronedarone Atrial Fibrillation Study after Electrical Cardioversion (DAFNE) [52]. Three different doses (800, 1200, or 1600 mg) of dronedarone daily were compared with placebo in patients following a successful electrical cardioversion. 800 mg per day delayed the time to recurrence of AF; 35 % dronedarone versus 10 % placebo at 6 months. Higher doses of dronedarone resulted in better ventricular rate control in patients who converted to atrial fibrillation. Dronedarone was not associated with any thyroid, pulmonary or ocular side effects. Although higher doses of dronedaone were associated with increases in the QT interval, there were no cases of torsades de pointes. The most important side effects associated with the use of dronedarone were gastrointestinal disturbance. Based on these results the dose of 400 mg twice daily was chosen. This dose was studied in patients with either atrial fibrillation or atrial flutter in the twin studies called The European Trial in Atrial Fibrillation or Flutter Patients Receiving Dronedarone for the Maintenance of Sinus Rhythm (EURIDIS) and the American-Australian-African Trial with Dronedarone in Atrial Fibrillation or Flutter Patients for the Maintenance of Sinus Rhythm (ADONIS) [53]. These trials randomised patients with a history of paroxysmal atrial fibrillation or atrial flutter to receive either dronedarone or placebo. Dronedarone increased the time to first recurrence of atrial fibrillation from 53 days in the placebo group to 116 days for those patients receiving dronedarone. Additionally in patients who had a recurrence of atrial fibrillation dronedarone significantly reduced the ventricular rate. A post hoc analysis revealed a 27 % reduction of relative risk of hospitalization and death with dronedarone treatment.

The effect of dronedarone in ventricular rate control for patients with permanent AF was studied in the Efficacy and Safety of Dronedarone for Control of Ventricular Rate (ERATO) [54]. The addition of dronedarone (800 mg per day) to standard rate-control therapy reduced the ventricular rate by 11.7 beats per minute after 2 weeks of treatment and by a mean of 24.5 bpm during exercise.

Dronedarone was studied in patient with moderate to severe left ventricular impairment irrespective of the rhythm in the Antiarrhythmic Trial with Dronedarone in Moderate-to- Severe Congestive Heart Failure Evaluating Morbidity Decrease (ANDROMEDA) [55]. Patients had a left ventricular ejection fraction less than 35 % and had been hospitalized with new or worsening heart failure. They also had to have had at least one episode of shortness of breath on minimal exertion or at rest (NYHA III or IV) or paroxysmal nocturnal dyspnoea within the month prior to admission. There was no restriction related to renal function.

After a median follow up period of 2 months, a significantly higher mortality rate was reported with dronedarone treatment (8.1 %) as compared with placebo (3.8 %). The worse the left ventricular function the higher the risk of death. This has lead to the avoidance of dronedarone in patients with severe LV dysfunction and heart failure.

To help address some of these issues a further study was carried out looking at patients with stable AF and at least one cardiovascular risk factor. The Assess the Efficacy of Dronedarone for the Prevention of Cardiovascular Hospitalization or Death from Any Cause in Patients with Atrial Fibrillation/Atrial Flutter (ATHENA) [56] had the composite primary end point of all-cause mortality and cardiovascular hospitalization. 4628 patients with a history of paroxysmal or persistent AF/atrial flutter were randomised to dronedarone 400 mg twice a day versus placebo with 12 months of follow-up. The use of dronedarone was associated with a significant 27 % reduction in the primary end point of death or cardiovascular hospitalization. The most frequently reported adverse effect of dronedarone was gastrointestinal, principally nausea and diarrhoea that in several cases led to drug discontinuation. The reduction in hospitalisations was a major reason for dronedarone gaining clinical approval in North America and more recently lead to a second draft guidance by National Institute for Clinical Excellence (NICE) revising its original recommendation that the drug should not be used to treat AF. It is therefore recommended that dronedarone should be considered as a second-line treatment in patients with additional cardiovascular risk factors whose AF has not been controlled by first-line therapy (usually including beta blockers).

Class IV

Verapamil and diltiazem block the L-type calcium channel and principally prolong the atrioventricular nodal refractory period. The VERDICT study showed no benefit in maintenance of sinus rhythm of verapamil over digoxin [57]. Two large trials which examined the use of verapamil in the maintenance of sinus rhythm following an electrical cardioversion both showed verapamil combined with quinidine was similar in efficacy to sotalol with a higher incidence of TdP in the sotalol group [58, 59]. Due to its negative inotropic effects verapamil should be used cautiously in patients with left ventricular dysfunction. As verapamil also suppresses sinus node automaticity it should also be avoided in sick sinus syndrome. Both verapamil and

diltiazem are similar in efficacy and side effects (other than constipation associated with verapamil). Calcium channel blockade may be a reasonable choice of drug for ventricular rate control in patients with preserved LV function and can be considered as an alternative to B blockers.

AAD's Not in the Vaughan Williams Classification

Some drugs such as digoxin, adenosine and ivabradine do not fit into the traditional Vaughan Williams classification.

Digoxin acts directly on the myocardium in order to increase the concentration of intracellular sodium and thus account for its positive inotropic effects. Of interest however this as well as its vagotonic effects actually shortens the atrial effective refractory period and therefore may actually increase the potential to develop AF in patients who are in sinus rhythm [60]. Its role in AF is therefore principally to slow AV conduction (through its vagotonic effects) and thus reduce the ventricular rate. It is not an ideal drug for acute ventricular rate control as the onset of action is 4–6 h and may not be as effective if the rate is partially sympathetically-driven. It continues to have an important role in the management of AF and is particularly effective when combined with a beta adrenergic blocker due to synergistic effects [5]. Recent data suggests that it may have deleterious effects and therefore its use if now relatively limited.

Adenosine is a metabolite of adenosine triphosphate which results in slowing of AV nodal conduction, shortening of the atrial myocardial refractory period and depression of sinus node automaticity [61]. Adenosine is highly effective in terminating supraventricular arrhythmias in which the AV node forms part of the reentrant circuit such as AV nodal reentry and orthodromic reciprocating tachycardia.

Additionally it can be used for diagnostic purposes such as transiently slowing AV conduction in SVT to identify the underlying rhythm and may also be helpful in differentiating SVT from VT (although very rarely adenosine may terminate a specific type of VT). Side effects such as facial flushing (due to cutaneous vasodilation), dyspnoea, and chest pressure have been reported to occur in about 30 % of patients [62]. Given the short half life of adenosine these side effects generally last less than 60 s. The downside to the short duration of action is that in some cases arrhythmias recur after several minutes after termination with adenosine [63].

Ivabradine is a novel selective inhibitor of the If channel in the SA node. It therefore reduces the sinus rate with no effect on either the AV node or intraventricular conduction times [64]. Although its principle clinical use is for symptom relief in patients with chronic stable angina it may also have a role in patients with an inappropriate sinus tachycardia. A recent study examining its use in 18 symptomatic patients with an inappropriate sinus tachycardia (defined as a nonparoxysmal tachyarrhythmia with a P-wave morphology and endocardial activation identical to sinus rhythm and an excessive increase of heart rate in response to minimal physical activity and emotional stress, and nocturnal normalization) showed a significant reduction

in heart rate on Holter and exercise stress tests [65]. Although this was a small study there may be a role for this drug in these patients where other drug therapies can be relatively ineffective and ablation therapy may carry some significant risks.

The Future: Novel AAD's

Given the significant cardiac and non-cardiac side effects associated with current AAD's there has been a huge interest in the development of novel 'atrial selective' drugs for the treatment of AF. These drugs can be broadly divided into amiodarone derivatives such as dronedarone, PM101 and budiodarone, selective Iks blockers such as HMR1556, atrial repolarization-delaying agents such as vernakalant and sodium channel blockers such as ranolazine.

Mention it is approved for angina (US) and being tested for AF (with dronedarone) and ICD shocks (NIH sponsored RAID study).

Atrial Repolarization Delaying Agents: Vernakalent

Vernakalant predominantly targets early-activating K+ channels and frequency-dependent Na+channels in the atria. It has been shown to have an efficacy of 52 % in the acute conversion of recent onset AF compared to a 4 % success rate with placebo [66]. More recently the results of the AVRO trial comparing vernakalant with amiodarone was presented. This randomised double blind multicentre superiority trial in 254 adult patients with AF showed that vernakalant has a higher efficacy for the conversion of AF as well as a greater rate of symptom relief (51.7 % converted with vernakalant versus 5.2 % with amiodarone). Treatment with vernakalant resulted in a rapid conversion to sinus rhythm, with a median conversion time of 11 min. Additionally it is well tolerated and appears to be relatively safe with no cases of ventricular arrhythmias or drug related deaths. This drug is currently under consideration for clinical approval in Europe and North America. The main side effects associated with its use appear to be dysgeusia (30 %), transient sneezing (17 %), hypotension (5 %) and bradycardia (5 %).

Sodium Channel Blockers: Ranolazine

Ranolazine has been shown to be effective as an anti-anginal agent when added to standard medical therapy most likely through various mechanisms but predominantly through its ability to inhibit the inward sodium current. In a similar mechanism it has been postulated that this may have anti-arrhythmic effects in the atria where rapid atrial rates during AF may result in oxidative stress and atrial myocardial

ischaemia. The Metabolic Efficiency with Ranolazine for Less Ischaemia in Non-ST-elevation acute coronary syndrome— Thrombolysis in Myocardial Infarction (MERLINTIMI 36) trial compared ranolazine with placebo in 6560 patients hospitalized with acute coronary syndromes. A significant reduction in tacharrhythmias (SVT and VT) was noted in patients commenced on ranolazine versus placebo on 7 day continuous cardiac monitoring [67]. There was no effect on sustained arrhythmias such as AF and VT and no overall effect on mortality or recurrent ischaemia. Further clinical studies are required to assess the clinical utility of ranolazine as an AAD.

Important Points

1. Anti-arrhythmic drugs alter the electrical properties of the heart principally by either prolonging the cardiac AP, decreasing conduction velocity, reducing focal automaticity or a combination of these effects.
2. The Vaughan Williams classification categorizes anti-arrhythmic drugs into groups according to their main mechanism of action. These are:

   Class I action block the fast sodium channels which are responsible for phase 0 of the action potential thus affecting its slope and amplitude. These drugs are subdivided according to the rate of binding and dissociation from the sodium channel. Class IB mechanism of action is associated with the most rapid onset of action and dissociation, IA has intermediate activities and IC the slowest.

   Class II action block beta adrenergic receptors prolonging the phase 2 and 3 (after chronic use) of the action potential and thus lengthen the effective refractory period.

   Class III agents prolong the action potential duration principally by inhibition of the potassium channels.

   Class IV action inhibits the slow calcium current and therefore depress phase II and III of the AP in certain tissues primarily the SN and AV nodes.

Preface

This book is intended to be a ready resource and guide for the evaluation of common symptoms and syndromes that originate in the primary cardiopulmonary system. It should prove particularly useful in the generation of a working differential diagnosis, consideration of diagnostic approach, and initial management decisions. It is not intended to be a comprehensive resource; rather, it follows the classic "emergency medicine approach" of considering first the worst-case scenario, and then exploring other possibilities quickly and efficiently. The image, video, and audio links embedded in the text should help the learner correlate bedside findings with reference material.

It is our hope that this guide will streamline the diagnostic approach to patients with "thoracic" complaints and make the learner more confident in his or her skills. The focus of this book is on differential diagnosis, confirmation of diagnosis, and essential steps towards initiating treatment. Therapeutic modalities change more rapidly that diagnostic approach and may have evolved since a specific chapter was completed. Treatment should always be guided by the latest literature, but is founded upon solid diagnostic acumen.

Philadelphia, PA, USA — Charles V. Pollack, Jr.

Contents

1 Achalasia 1
Christopher J. Rees, Victoria G. Riese, and Charles V. Pollack, Jr.

2 Acute Coronary Syndrome: Non–ST-Segment Elevation Myocardial Infarction 11
Charles V. Pollack, Jr. and Victoria G. Riese

3 Acute Coronary Syndrome: ST-Segment Elevation Myocardial Infarction 43
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

4 Acute Coronary Syndrome: Unstable Angina 73
Charles V. Pollack, Jr. and Victoria G. Riese

5 Acute Pericarditis 97
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

6 Anomalous Coronary Arteries 113
Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

7 Anxiety 125
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

8 Aortic Regurgitation 133
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

9 Aortic Stenosis 149
Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

10 Aspiration 169
Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

11 Asthma 185
Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

12 Atrial Fibrillation 201
Charles V. Pollack, Jr., Melissa Platt, and Victoria G. Riese

13 Bradyarrhythmias 213
Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

14 Bronchiectasis 233
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

15 Bronchiolitis 247
Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

16 Carbon Monoxide Poisoning 259
Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, Victoria G. Riese, and Jaime Friel Blanck

17 Chest Neoplasms 269
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

18 Chronic Obstructive Pulmonary Disease 277
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

19 Cor Pulmonale 297
Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

20 Costochondritis 311
Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

21 Cyanide Poisoning 319
Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

22 Cyanotic Congenital Heart Disease 327
Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

23 Cystic Fibrosis 339
Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

24 Diabetic Ketoacidosis 355
Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

25 Duchenne Muscular Dystrophy 379
Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

26 Epiglottitis 391
Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

27 Esophageal Rupture 405
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

28 Esophagitis 417
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

29 Foreign Body Aspiration 427
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

30 Gastroesophageal Reflux Disease 441
Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

31 Goiter 451
Christopher J. Rees, Charles V. Pollack, Jr., and Jaime Friel Blanck

32 Heart Failure 471
Charles V. Pollack, Jr. and Victoria G. Riese

33 Hemoptysis 493
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

34 Herpes Zoster 505
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

35 Hiatal Hernia 515
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

36 Hypertension 525
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

37 Hypertrophic Cardiomyopathy 545
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

38 Idiopathic Pulmonary Fibrosis 557
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

39 Infective Endocarditis 575
Christopher J. Rees, Charles V. Pollack, Jr., and Jaime Friel Blanck

40 Interstitial Lung Disease 595
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

41 Ischemic Cardiomyopathy 613
Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Jaime Friel Blanck

42 Kawasaki Disease 625
Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

43 Laryngospasm 643
Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

44 Mallory-Weiss Syndrome 653
Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

45 Mediastinal Masses 661
Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

46 Mediastinitis 669
Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

47 Mitral Valve Prolapse 679
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

48 Mitral Valve Regurgitation 693
Charles V. Pollack, Jr. and Jaime Friel Blanck

49 Mitral Valve Stenosis 707
Charles V. Pollack, Jr. and Jaime Friel Blanck

50 Myocarditis 719
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

51 Neuromuscular Disease: Myasthenia Gravis, Guillain-Barré, Amyotrophic Lateral Sclerosis 743
Charles V. Pollack, Jr. and Jaime Friel Blanck

52 Noncardiogenic Pulmonary Edema 759
Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

53 Peptic Ulcer Disease 769
Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

54 Pericardial Effusion 779
Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Jaime Friel

55 Pleural Effusion 797
Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

56 Pleurisy 809
Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

57 Pneumoconiosis 819

Chapter 1
Achalasia

Christopher J. Rees, Victoria G. Riese, and Charles V. Pollack, Jr.

Name and Synonyms

Achalasia

Incidence/Epidemiology

- Achalasia is a rare disease with an annual incidence of 1–2/100,000 persons.
- It affects men and women with equal frequency.
- It usually presents between the ages of 20 and 40, but may occur at any adult age.
- Onset before adolescence is rare.

Differential Diagnosis

- Achalasia is the most common motility disorder of the esophagus.
- It most often causes dysphagia (difficulty swallowing, as opposed to odynophagia—painful swallowing), so the differential is the differential for dysphagia.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_1

- Other diseases that may present with dysphagia and associated esophageal dilatation (secondary achalasia) include gastric cancer; infiltrative diseases such as amyloidosis, sarcoidosis, eosinophilic gastritis, and neurofibromatosis; and infections such as Chagas disease in South America.

Pathophysiology and Etiology

- Achalasia is a motility disorder of the esophagus; the cause is unknown.
- Histopathologically, achalasia is associated with degeneration of neurons in the myenteric plexus of the esophageal wall near the lower esophageal sphincter (LES). There is also an associated inflammatory response with an influx of inflammatory cells.
- The degeneration is most marked within the inhibitory neurons that allow for relaxation of the LES. This leads to a sustained contraction/increase in tone of the LES, resulting in an increase in LES pressure.
- Degeneration of the inhibitory neurons within the myenteric plexus in the lower two thirds of the esophagus affects the smooth muscle and causes aperistalsis.
- The cause of the degeneration is unknown. It has been ascribed to autoimmune phenomenon and sometimes to chronic viral infections from herpes simplex virus, measles virus, and HSV-1, but there is no conclusive evidence for any of these putative mechanisms.

Presentation

Typical/"Classic"

- Dysphagia (difficulty with swallowing) is the most common presenting symptom of achalasia, occurring in about 90 % of patients. Typically, the dysphagia is to solids and liquids equally.
- Most patients (about 75 %) also report regurgitation of undigested food. The regurgitated food remains in the esophagus, so usually there is no "acid taste" as in reflux. This has been described as a "bland reflux."
- Many patients describe an epigastric or retrosternal fullness after eating that may be severe enough to provoke attempts to induce vomiting, leading to confusion with eating disorders.
- Other commonly reported symptoms include difficulty belching, substernal chest pain associated with reflux, and frequent hiccups.
- Symptoms usually progress gradually. The mean time from symptom onset until diagnosis is about 5 years. This reflects the insidious nature of the symptoms, more than any particular difficulty in diagnosis.

- Some patients are noted to perform mechanical maneuvers (raising the arms above the head, standing erect and hyperextending the back) to help clear the esophagus. These actions may be noticed more by family members.

Atypical

- In retrospect, most patients will have years of somewhat typical symptoms before presentation.
- Most patients will have been treated for gastroesophageal reflux (GERD) before consideration of the diagnosis.
- Patients may present with chest pain, especially with eating. This may have been considered esophageal spasm and not responded to treatment.

Primary Differential Considerations

- Other causes of dysphagia should be considered, including
  - Esophageal tumors
  - Reflux /GERD
  - Connective tissue disorders, such as systemic sclerosis
  - Esophageal perforation
  - Esophageal spasm or stricture
  - Gastric cancer that involves the lower esophagus
  - Much rarer considerations:
    - Chagas disease
    - Plummer–Vinson syndrome

History and Physical Exam

Findings That Confirm Diagnosis

- The history usually is very suggestive of the diagnosis, although there are no absolutely confirmatory findings on history and physical exam. Physical exam usually is normal, although patients may have unintended weight loss.
- Confirmation is with esophageal manometry.

Factors That Suggest Diagnosis

- The historical features as described above suggest the diagnosis.
- An especially suggestive historical feature is dysphagia to solids and liquids equally.

Factors That Exclude Diagnosis

- Early in the course of illness, esophageal manometry may be nondiagnostic, so a high index of suspicion needs to be maintained if the symptoms continue or progress.

Ancillary Studies

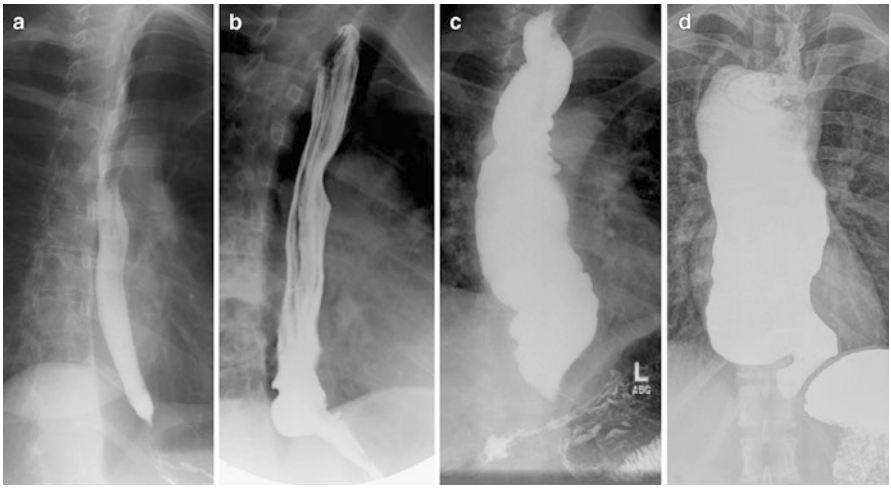
Laboratory

- Lab tests generally are not helpful in the diagnosis.

Imaging

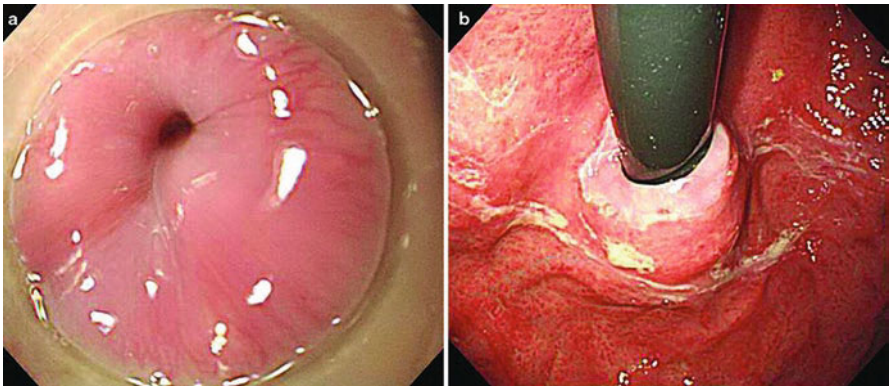
- Chest x-ray may demonstrate widening of the esophagus or mediastinum, but more commonly is normal, especially early in the disease course.
- Barium swallowing studies may be helpful in suggesting the diagnosis, especially later in the course of illness.
- Classically, the barium esophagram demonstrates a proximally dilated esophagus that narrows to a contracted gastroesophageal junction, giving the classic "bird-beak" appearance of the esophagus.

Classic "bird-beak" appearance of the esophagus on barium esophagram in achalasia. [Mittal R. Esophageal motor disorders. In: Orlando RC, editor. Atlas of esophageal diseases. 2nd ed. Philadelphia: Current Medicine; 2002. p 163–78.]



Examples of progressive dilation of the esophagus in different patients with achalasia. a Normal diameter esophagus leading to a bird's beak at the LES. b Minimal esophageal dilation (from 4 to 7 cm). c Progressive esophageal dilation (from 7 to 10 cm) with preserved esophageal axis. d Greater dilation (>10 cm) and initial sigmoidal course of the distal esophagus. [From article: A controversy that has been tough to swallow: is the treatment of achalasia now digested? J Gastrointest Surg. 2010 Feb;14 Suppl 1:S33-45. https://doi.org/10.1007/s11605-009-1013-5, at http://link.springer.com/article/10.1007%2Fs11605-009-1013-5; by Garrett R. Roll, Charlotte Rabl, Ruxandra Ciovica, Sofia Peeva, Guilherme M. Campos, © The Author(s) 2009; licensed under Creative Commons Attribution Noncommercial License https://creativecommons.org/licenses/by-nc/2.0/] *Caption from original*

- Other suggestive findings on barium study include a dilated esophagus, aperistalsis of the esophagus, and poor/delayed emptying of the barium into the stomach.
- Barium studies may be falsely negative in up to one third of cases.
- The diagnosis usually is confirmed by esophageal manometry, which is usually performed at specialized, experienced centers.
- Currently, the procedure of choice is high-resolution manometry (HRM) with or without esophageal pressure topography (HRMEPT).
- The classic finding on manometry is aperistalsis of the distal two thirds of the esophagus with incomplete relaxation of the LES. Increased pressure within the LES is a supportive finding but is not diagnostic.
- HRMEPT allows subtyping of achalasia, which may help in deciding treatment.
- Endoscopy (usually done when considering esophagitis, peptic ulcer disease, or gastritis in the diagnosis) usually is normal, though itmay demonstrate a dilated esophagus with retained products.



Endoscopic appearance of achalasia. (**a**) Sustained contraction of the lower esophageal sphincter as viewed from the proximal esophagus. (**b**) Retroflexed view of the LES from the stomach. [Park JM. Miscellaneous esophageal diseases. In: Chun HJ, Yang S-K, Choi M-G, editors. Clinical gastrointestinal endoscopy: a comprehensive atlas. Heidelberg: Springer. 2014. p. 87–98.] *Caption adapted from original*

Special Populations

Age

- Achalasia usually presents between the ages of 20 and 40 but may occur at any adult age.
- May be seen in adolescence, but is rare.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first step.
- It is critical to consider malignancy in the differential diagnosis.

Mimics

- Any disease process that presents predominately with dysphagia can mimic achalasia.

- It is important to consider malignancy and other mechanical causes of dysphagia.
- Gastric cancer close to the gastroesophageal junction is a mimic of achalasia that must be considered.
- Space-occupying lesions (such as cancer) usually present with dysphagia that is greater with solids than liquids, but as they enlarge, they may produce dysphagia to both.
- Another diagnosis that may be confused with achalasia when evaluating a patient for dysphagia is myasthenia gravis. Myasthenia usually produces both dysphagia and dysphonia (decrease in tone/quality of voice).

Time-Dependent Interventions

- There are no particular time-dependent interventions in the evaluation of achalasia other than consideration of and evaluation for malignancy.

Overall Principles of Treatment

- Treatment is aimed at reducing the resting pressure of the LES.
- The first step usually is progressive, endoscopy-guided dilatation of the LES.
- If symptoms persist after three attempts at dilatation, or patients cannot tolerate dilatation, surgical myotomy often is performed.
- Patients who are not surgical candidates, or those who decline surgery, may be offered a trial of endoscopically guided direct injection of botulinum toxin into the LES.
- If all other treatments are unsuccessful, or the patient is not a candidate for surgery or endoscopy, a trial of oral nitrates or calcium channel blockers may be attempted.

Disease Course

- Achalasia is a chronically progressive disease; without treatment, esophageal dilatation will continue.
- Ten to fifteen percent of patients will develop end-stage disease even with treatment.
- Up to 5 % eventually may require complete esophagectomy, especially when the esophageal diameter exceeds 6 cm (megaesophagus).
- Patients with achalasia are at increased risk for squamous cell carcinoma of the esophagus. The absolute risk is low, however, so endoscopic surveillance is not recommended.

Chapter 2
Acute Coronary Syndrome: Non–ST-Segment Elevation Myocardial Infarction

Charles V. Pollack, Jr. and Victoria G. Riese

Name and Synonyms

Non–ST-Segment Elevation Myocardial Infarction

- NSTEMI, subendocardial MI, non-Q-wave MI (NQMI), troponin-positive ACS

Incidence/Epidemiology

- In the middle of the continuum of diagnoses collectively called acute coronary syndrome (ACS)—between unstable angina (UA) and ST-segment elevation MI (STEMI).
- More common than STEMI.

	STEMI	NSTEMI/UA
Pathogenesis	Fully occlusive thrombus	Less than fully occlusive thrombus
Incidence		Higher than that of STEMI
Patient profile		Older; higher co-morbidity (diabetes, renal failure) than STEMI patients
Time course	Minutes to hours	Up to a few days
Clinical manifestations		Similar to STEMI
Imaging studies		Similar to STEMI
EKG	ST elevations	No ST elevations[a]
Biomarkers	Elevated	Elevated
Therapy	See Table 2.54	See Table 2.54
Rehabilitation		Similar to STEMI
Complications		Similar to STEMI
Prognosis		Mortality lower in-hospital, higher at 6 months and 4 years than with STEMI

[a]ST elevations may be seen in Prinzmetal's angina

STEMI and NSTEMI/UA: a comparison. [Adelmann GA. Coronary artery disease. In: Adelmann GA, editor. Cardiology essentials in clinical practice. London: Springer; 2011. p. 23–95. Book https://doi.org/10.1007/978-1-84996-305-3] *Caption from original*

- Incidence varies widely by demographics and risk profiles; patients with NSTEMI tend to be older and have more co-morbidities than STEMI patients.
- Of the more than 1.2 million MIs in United States each year; most are NSTEMI, and as troponin assays become increasingly sensitive, there are fewer cases diagnosed as UA and more as NSTEMI.

Differential Diagnosis

- Includes all other causes of chest pain.
- Includes other causes of "anginal equivalents" in susceptible populations, e.g.:
  - Dyspnea
  - Back pain
  - Jaw pain
  - Shoulder pain
  - Epigastric pain
  - Palpitations
  - Dizziness
  - Weakness
  - Nausea
  - Syncope

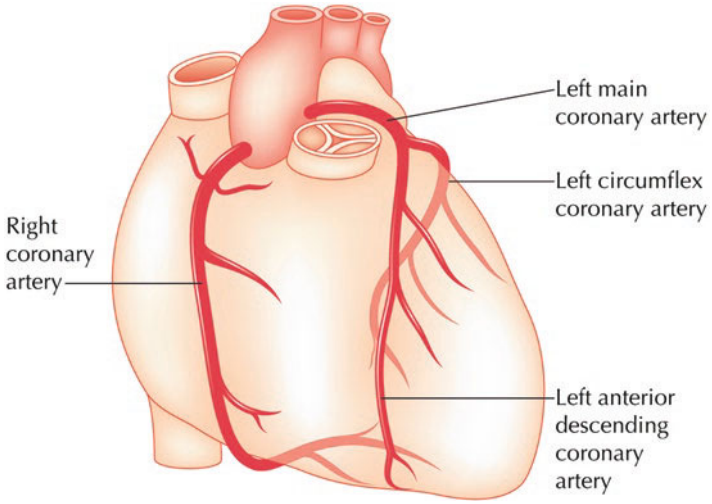
Pathophysiology and Etiology

- ACS is the result of ischemia (diminished blood flow / oxygen delivery) to myocardium.
- If ischemia persists, frank infarction (muscle death) may occur.
- Infarction results in breakdown of cell membranes, allowing release of intracellular proteins (such as myoglobin, troponins, and CPK-MB) into the circulation, where they may be detected in peripheral blood.
- NSTEMI is defined by this protein (enzyme) "leak," and it is that lab finding that differentiates it from UA.
    - Other causes of elevated troponin include:
        - Renal insufficiency
        - Heart failure
        - Pulmonary embolism
        - Septic shock
        - Nonthrombotic causes

Demand ischemia: a mismatch between myocardial oxygen demand and supply in the absence of flow-limiting stenosis (i.e., systemic inflammatory response, hypotension, tachyarrthmias)
Myocardial ischemia in the absence of fixed obstructive coronary disease: an imbalance of the autonomic nervous system and increased catecholamine effect on the myocardial cells (i.e., vasospastic angina, acute stroke or intracranial hemorrhage and subarachnoid hemorrhage)
Direct myocardial damage: cell injury by traumatic or inflammatory process (i.e., pericarditis and myocarditis)
Myocardial strain: volume and pressure overload of both ventricles (i.e., congestive heart failure, pulmonary embolism)

Nonthrombotic mechanisms of troponin elevation in ICU setting. [Lazzeri C, Bonizzoli M, Cianchi G, Gensini GF, Peris A. Troponin I in the intensive care unit setting: from the heart to the heart. Intern Emerg Med. 2008 Mar;3(1):9-16. https://doi.org/10.1007/s11739-008-0089-3] *Caption from original*

- Most NSTEMI occurs as a result of fracture or frank rupture of atherosclerotic plaque in an epicardial artery, but often the artery that is fully occluded is downstream from the plaque and is actually occluded by a platelet aggregate embolism from upstream. It also may occur from incomplete obstruction at the site of plaque and poor collateral circulation upstream.



Normal coronary anatomy. [Achenbach S. Normal coronary anatomy. In: Budoff MJ, Narula J, Achenbach SS, editors. Atlas of cardiovascular computed tomography. Philadelphia: Current Medicine; 2007] *Caption from original*

- Atherosclerosis is a product of diverse inherited and acquired conditions, including:
  - Family history
  - Hyperlipidemia
  - Hypertension
  - Diabetes mellitus
  - Tobacco abuse

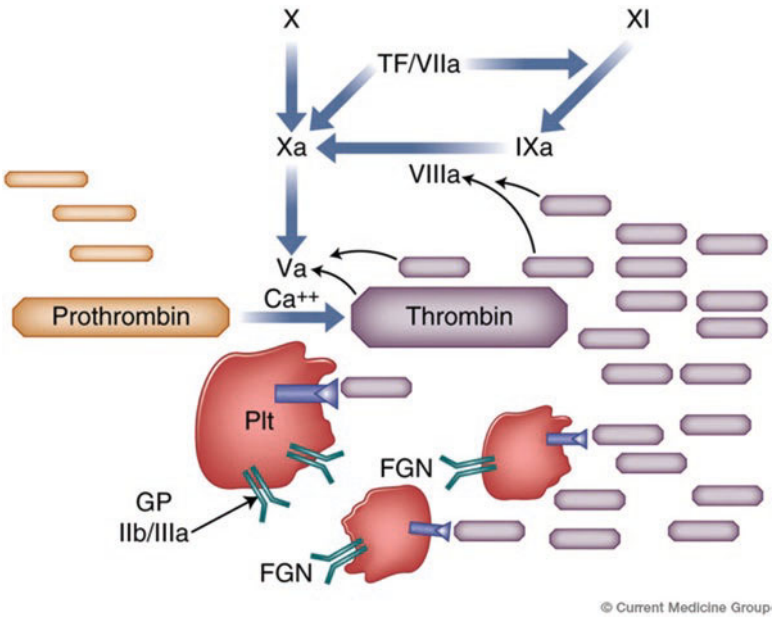
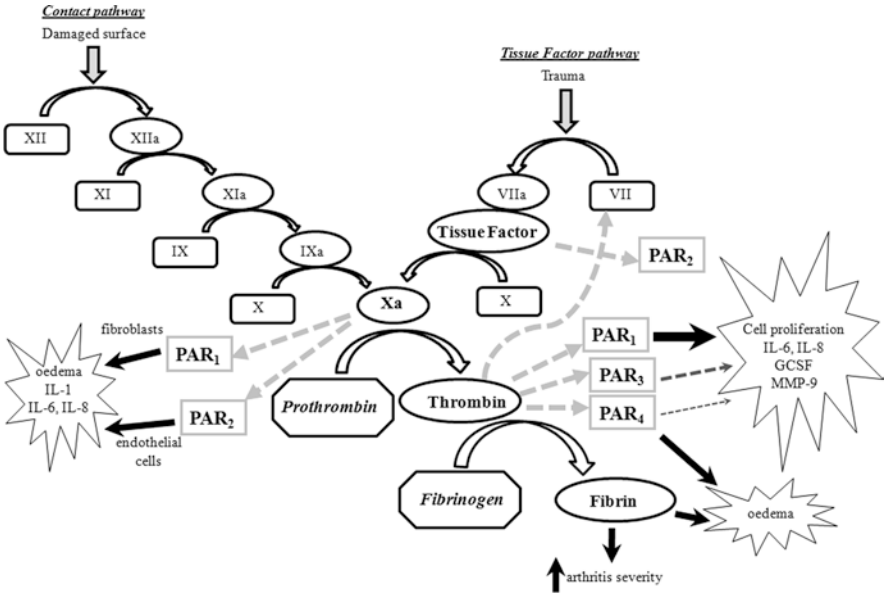
Main known risk factors for atherosclerosis in 16 patients studied. [Watt S, Aesch B, Lanotte P, Tranquart F, Quentin R. Viral and bacterial DNA in carotid atherosclerotic lesions. Eur J Clin Microbiol Infect Dis. 2003 Feb;22(2):99-105. https://doi.org/10.1007/s10096-002-0867-1] *Caption adapted from original*

- Plaque rupture initiates a complex thrombo-inflammatory response locally including activation of:
  - Coagulation



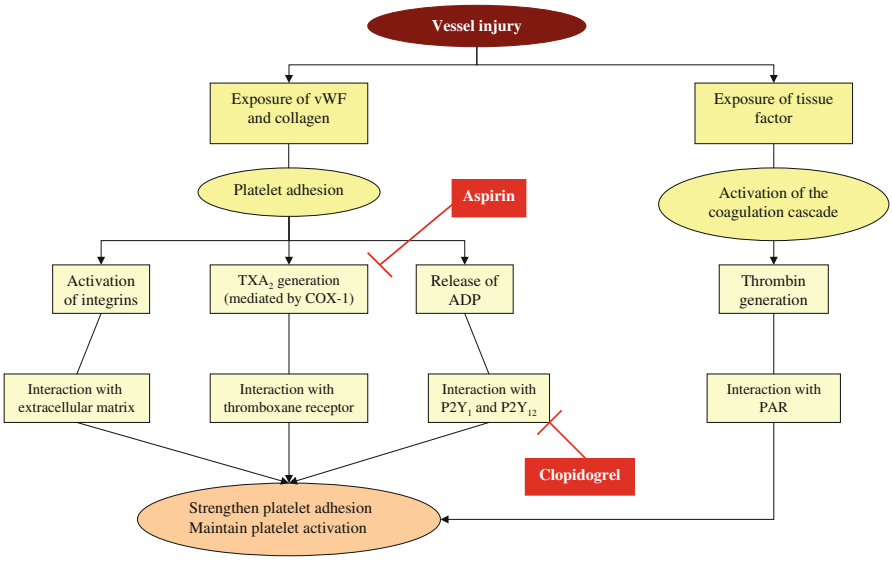
Networking of coagulation cascade and aggregation of platelets (Plt). The extrinsic limb triggers activation of the coagulation cascade when tissue factor (TF) is exposed in a disrupted plaque. Coagulation factor VII is activated (VIIa) and can activate factor X to Xa and promote perpetuation of the coagulation process via the intrinsic limb that results in formation of IXa and VIIIa. The prothrombinase complex of Xa, Va, Ca^{++} forms on a phospholipid surface (*eg*, membrane of a platelet) and converts prothrombin to thrombin. The thrombin that is formed binds to the thrombin receptor on platelets promoting activation and aggregation of platelets, as well as amplifying the coagulation cascade by promoting formation of VIIIa and Va. This diagram depicts the amplification nature of the coagulation process because one molecule of Xa leads to the downstream production of a large number of thrombin molecules (stoichiometric relationship not completely depicted to prevent obscuring the diagram with thrombin molecules). Activated platelets express numerous copies of the active form of the fibrinogen receptor GP IIb/IIIa on their

surface. GP IIb/IIIa recognizes specific amino acid sequences on circulating ligands. One such ligand is fibrinogen (FGN), which has multiple copies of the RGD amino acid sequence and serves to bridge platelets together, promoting formation of aggregates. The more aggregates formed, the greater the surface area for the prothrombinase complex and amplification of the reactions of the coagulation cascade. [Antman E. Acute coronary syndromes. In: Libby P, editor. Essential atlas of cardiovascular disease. Philadelphia: Current Medicine; 2009. ISBN: 978-1-57340-309-2] *Caption from original*



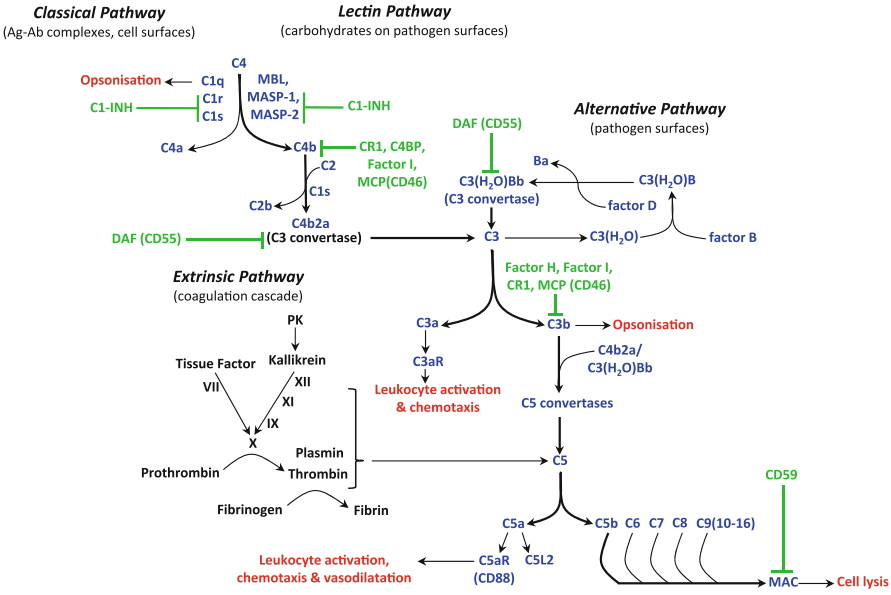
A simplified diagram of the coagulation cascade and its links with PARs and inflammation. Two pathways are involved in coagulation, with the major one being the tissue factor pathway. Most of the coagulation factors are serine proteinases that are present as inactive zymogens (rectangles) that when activated (ovals; lowercase 'a' indicates an active form) can catalyze the next reaction in the cascade. The two pathways converge to activate factor X, thrombin and fibrin. [Russell FA, McDougall JJ. Proteinase-activated receptors and arthritis. In: Vergnolle N, Chignard M, editors. Proteases and their receptors in inflammation. Basel: Springer; 2011. p. 217-42. Book https://doi.org/10.1007/978-3-0348-0157-7] *Caption adapted from original*

- Platelets



Mechanisms of platelet activation. [Ajjan R, Storey RF, Grant PJ. Aspirin resistance and diabetes mellitus. Diabetologia. 2008 Mar;51(3):385-90. https://doi.org/10.1007/s00125-007-0898-3] *Caption adapted from original*

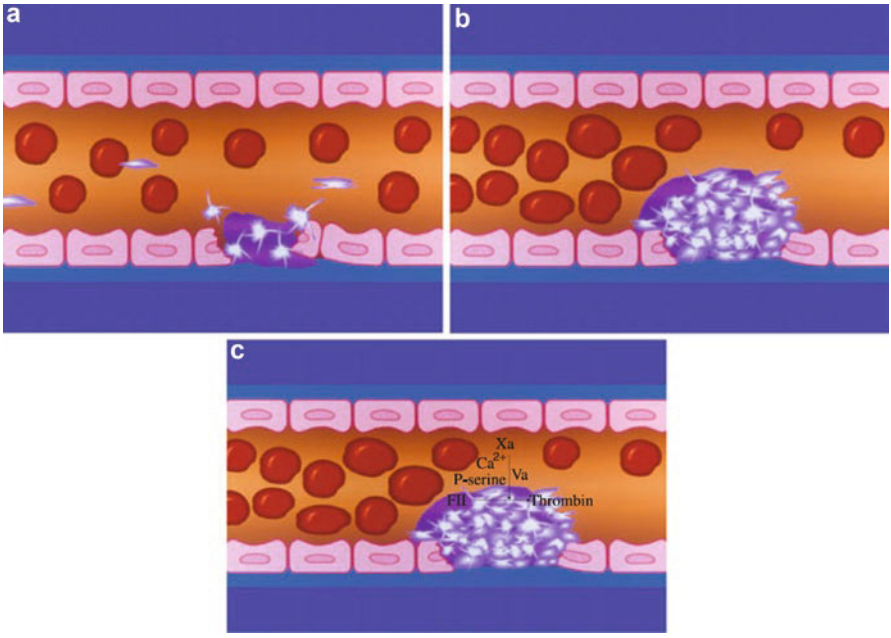
- Complement



Common pathways for complement activation. [From article: Complement activation in the injured central nervous system: another dual-edged sword? J Neuroinflammation. 2012 Jun 21;9:137. https://doi.org/10.1186/1742-2094-9-137

at http://link.springer.com/article/10.1186/1742-2094-9-137 by Faith H Brennan, Aileen J Anderson, Stephen M Taylor, Trent M Woodruff, Marc J Ruitenberg, © 2012 Brennan et al.; licensee BioMed Central Ltd.; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption adapted from original*

- This response results in local aggregation of activated platelets that are subsequently linked via strands of fibrinogen connecting the platelets' glycoprotein IIb/IIIa membrane receptors.



Platelet adhesion at the site of injury and aggregation with one another (a). Platelet plug consolidation (b) and platelets expressing procoagulant activity on their surface with subsequent thrombin generation (c). Procoagulant factors are represented by roman numbers. P-serine, phosphatidylserine. [Tripodi A. Haemostasis abnormalities in chronic liver failure. In: Ginès P, Kamath PS, Arroyo V, editors. Chronic liver failure. New York: Springer; 2011. p. 289-303. - Takayasu's disease
- Kawasaki's disease

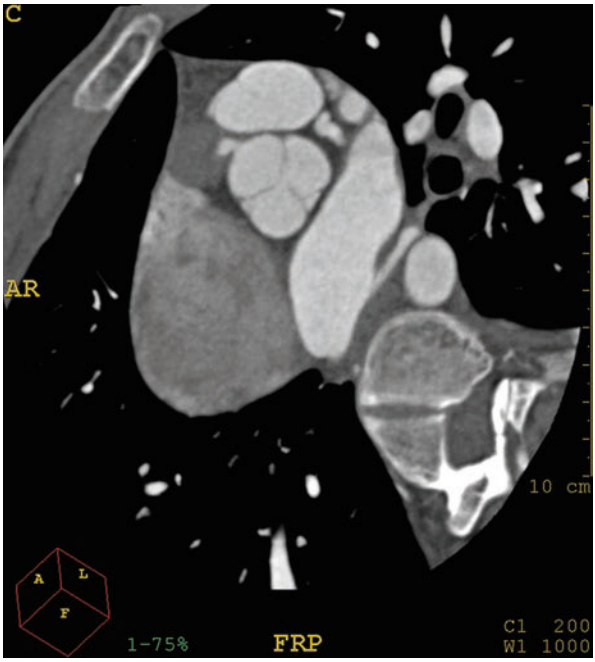

Image obtained from a patient with an acute myocardial infarction caused by thrombosis of a right coronary artery Kawasaki aneurysm (*arrow*). Kawasaki disease results from a mucocutaneous viral infection acquired during childhood. Typically, multiple aneurysms may develop in the coronaries and in other systemic vessels. Thrombosis of these aneurysms may occur later in life. [Garcia MJ. Intracardiac, myocardial and extracardiac abnormalities. In: Budoff MJ, Achenbach S, Narula J, editors. Atlas of cardiovascular computed tomography. Philadelphia: Current Medicine; 2007] *Caption from original*

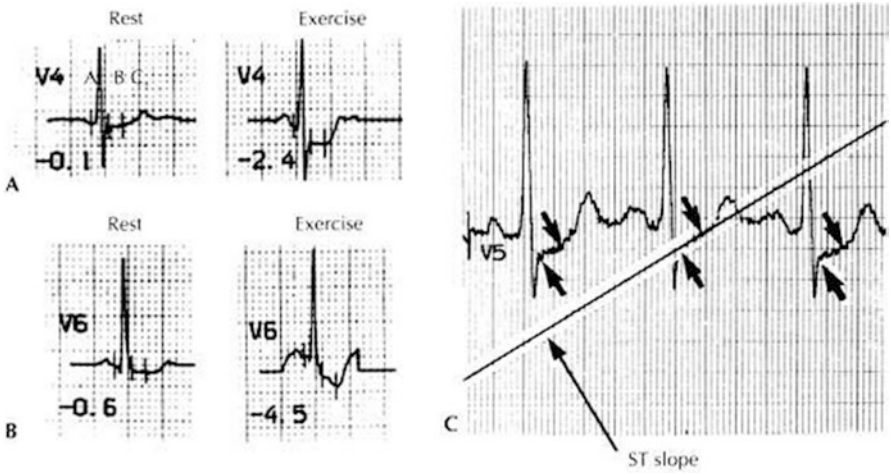
- Cocaine- or methamphetamine-induced vasospasm

Presentation

Typical/"Classic"

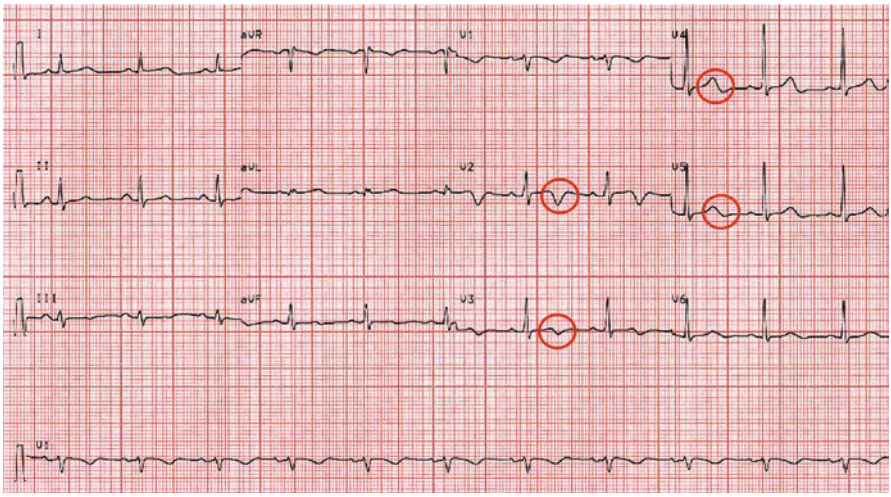
- Pressure-like chest pain starting substernally and radiating toward left shoulder or left jaw.
- Pain is classically associated with diaphoresis, dyspnea, and nausea.
- Pain often accompanied by tachycardia; blood pressure is variable, with very high and very low presenting blood pressures associated with poorer prognosis.

- Pain often starts with exertion; may be improved with rest or with use of nitroglycerin. May also start at rest and often persists >20 minutes before presentation.
- Pain unchanged with movement, positioning, or deep breathing.
- In describing pain, patient may hold clenched fist over chest ("Levine sign").
- Notable for absence of specific, diagnostic ECG findings:
  - Persistent ST-segment elevation is ABSENT
  - ST-segment depression confers higher risk of poor outcomes but IS NOT diagnostic of NSTEMI
    - Particularly high risk when depression is "dynamic"—that is, present when patient is experiencing pain and resolved when that pain is relieved.



A, Example of ischemic horizontal ST-segment depression. The J-point (B) is depressed 0.3 mm relative to the PQ junction (A), and ST-80 (C) is depressed 0.1 mm at rest. During exercise, the J-point and ST-80 are depressed 2.4 mm. The reported net difference in ST-80 depression would be 2.3 mm. B, Example of downsloping ST-segment depression. The second patient reveals 0.6-mm ST-80 depression at rest, which worsens with exercise, resulting in J-point depression of 2.5 mm and ST-80 depression of 4.5 mm during exercise. The reported net difference in ST-80 depression would be 3.9 mm. [Chaitman B. Chapter 2. In: Beller GA. Chronic ischemic heart disease. Philadelphia: Current Medicine; 1995 (Braunwald E, editor. Atlas of heart diseases; vol. 5). ISBN: 1-878132-29-6, 2002-01-23; Chaitman, Bernard; Beller, George; Braunwald, Eugene] *Caption adapted from original*

- T-wave inversion confers higher risk in patients with symptoms of ACS but IS NOT diagnostic of NSTEMI.



Electrocardiogram with T-wave inversions in leads V1 to V4. [From article: Triptans and troponin: a case report. Orphanet J Rare Dis. 2009 Jun 18;4:15. https://doi.org/10.1186/1750-1172-4-15, at http://link.springer.com/article/10.1186/1750-1172-4-15; by Claudia R Weder, Markus Schneemann, © Weder and Schneemann. 2009; licensee BioMed Central Ltd.; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

Atypical

- NSTEMI has been discovered in patients with virtually any complaint localized above the umbilicus.
- "Anginal equivalents" listed above include different distributions of pain (e.g. epigastric, jaw, neck, back) and some presentations that are not painful at all (e.g. palpitations, nausea, syncope).
    - Patients with NSTEMI who present without chest pain as their chief complaint frequently experience delays in diagnosis and therefore delays in treatment.
    - Atypical presentations more common in women, in elderly, and in diabetics.
- Elevated troponin levels are the defining and unifying feature of all NSTEMI presentations. Because of the time required for troponin to leak out of dying myocardial cells, the first troponin assay is often not elevated in patients who present soon after onset of symptoms.

Primary Differential Considerations

- Primary differential considerations include pain mimics to NSTEMI and are diverse, including life-threatening and more benign causes:
  - Aortic dissection
  - Pulmonary embolism
  - Peptic and esophageal disease, hiatal hernia
  - Costochondritis
  - Pneumonia
  - Pneumothorax
  - Pleurisy
  - Anxiety and panic disorders
  - Biliary colic
  - Herpes zoster

	Helpful clinical features
Cardiovascular	
Angina	Retrosternal chest pressure, squeezing, heaviness. Associated with exertion or emotional stress, relieved by rest or nitroglycerin. Usually between 2 and 20 min in duration.
Aortic stenosis	Similar features as for angina, but with late-peaking systolic murmur radiating to carotids. May be associated with syncope or signs of left heart failure.
Pericarditis	Sharp, retrosternal, pleuritic chest pain lasting hours to days. May be associated with friction rub and may be alleviated by leaning forward.
Aortic dissection	Sudden onset of tearing, ripping chest pain radiating to back. Associated with underlying hypertension.
Pulmonary embolism	Ipsilateral pleuritic pain associated with dyspnea, tachycardia, possible cor pulmonale. May have irritative cough or hemoptysis or present with syncope. Usually sudden onset.
Pulmonary	
Pneumonia/ pleuritis/pleural effusion	Pleuritic pain, lateralizing to side of infection/ inflammation. May be associated with fevers, dyspnea, cough. Exam with pleural rub, consolidation, or dullness to percussion.
Asthma/COPD exacerbation	Chest "tightness" associated with more prominent findings of dyspnea, tachypnea and diffuse wheezing.
Spontaneous pneumothorax	Sudden onset of pleuritic pain. Unilateral and associated with dyspnea. More common in thin, young males or patients with emphysematous disease. Decreased breath sounds and hyperresonance on side of pneumothorax.
Chest wall	
Muscle spasm/ strain	Associated with prior increased physical activity/ weight lifting. Pain variable in character but usually reproducible with palpation.

	Helpful clinical features
Costochondritis	Sharp, sudden onset pain that is short in duration. May be reproducible with palpation.
Herpes zoster	Sharp, burning, superficial neuropathic pain. May have allodynia, vesicular rash on exam. Unilateral dermatomal distribution.
Rib fracture	Prior trauma or known metastatic disease of bone. Point tenderness over affected rib(s). Pain is usually pleuritic.
Cervical/thoracic nerve root compression	Intermittent neuropathic pain often associated with neck movement or position. Usually unilateral.
Gastrointestinal	
Mediastinitis/ esophageal rupture	Often preceded by esophageal procedure or forceful vomiting. Pt. may have fever, associated septic shock. Symptoms vary from burning chest discomfort to severe dyspnea.
Esophageal reflux	Burning pain, often associated with nausea, belching. Usually worse at night and after large meals. Alleviated by antacids.
Esophageal spasm	Sudden onset, sharp, retrosternal pain. May be relieved by nitroglycerine and exacerbated by cold liquids. Sometimes associated with dysphagia.
Pancreatitis	Sharp epigastric pain, usually constant and prolonged. Exacerbated by food and often associated with nausea/vomiting. Alcohol and gallstones are risk factors.
Peptic ulcer	Sharp or burning epigastric pain. Often relieved by food or antacids. May be associated with occult GI bleeding or massive acute blood loss.
Psychogenic	
Anxiety/panic disorder	May be unable to distinguish from anginal pain, but usually has atypical features such as prolonged duration and no exertional component. Should be a diagnosis of exclusion at initial workup.

Differential diagnosis of acute chest pain. [McClintic BR, Rosenblatt RL. Approach to the patient with chest pain. In: Bisognano JD, Beck R, Connell R, editors. Manual of outpatient cardiology. London: Springer; 2012. p. 349-71. Book https://doi.org/10.1007/978-0-85729-944-4] *Caption from original*

History and Physical Exam

Findings That Confirm Diagnosis

- None

Factors That Suggest Diagnosis

- Nature and history of pain with presence of risk factors

Factors That Exclude Diagnosis

- None

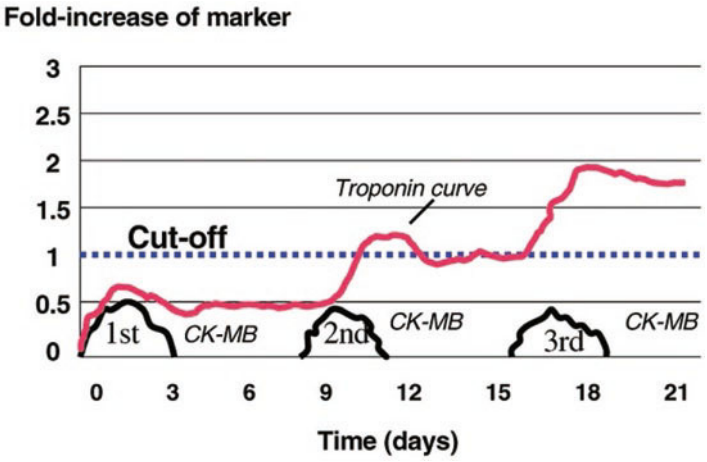
Ancillary Studies

Laboratory

- CBC: no diagnostic findings.
- Electrolytes: no diagnostic findings.
- Renal function: no diagnostic findings, but renal insufficiency/failure is a risk factor for ACS and may complicate treatment.
- Coagulation studies: no diagnostic findings but should be performed before initiation of therapy.
- Cardiac enzymes: Elevation in troponin (I or T) levels is a required part of universal diagnosis of myocardial infarction.
    - Elevated enzyme levels differentiate NSTEMI from UA
    - Time course is critical
        - Depending on specific troponin assay and volume of muscle infarcted, generally takes about 6 hours after onset of symptoms for troponin levels to rise
        - A negative troponin within 6 hours of reliable onset time of symptoms is not particularly helpful
            - If onset time unclear, start at time of presentation
            - Negative troponin does NOT exclude angina

- Positive troponin is *always* helpful, but use caution in interpreting levels in patients with renal insufficiency

- Levels of MB band of CPK enzyme still sometimes used to identify NSTEMI
  - Can sometimes be specifically helpful, e.g., in repeated chest pain presentations within 2-3 days, when troponin levels from first infarct will remain elevated, but CPK-MB may have returned to normal in interim



Summation model. Temporal release of cardiac markers CK-MB and troponins during repetitive episodes of ischaemia causing myocardial necroses in the setting of an acute coronary syndrome. Compared with the release and clearance of CK-MB 48-72 h after each episode (indicated as 1st, 2nd and 3rd), troponin release is cumulative. [From article: Implications of troponin testing in clinical medicine. Curr Control Trials Cardiovasc Med. 2001; 2(2): 75–84. https://doi.org/10.1186/cvm-2-2-075, at http://link.springer.com/article/10.1186/cvm-2-2-075; by Britta U Goldmann, Robert H Christenson, Christian W Hamm, Thomas Meinertz, E Magnus Ohman, © BioMed Central Ltd 2001; Available under Open Access, licensed under Creative Commons Attribution License https://creativecommons.org/licenses/by/2.0/] *Caption from original*

- BNP levels may offer some prognostic significance.

Electrocardiography

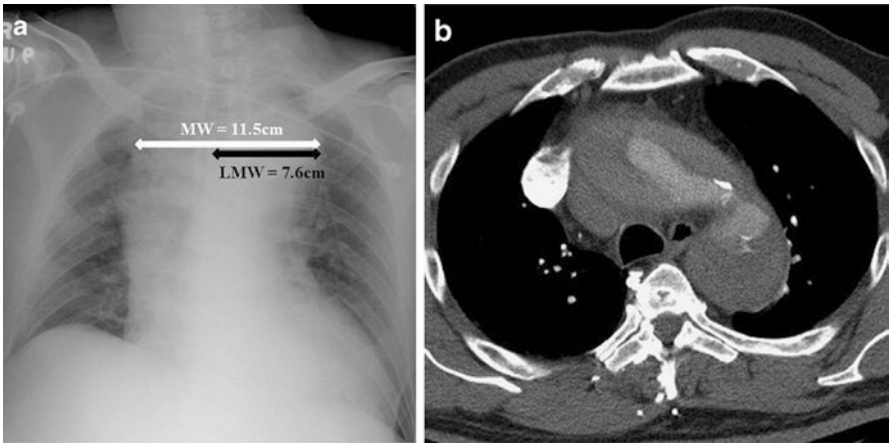
- No diagnostic findings.
- Per national quality standards in the United States, ECG should be obtained within 10 minutes of arrival in an emergency department.

Imaging

- No diagnostic findings for NSTEMI on chest x-ray (CXR).
- Findings of heart failure (cardiomegaly, pulmonary congestion) on CXR portend a poorer prognosis for NSTEMI.

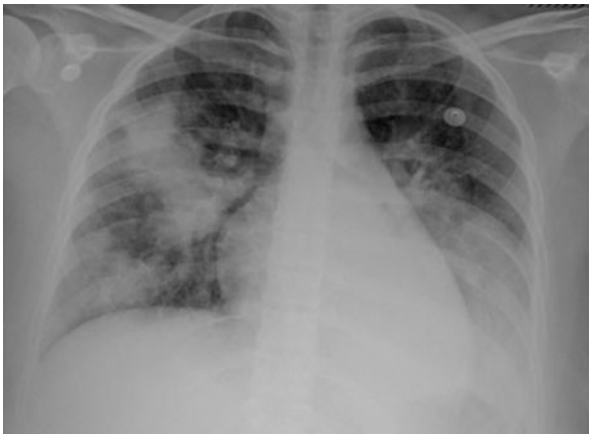
Frontal chest radiograph reveals typical features of pulmonary interstitial edema in a patient with congestive heart failure, manifested by peribronchial cuffing, indistinctness of the pulmonary vessels, and Kerley B lines. Note the cephalization or redistribution of the pulmonary vasculature and mild cardiomegaly. [Boiselle PM, Dass C, Steiner RM. Radiologic imaging in the critically ill patient. In: Criner GF, Barnette RE, D'Alonzo GE, editors. Critical care study guide. 2e, New York: Springer; 2010. p. 181-207. Book https://doi.org/10.1007/978-0-387-77452-7] *Caption from original*

- Findings of a widened mediastinum suggest consideration of aortic dissection but do not exclude NSTEMI. Check differential blood pressures in the upper extremities.



Acute type A aortic dissection in a 46-year-old man. A) AP chest radiograph showing marked widening of the mediastinum with MW and LMW measuring 11.5 and 7.6 cm, respectively. B) Corresponding selected image of CT aortogram confirms type A aortic dissection. [From article: Diagnostic accuracy of mediastinal width measurement on posteroanterior and anteroposterior chest radiographs in the depiction of acute nontraumatic thoracic aortic dissection. Emerg Radiol. 2012 Aug;19(4):309-15. https://doi.org/10.1007/s10140-012-1034-3 at http://link.springer.com/article/10.1007/s10140-012-1034-3 by Vincent Lai, Wai Kan Tsang, Wan Chi Chan, Tsz Wai Yeung, licensed under Creative Commons Attribution License, https://creativecommons.org/licenses/by/2.0/] *Caption from original*

- Findings of pneumonia suggest consideration of that differential but do not exclude NSTEMI. Check for signs of infection. Frank septic shock may result in elevated troponin levels.

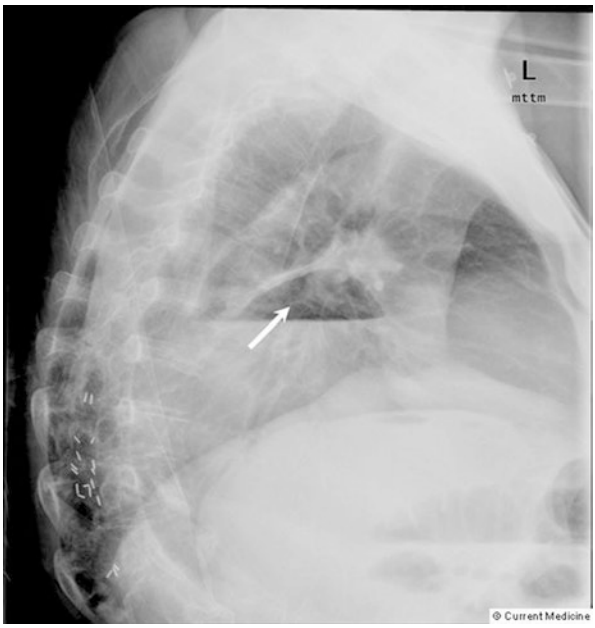


Chest radiograph showing right upper/lower lung field opacities and left lower lung field opacity consistent with pneumonia. [Tsigrelis C, Mohammad M, Fraimow HS, Dellinger RP, Marchesani D, Reboli AC. Secondary bacterial pneumonia due to Staphylococcus aureus complicating 2009 influenza A (H1N1) viral infection. Infection. 2010 Jun;38(3):237-9. https://doi.org/10.1007/s15010-010-0009-0, 2010-06-01] *Caption adapted from original*

- Findings of pneumothorax suggest consideration of that differential but do not exclude NSTEMI. Evaluate oxygenation status.

Posteroanterior upright chest X-ray shows large pneumothorax of the right lung. [Kim SH, Yoo WH. Recurrent pneumothorax associated with pulmonary nodules after leflunomide therapy in rheumatoid arthritis: a case report and review of the literature. Rheumatol Int. 2011 Jul;31(7):919-22. https://doi.org/10.1007/s00296-009-1240-9] *Caption adapted from original*

- Findings of hiatal hernia suggest consideration of that differential but do not exclude NSTEMI.



Radiograph of large hiatal hernia. [Aurigemma G, Tighe D, Oh J, Espinoza R. Pericardial disease and cardiac masses. In: Solomon S, editor. Atlas of echocardiography. Philadelphia: Current Medicine; 2008. ISBN: 1-57340-217-6] *Caption from original*

Risk Scoring

- TIMI Risk Score may be helpful in establishing short-term prognosis, which helps drive intensity of therapy.

- Age ≥65 years
- History of known CAD (documented prior coronary artery stenosis >50%)
- ≥3 conventional cardiac risk factors (age, male sex, family history, hyperlipidemia, diabetes mellitus, smoking, obesity)
- Use of aspirin in the past 7 days
- ST-segment deviation (persistent depression or transient elevation)
- Increased cardiac biomarkers (troponins)
- ≥2 anginal events in the preceding 24 h

TIMI = Thrombosis in Myocardial Infarction; CAD = coronary artery disease

Score = sum of number of above characteristics

TIMI = Thrombosis in Myocardial Infarction; CAD = coronary artery disease

Score = sum of number of above characteristics

TIMI risk score for unstable angina and NSTEMI. [Stillman AE, Oudkerk M, Ackerman M, Becker CR, Buszman PE, Feyter PJ, Hoffmann U, Keadey MT, Marano R, Lipton MJ, Raff GL, Reddy GP, Rees MR, Rubin GD, Schoepf UJ, Tarulli G, Beek EJR, Wexler L, White CS. Use of multidetector computed tomography for the assessment of acute chest pain: a consensus statement of the North American Society of Cardiac Imaging and the European Society of Cardiac Radiology. Int J Cardiovasc Imaging. 2007 Aug;23(4):415-27. https://doi.org/10.1007/s10554-007-9226-8] *Caption from original*

Value	TIMI risk score[a] (95% CI)	Modified TIMI risk score[b] (95% CI)
Sensitivity	53.7 (44.9–62.3)	58.1 (49.8–66.4)
Specificity	75.2 (72.1–78.2)	82.6 (80.0–85.2)
Negative predictive value	90.6 (88.2–927)	92.2 (90.2–94.1)
Positive predictive value	26.6 (21.5–32.3)	35.9 (29.6–42.2)

[a] Using a cut point of 3 (less than 3 vs. 3 or greater)

[b] Using a cut point of 2 (less than 2 vs. 2 or greater)

A summary of the TIMI risk score and modified TIMI risk scores as predictors of 30-day myocardial infarction/revascularization/death. [Jaffery Z, Hudson MP, Jacobsen G, Nowak R, McCord J. Modified Thrombolysis in Myocardial Infarction (TIMI) risk score to risk stratify patients in the emergency department with possible acute coronary syndrome. J Thromb Thrombolysis. 2007 Oct;24(2):137-44. DOI: https://doi.org/10.1007/s11239-007-0013-0] *Caption from original*

Special Populations

Age

- Risk for NSTEMI increases with age, starting at age 40 in men and at menopause in women.
  - Age is a risk factor for mortality from NSTEMI.
  - Likelihood of atypical presentation with NSTEMI increases with age.

Co-morbidities

- Hypertension, diabetes, and renal failure are important co-morbidities in NSTEMI risk and prognosis.
- Obesity is a weaker predictor of NSTEMI risk.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- ECG must be performed as soon as the diagnosis of ACS is even considered.

Mimics

- All differential considerations listed under Primary Differential Considerations.
  - Of these, only aortic dissection and pulmonary embolism are also life-threatening.

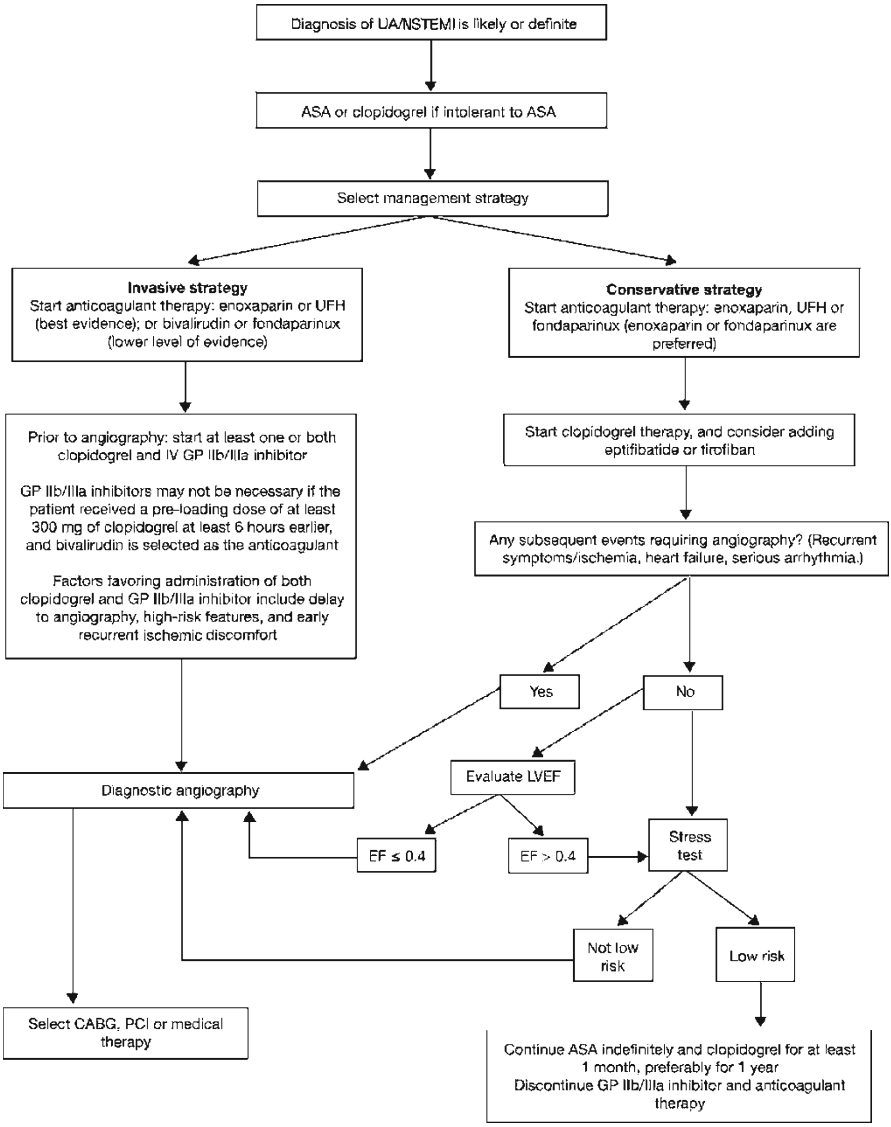
Time-Dependent Interventions

- Stabilization of the NSTEMI patient is time sensitive; unlike in STEMI, restoration of perfusion is not extremely time sensitive.
  - Current guidelines call for diagnostic angiography in 24–48 hours to establish preferred course of management.

- Unless contraindicated (allergy, active bleeding), 324–325 mg aspirin should be administered immediately upon suspicion of an acute coronary syndrome.
- Anticoagulation therapy should be initiated upon confirmation of ACS diagnosis or with high suspicion in high-risk patients.
- Extremes of blood pressure should be promptly treated to avert shock (hypotension) or undue myocardial oxygen demand (hypertension).
- Airway and oxygenation should be monitored and supported as necessary.
- Patients with NSTEMI should be on continuous cardiac monitoring to evaluate for dangerous arrhythmias.
- Consider early initiation of dual antiplatelet therapy (aspirin plus an ADP receptor antagonist—ticagrelor or clopidogrel).

Overall Principles of Treatment

- Immediate stabilization of the patient with control of blood pressure, pulse rate, and pain is critical. The patient may require resuscitation, intubation, and intensive support.
- Medical management with anticoagulation and antiplatelet therapy is important.
  - Bleeding risk should also be assessed so that the risk of treatment-related hemorrhage can be minimized
- The higher the patient's risk, the more disproportionately s/he benefits from aggressive therapy.



Algorithm for the initial management of patients with UA/NSTEMI with an invasive or conservative treatment strategy [1] Abbreviations: ASA, aspirin; CABG, coronary artery-bypass grafting; EF, ejection fraction; GP, glycoprotein; IV, intravenous; LVEF, left ventricular ejection fraction; PCI, percutaneous coronary intervention; UA/NSTEMI, unstable angina/non-ST-elevation myocardial infarction; UFH, unfractionated heparin. [Cohen M. High-risk acute coronary syndrome patients with non-ST-elevation myocardial infarction: definition and treatment. Cardiovasc Drugs Ther. 2008 Oct;22(5):407-18. https://doi.org/10.1007/s10557-008-6120-0] *Caption from original*

Disease Course

- NSTEMI mortality is 6–10 %, depending on the population studied, over 6 months.

Chapter 3
Acute Coronary Syndrome: ST-Segment Elevation Myocardial Infarction

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

ST-Segment Elevation Myocardial Infarction

- STEMI, ST-elevation MI, acute MI, transmural MI, Q-wave MI

Incidence/Epidemiology

- At the highest-acuity end of the continuum of diagnoses collectively called acute coronary syndrome (ACS)
- Highest pre- and in-hospital 30-day mortality of ACS spectrum
- Incidence varies widely by demographics and risk profiles
- More than 1.2 million MIs in US each year; about 20 % are STEMI

Differential Diagnosis

- Includes all other causes of chest pain

https://doi.org/10.1007/978-3-319-63895-9_3

- Includes other causes of "anginal equivalents" in susceptible populations, e.g.:
- Dyspnea
- Back pain
- Jaw pain
- Shoulder pain
- Epigastric pain
- Palpitations
- Dizziness
- Weakness
- Nausea
- Syncope

Pathophysiology and Etiology

- ACS is the result of ischemia (diminished blood flow / oxygen delivery) to myocardium
- If ischemia persists, frank infarction (muscle death) may occur
- Infarction results in breakdown of cell membranes, allowing release of intracellular proteins (such as myoglobin, troponins, and CPK-MB) into the circulation, where they may be detected in peripheral blood draw
- STEMI is most extreme and acute form of ACS, with "transmural" ischemia that results in characteristic acute findings on ECG (see below)
- Most STEMI occurs as a result of fracture or frank rupture of atherosclerotic plaque in an epicardial artery

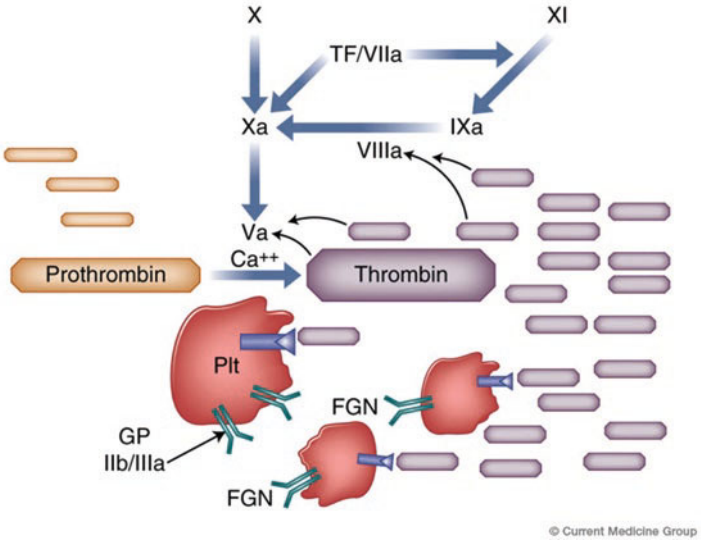
Hypertension and diabetes	2
Smoking, hypertension and hypercholesterolemia	1
Smoking, hypertension, hypercholesterolemia and diabetes	2

[a] Hypertension was defined as a diastolic arterial pressure >95 mm Hg and hypercholesterolemia >6 mmol/l

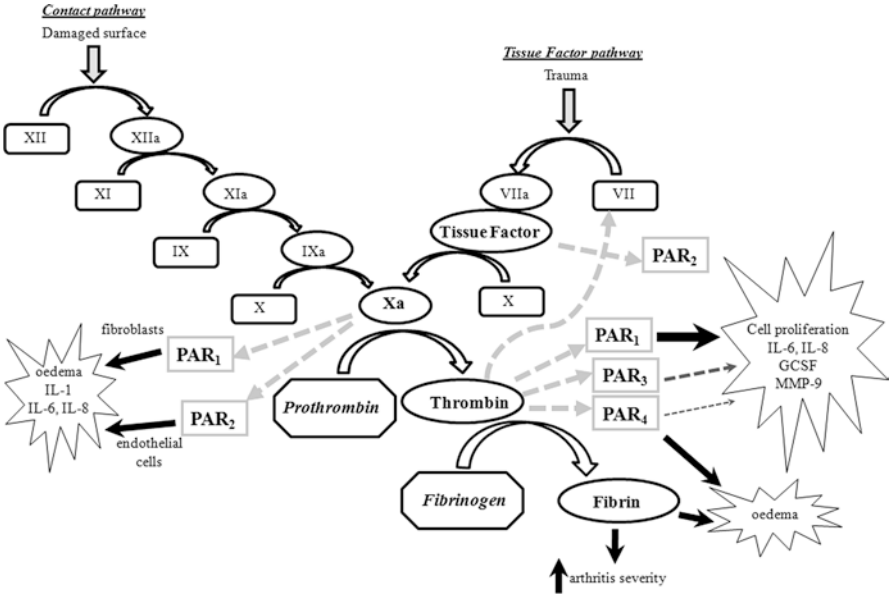
Main known risk factors for atherosclerosis in 16 patients studied. [Watt S, Aesch B, Lanotte P, Tranquart F, Quentin R. Viral and bacterial DNA in carotid atherosclerotic lesions. Eur J Clin Microbiol Infect Dis. 2003 Feb;22(2):99-105. https://doi.org/10.1007/s10096-002-0867-1, 2003-02-01] *Caption adapted from original*

- Plaque rupture initiates a complex thrombo-inflammatory response locally, including activation of:
  - Coagulation



Networking of coagulation cascade and aggregation of platelets (Plt). The extrinsic limb triggers activation of the coagulation cascade when tissue factor (TF) is exposed in a disrupted plaque. Coagulation factor VII is activated (VIIa) and can

activate factor X to Xa and promote perpetuation of the coagulation process via the intrinsic limb that results in formation of IXa and VIIIa. The prothrombinase complex of Xa, Va, Ca^{++} forms on a phospholipid surface (*eg*, membrane of a platelet) and converts prothrombin to thrombin. The thrombin that is formed binds to the thrombin receptor on platelets promoting activation and aggregation of platelets, as well as amplifying the coagulation cascade by promoting formation of VIIIa and Va. This diagram depicts the amplification nature of the coagulation process because one molecule of Xa leads to the downstream production of a large number of thrombin molecules (stoichiometric relationship not completely depicted to prevent obscuring the diagram with thrombin molecules). Activated platelets express numerous copies of the active form of the fibrinogen receptor GP IIb/IIIa on their surface. GP IIb/IIIa recognizes specific amino acid sequences on circulating ligands. One such ligand is fibrinogen (FGN), which has multiple copies of the RGD amino acid sequence and serves to bridge platelets together, promoting formation of aggregates. The more aggregates formed, the greater the surface area for the prothrombinase complex and amplification of the reactions of the coagulation cascade. [Antman E. Acute coronary syndromes. In: Libby P, editor. Essential atlas of cardiovascular disease. Philadelphia: Current Medicine; 2009. ISBN: 978-1-57340-309-2, 2009-05-21; Antman, Elliott] *Caption from original*



A simplified diagram of the coagulation cascade and its links with PARs and inflammation. Two pathways are involved in coagulation, with the major one being the tissue factor pathway. Most of the coagulation factors are serine proteinases that are present as inactive zymogens (rectangles) that when activated (ovals; lowercase 'a' indicates an active form) can catalyze the next reaction in the cascade. The two

pathways converge to activate factor X, thrombin and fibrin. [Russell FA, McDougall JJ. Proteinase-activated receptors and arthritis. In: Vergnolle N, Chignard M, editors. Proteases and their receptors in inflammation. Basel: Springer; 2011. p. 217-42. - Takayasu's disease
- Kawasaki's disease

Image obtained from a patient with an acute myocardial infarction caused by thrombosis of a right coronary artery Kawasaki aneurysm (*arrow*). Kawasaki disease results from a mucocutaneous viral infection acquired during childhood. Typically, multiple aneurysms may develop in the coronaries and in other systemic vessels. Thrombosis of these aneurysms may occur later in life. [Garcia MJ. Intracardiac, myocardial and extracardiac abnormalities. In: Budoff MJ, Achenbach S, Narula J, editors. Atlas of cardiovascular computed tomography. Philadelphia: Current Medicine; 2007] *Caption from original*

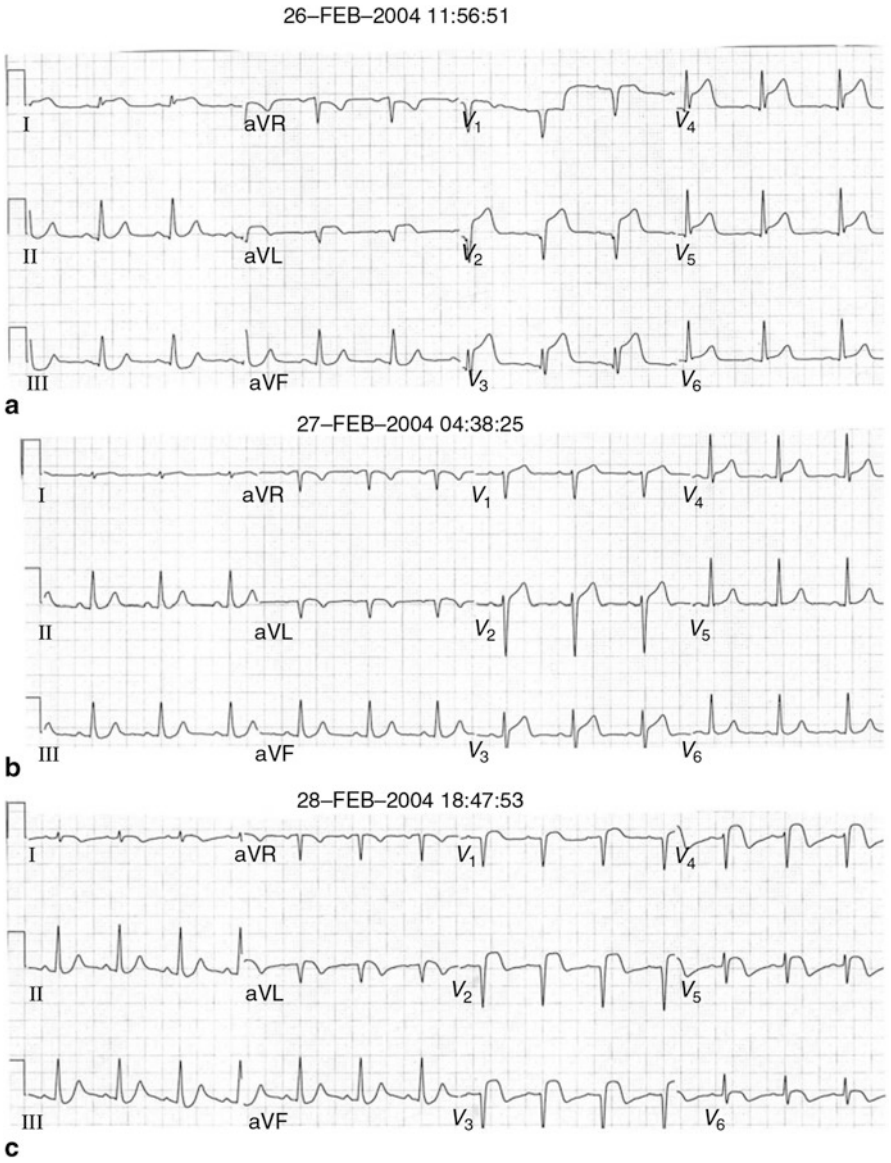
- Cocaine- or methamphetamine-induced vasospasm

Presentation

Typical/"Classic"

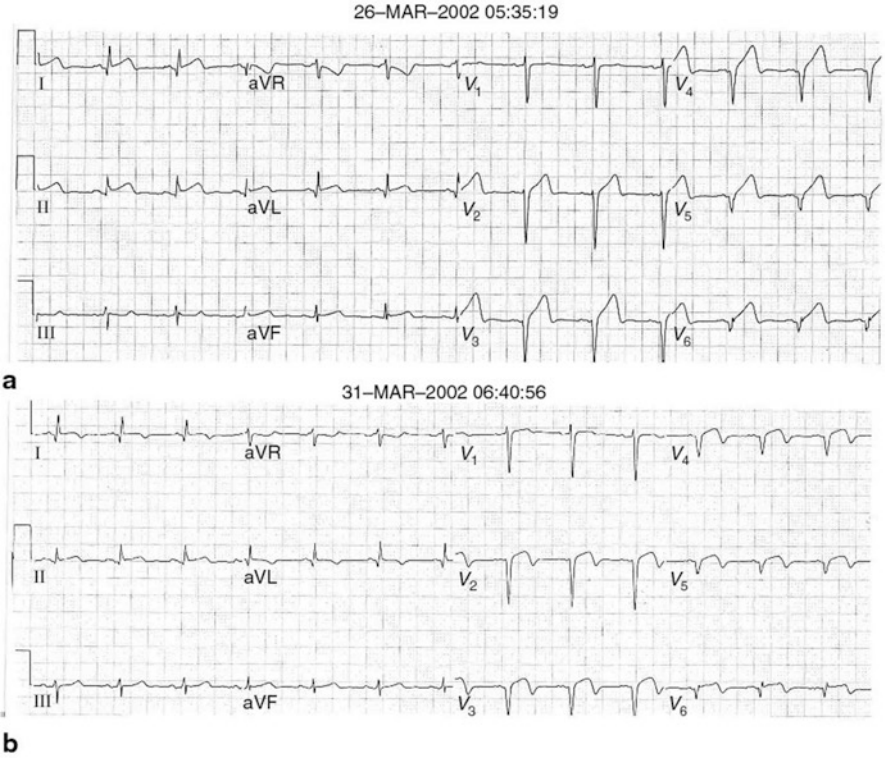
- Pressure-like chest pain starting substernally and radiating toward left shoulder or left jaw
- Pain is classically associated with diaphoresis, dyspnea, and nausea
- Pain often accompanied by tachycardia; blood pressure is variable with very high and very low presenting blood pressures associated with poorer prognosis
- Pain often starts with exertion; may be improved with rest or with use of nitroglycerin. May also start at rest and often persists >20 minutes before presentation
- Pain unchanged with movement, positioning, or deep breathing

- In describing pain, patient may hold clenched fist over chest ("Levine sign")
- Defined (as name implies) by specific ECG findings:
  - ST-segment elevation in two or more contiguous leads OR



Electrocardiogram of a 51-year-old man with acute anterior-superior myocardial infarction caused by total occlusion of left anterior descending coronary artery proximal to the first septal perforator and the first diagonal branch; there was also

40% occlusion of the first obtuse marginal branch of the left circumflex artery and 70% occlusion of the right coronary artery. Kinesis involved large portion of the anterior wall and the apex. with an estimated left ventricular ejection fraction of 15%. In (a): ST elevation in leads aVL and V1–6, with reciprocal ST depression in leads III and aVR. In (b): one day later "pseudonormalization" with slight ST elevation in the leads V 2–3 and T wave inversion in lead aVL as the only abnormalities. In (c): on the following day when chest pain resolved. ST elevation and T wave inversion in leads I, aVL and V 1–6 with reciprocal ST depression in the leads III, aVF compatible with the evolution of the infarction pattern. Incipient T wave inversion in leads a VL, V 2–6. [Surawicz B. Ventricular repolarization in myocardial ischemia and myocardial infarction: theory and practice. In: Macfarlane PW, van Oosterom A, Pahlm O, Kligfield P, Janse M, Camm J, editors. Comprehensive electrocardiology. London: Springer; 2011. p. 803-31. Book https://doi.org/10.1007/978-1-84882-046-3; Chapter: 18; Chapter https://doi.org/10.1007/978-1-84882-046-3_18, 2010-01-01] *Caption from original*



Electrocardiogram of a 47-year-old woman with anterolateral myocardial infarction (MI) caused by total occlusion of left anterior descending coronary artery in midportion associated with 50–70% occlusion of the co-dominant left anterior circumflex artery. Anterior wall and apex were akinetic with an estimated left ventricular

ejection fraction of 30%. In (a): Q waves with ST elevation in leads I, aVL, V 3–6 and reciprocal ST depression in aVR. In (b) 5 days later after an emergent percutaneous intervention evolution of ECG pattern of anterior MI with T wave inversion in leads I, aVL and V 2–6. Residual ST elevation is present in the above leads. [Surawicz B. Ventricular repolarization in myocardial ischemia and myocardial infarction: theory and practice. In: Macfarlane PW, van Oosterom A, Pahlm O, Kligfield P, Janse M, Camm J, editors. Comprehensive electrocardiology. London: Springer; 2011. p. 803-31. Simultaneous ST-segment elevation in inferior and precordial leads following ingestion of a lethal dose of desipramine: a novel Brugada-like EKG pattern. J Interv Card Electrophysiol. 2010 Jun;28(1):35-8. https://doi.org/10.1007/s10840-009-9412-9, 2010-04-13] *Caption from original*

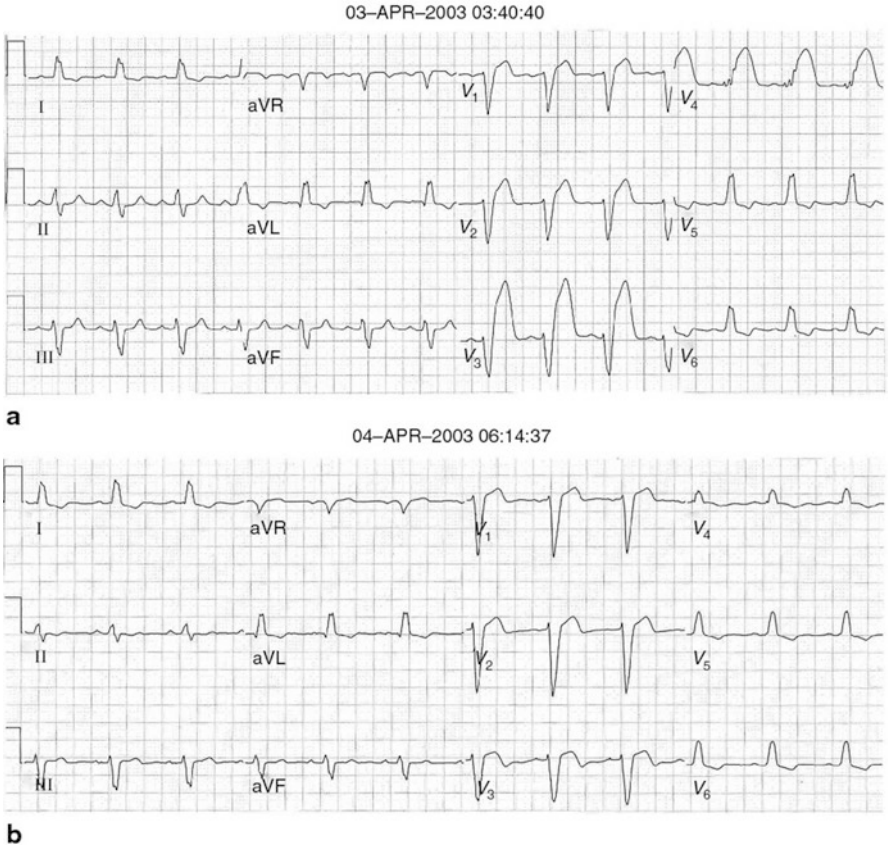
- Known-to-be-new left bundle branch block in presence of anginal symptoms



Electrocardiogram of a 58-year-old man with left bundle branch block (LBBB) and acute anterior myocardial infarction (MI). In (a), in addition to secondary ST and T changes of LBBB, there is primary ST elevation in leads $V_{2–4}$-indicative of acute injury pattern. No reciprocal ST depression is discernible. In (b), after percutaneous intervention, primary ST elevation subsided, but primary T-wave inversion in leads $V_{2–3}$ is compatible with evolution of anterior MI pattern. [Surawicz B. Ventricular repolarization in myocardial ischemia and myocardial infarction: theory and practice. In: Macfarlane PW, van Oosterom A, Pahlm O, Kligfield P, Janse M, Camm J, editors. Comprehensive electrocardiology. London: Springer; 2011. p. 803-31. Book https://doi.org/10.1007/978-1-84882-046-3; Chapter: 18; Chapter https://doi.org/10.1007/978-1-84882-046-3_18, 2010-01-01] *Caption from original*

Atypical

- STEMI has been discovered in patients with virtually any complaint localized above the umbilicus.
- "Anginal equivalents" listed above include different distributions of pain (e.g., epigastric, jaw, neck, back) and some presentations that are not painful at all (e.g., palpitations, nausea, syncope).
  - Patients with STEMI who present without chest pain frequently experience delays in diagnosis and therefore delays in treatment.
  - Atypical presentations more common in women, in elderly, and in diabetics.
- Diagnostic ECG findings are the defining and unifying feature of all STEMI presentations.

Primary Differential Considerations

- Primary differential considerations include pain mimics to STEMI and are diverse, including life-threatening and more benign causes:
  - Aortic dissection
  - Pulmonary embolism
  - Peptic and esophageal disease, hiatal hernia
  - Costochondritis
  - Pneumonia
  - Pneumothorax
  - Pleurisy
  - Anxiety and panic disorders
  - Biliary colic
  - Herpes zoster

	Helpful clinical features
Cardiovascular	
Angina	Retrosternal chest pressure, squeezing, heaviness. Associated with exertion or emotional stress, relieved by rest or nitroglycerin. Usually between 2 and 20 min in duration.
Aortic stenosis	Similar features as for angina, but with late-peaking systolic murmur radiating to carotids. May be associated with syncope or signs of left heart failure.
Pericarditis	Sharp, retrosternal, pleuritic chest pain lasting hours to days. May be associated with friction rub and may be alleviated by leaning forward.
Aortic dissection	Sudden onset of tearing, ripping chest pain radiating to back. Associated with underlying hypertension.
Pulmonary embolism	Ipsilateral pleuritic pain associated with dyspnea, tachycardia, possible cor pulmonale. May have irritative cough or hemoptysis or present with syncope. Usually sudden onset.
Pulmonary	
Pneumonia/ pleuritis/pleural effusion	Pleuritic pain, lateralizing to side of infection/ inflammation. May be associated with fevers, dyspnea, cough. Exam with pleural rub, consolidation, or dullness to percussion.
Asthma/COPD exacerbation	Chest "tightness" associated with more prominent findings of dyspnea, tachypnea and diffuse wheezing.
Spontaneous pneumothorax	Sudden onset of pleuritic pain. Unilateral and associated with dyspnea. More common in thin, young males or patients with emphysematous disease. Decreased breath sounds and hyperresonance on side of pneumothorax.
Chest wall	
Muscle spasm/ strain	Associated with prior increased physical activity/ weight lifting. Pain variable in character but usually reproducible with palpation.

	Helpful clinical features
Costochondritis	Sharp, sudden onset pain that is short in duration. May be reproducible with palpation.
Herpes zoster	Sharp, burning, superficial neuropathic pain. May have allodynia, vesicular rash on exam. Unilateral dermatomal distribution.
Rib fracture	Prior trauma or known metastatic disease of bone. Point tenderness over affected rib(s). Pain is usually pleuritic.
Cervical/thoracic nerve root compression	Intermittent neuropathic pain often associated with neck movement or position. Usually unilateral.
Gastrointestinal	
Mediastinitis/ esophageal rupture	Often preceded by esophageal procedure or forceful vomiting. Pt. may have fever, associated septic shock. Symptoms vary from burning chest discomfort to severe dyspnea.
Esophageal reflux	Burning pain, often associated with nausea, belching. Usually worse at night and after large meals. Alleviated by antacids.
Esophageal spasm	Sudden onset, sharp, retrosternal pain. May be relieved by nitroglycerine and exacerbated by cold liquids. Sometimes associated with dysphagia.
Pancreatitis	Sharp epigastric pain, usually constant and prolonged. Exacerbated by food and often associated with nausea/vomiting. Alcohol and gallstones are risk factors.
Peptic ulcer	Sharp or burning epigastric pain. Often relieved by food or antacids. May be associated with occult GI bleeding or massive acute blood loss.
Psychogenic	
Anxiety/panic disorder	May be unable to distinguish from anginal pain, but usually has atypical features such as prolonged duration and no exertional component. Should be a diagnosis of exclusion at initial workup.

Differential diagnosis of acute chest pain. [McClintic BR, Rosenblatt RL. Approach to the patient with chest pain. In: Bisognano JD, Beck R, Connell R, editors. Manual

of outpatient cardiology. London: Springer. p. 349-71. Book https://doi.org/10.1007/978-0-85729-944-4; Chapter: 13; Chapter https://doi.org/10.1007/978-0-85729-944-4_13, 2012-01-01] *Caption from original*

History and Physical Exam

Findings That Confirm Diagnosis

- None

Factors That Suggest Diagnosis

- Nature and history of pain with presence of risk factors.

Factors That Exclude Diagnosis

- None

Ancillary Studies

Laboratory

- CBC: no diagnostic findings
- Electrolytes: no diagnostic findings
- Renal function: no diagnostic findings, but renal insufficiency/failure is a risk factor for ACS and may complicate treatment
- Coagulation studies: no diagnostic findings but should be performed before initiation of anticoagulation therapy
- Cardiac enzymes: will be elevated in STEMI, but presentation often precedes abnormal test values. Elevation of enzymes is NOT required for diagnosis of STEMI.
    - Elevation in troponin (I or T) levels is part of universal diagnosis of myocardial infarction

Electrocardiography

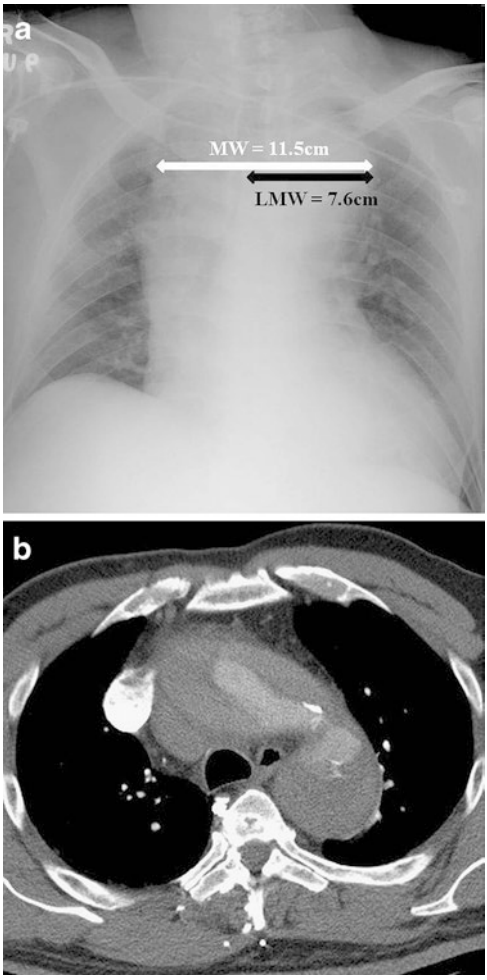
- As above, STEMI is defined by the ECG
- Per national quality standards in the United States, ECG should be obtained within 10 minutes of arrival in an emergency department

Imaging

- No diagnostic findings for STEMI on chest x-ray (CXR)
- Findings of heart failure (cardiomegaly, pulmonary congestion) on CXR portend a poorer prognosis on STEMI

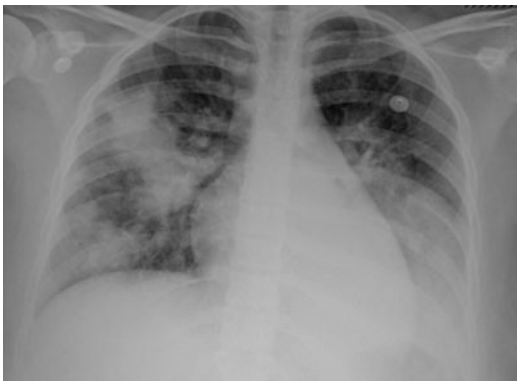
Frontal chest radiograph reveals typical features of pulmonary interstitial edema in a patient with congestive heart failure, manifested by peribronchial cuffing, indistinctness of the pulmonary vessels, and Kerley B lines. Note the cephalization or redistribution of the pulmonary vasculature and mild cardiomegaly. [Boiselle PM, Dass C, Steiner RM. Radiologic imaging in the critically ill patient. In: Criner GJ, Barnette RE, D'Alonzo GE, editors. Critical care study guide. New York: Springer; 2010. p. 181-207. Book https://doi.org/10.1007/978-0-387-77452-7; Chapter: 11; Chapter https://doi.org/10.1007/978-0-387-77452-7_11, 2010-01-01] *Caption from original*

- Findings of a widened mediastinum suggest consideration of aortic dissection but do not exclude STEMI. Check differential blood pressures in the upper extremities.



Acute type A aortic dissection in a 46-year-old man. A) AP chest radiograph showing marked widening of the mediastinum with MW and LMW measuring 11.5 and 7.6 cm, respectively. B) Corresponding selected image of CT aortogram confirms type A aortic dissection. [From article: Diagnostic accuracy of mediastinal width measurement on posteroanterior and anteroposterior chest radiographs in the depiction of acute nontraumatic thoracic aortic dissection. Emerg Radiol. 2012 Aug;19(4):309-15. https://doi.org/10.1007/s10140-012-1034-3, at http://link.springer.com/article/10.1007%2Fs10140-012-1034-3; by Vincent Lai, Wai Kan Tsang, Wan Chi Chan, Tsz Wai Yeung, © The Author(s) 2012; licensed under Creative Commons Attribution License https://creativecommons.org/licenses/by/2.0/] *Caption from original*

- Findings of pneumonia suggest consideration of that differential but do not exclude STEMI. Check for signs of infection.



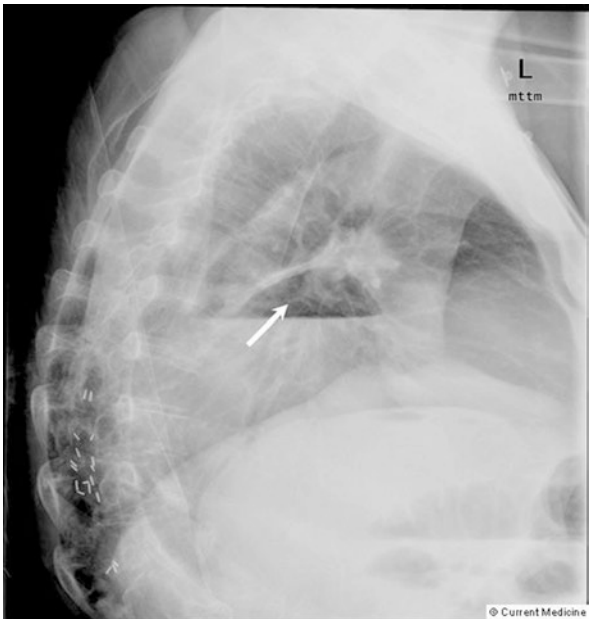
Chest radiograph showing right upper/lower lung field opacities and left lower lung field opacity consistent with pneumonia. [Tsigrelis C, Mohammad M, Fraimow HS, Dellinger RP, Marchesani D, Reboli AC. Secondary bacterial pneumonia due to Staphylococcus aureus complicating 2009 influenza A (H1N1) viral infection. Infection. 2010 Jun;38(3):237-9. https://doi.org/10.1007/s15010-010-0009-0, 2010-06-01] *Caption adapted from original*

- Findings of pneumothorax suggest consideration of that differential but do not exclude STEMI. Evaluate oxygenation status.

Posteroanterior upright chest X-ray shows large pneumothorax of the right lung. [Kim SH, Yoo WH. Recurrent pneumothorax associated with pulmonary nodules after leflunomide therapy in rheumatoid arthritis: a case report and review of the

literature. Rheumatol Int. 2011 Jul;31(7):919-22. https://doi.org/10.1007/s00296-009-1240-9, 2011-06-21] *Caption adapted from original*

- Findings of hiatal hernia suggest consideration of that differential but do not exclude STEMI



Radiograph of large hiatal hernia. [Aurigemma G, Tighe D, Oh J, Espinoza R. Pericardial disease and cardiac masses. In: Solomon S, editor. Atlas of echocardiography. Philadelphia: Current Medicine; 2008.] *Caption from original*

Special Populations

Age

- Risk for STEMI increases with age, starting at age 40 in men and at menopause in women.
  - Age is a risk factor for mortality from STEMI.
  - Likelihood of atypical presentation with STEMI increases with age.

Pediatric Considerations

- A congenital abnormality of the coronary vasculature, in which there is an anomalous origin of the left coronary artery arising from the pulmonary artery (ALCAPA), may occur in infancy. It presents with various symptoms of cardiac ischemia (diaphoresis when feeding) and if not recognized and corrected surgically, may cause irreversible myocardial damage.

Co-morbidities

- Hypertension, diabetes, and renal failure are important comorbidities in STEMI risk and prognosis.
- Obesity is a weaker predictor of STEMI risk.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- ECG must be performed as soon as the diagnosis of STEMI is even considered.

Mimics

- All differential considerations listed above.
  - Of these, only aortic dissection and pulmonary embolism are also life-threatening.

Time-Dependent Interventions

- Restoration of myocardial perfusion is time sensitive.
  - If possible, STEMI should be managed in the cardiac cath laboratory within 90 minutes of initial evaluation.
  - Outcomes worsen with each 30–60-minute delay in restoration of flow.
  - If interventional management is not possible, evaluation for fibrinolytic therapy should be performed immediately, with a goal of delivering lytic therapy to appropriate STEMI patients within 30 minutes of initial evaluation.

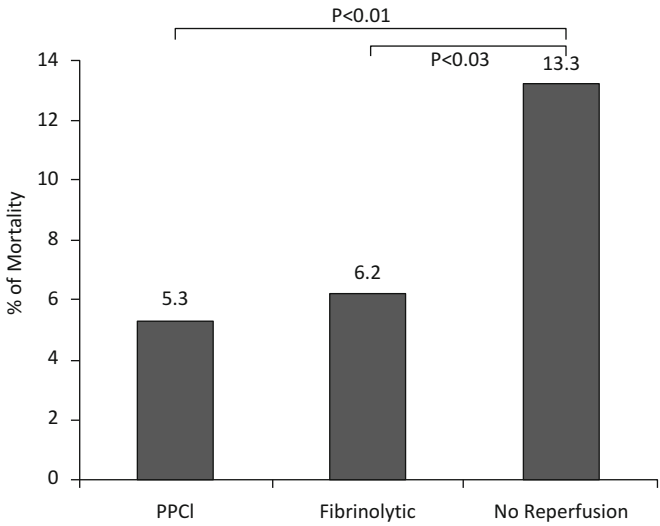
- Unless contraindicated (allergy, active bleeding), 324-325 mg aspirin should be administered immediately upon suspicion of an acute coronary syndrome.
- Extremes of blood pressure should be promptly treated to avert shock (hypotension) or undue myocardial oxygen demand (hypertension).
- Airway and oxygenation should be monitored and supported as necessary.
- Patients with STEMI should be on continuous cardiac monitoring to evaluate for dangerous arrhythmias.

Overall Principles of Treatment

- Immediate stabilization of the patient with control of blood pressure, pulse rate, and pain is critical. The patient may require resuscitation, intubation, and intensive support.
- Measures to reperfuse infarcting myocardium are essential and are time sensitive.

Disease Course

- STEMI mortality is highest in the prehospital setting.
- Once at the emergency department, in-hospital STEMI mortality among patients receiving reperfusion therapy is around 6 %.



In-hospital mortality of STEMI patients. [Dharma S, Juzar DA, Firdaus I, Soerianata S, Wardeh AJ, Jukema JW. Acute myocardial infarction system of care in the third

world. Neth Heart J. 2012 Jun;20(6):254-9. https://doi.org/10.1007/s12471-012-0259-9, 2012-06-01] *Caption from original*

Chapter 4
Acute Coronary Syndrome: Unstable Angina

Charles V. Pollack, Jr. and Victoria G. Riese

Name and Synonyms

Unstable angina

- Troponin-negative acute coronary syndrome (ACS)

Incidence/Epidemiology

- Because unstable angina is a clinical diagnosis with inconsistent defining criteria, the true incidence is unknown.

C. V. Pollack, Jr. (✉)
Department of Emergency Medicine, Thomas Jefferson University, Philadelphia, PA, USA

V. G. Riese
Librarian Consultant, Eldersburg, MD, USA

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_4

Progressive angina (grade IB)
Characterized by either new-onset angina pectoris or chronic angina with an increase in frequency or severity of episodes
Angina at rest (grades IIB and IIIB)
Recurrent angina with transient ST- or T-wave changes
Early postinfarction angina (grades IIC and IIIC)
Recurrent angina within 30 d following MI; angina either at rest or related to minimal exercise

Classification of unstable angina [Prasad A, Holmes D, Kleiman N. Use of percutaneous coronary intervention in unstable angina and acute myocardial infarction. In: Califf RM, editor. Acute myocardial infarction and other acute ischemic syndromes. 2nd ed. Philadelphia: Current Medicine; 2001. Chapter 7. (Braunwald E, editor. Atlas of heart diseases; vol. 8.)]

- Unstable angina is considered a "non-ST-segment-elevation" (NSTE) ACS. NSTE-ACS (which also includes NSTE myocardial infarction [NSTEMI]) is much more common than STEMI.

	STEMI	NSTEMI/UA
Pathogenesis	Fully occlusive thrombus	Less than fully occlusive thrombus
Incidence		Higher than that of STEMI
Patient profile		Older; higher co-morbidity (diabetes, renal failure) than STEMI patients
Time course	Minutes to hours	Up to a few days
Clinical manifestations		Similar to STEMI
Imaging studies		Similar to STEMI
EKG	ST elevations	No ST elevations[a]
Biomarkers	Elevated	Elevated
Therapy	See Table 2.54	See Table 2.54
Rehabilitation		Similar to STEMI
Complications		Similar to STEMI
Prognosis		Mortality lower in-hospital, higher at 6 months and 4 years than with STEMI

[a]ST elevations may be seen in Prinzmetal's angina

STEMI and NSTEMI/UA: a comparison. [Adelmann GA. Cardiology essentials in clinical practice. London: Springer; 2011. Chapter 2, Coronary artery disease; p. 23-95. Book https://doi.org/10.1007/978-1-84996-305-3; Chapter: 2; Chapter https://doi.org/10.1007/978-1-84996-305-3_2, 2010-01-01] Caption from original

- Incidence varies widely by demographics and risk profiles; patients with NSTE-ACS tend to be older and to have more comorbidities than STEMI patients.

- About 1 million patients are hospitalized with a diagnosis of unstable angina in the US each year, but in the absence of a consistent definition, it is likely that this is an overestimation, with some patients going on to complete MI and others more properly diagnosed as having either stable angina or noncoronary chest pain.

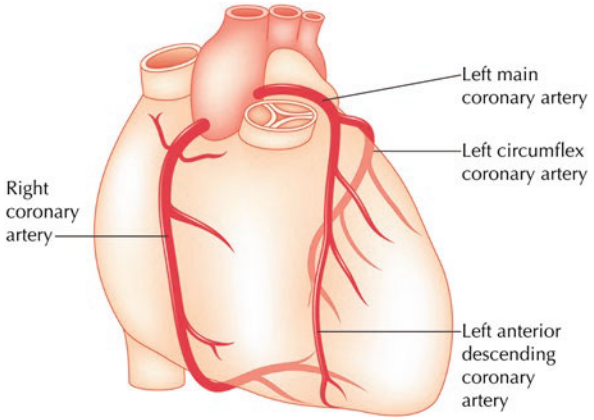
Differential Diagnosis

- Includes all other causes of chest pain
- Includes other causes of "anginal equivalents" in susceptible populations, e.g.:
  - Dyspnea
  - Back pain
  - Jaw pain
  - Shoulder pain
  - Epigastric pain
  - Palpitations
  - Dizziness
  - Weakness
  - Nausea
  - Syncope

Pathophysiology and Etiology

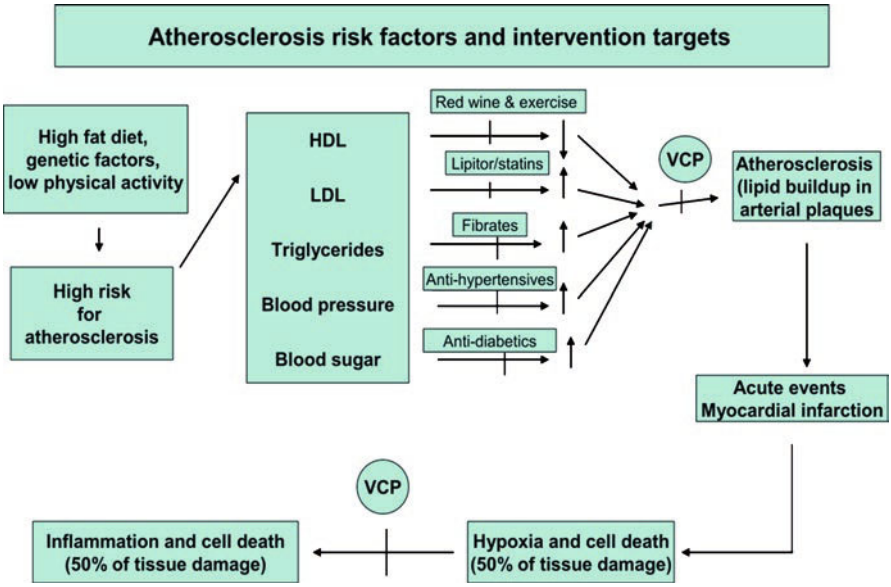
- ACS is the result of ischemia (diminished blood flow / oxygen delivery) to myocardium.
- If ischemia persists, frank infarction (muscle death) may occur.
- Infarction results in breakdown of cell membranes, allowing release of intracellular proteins (such as myoglobin, troponins, and CPK-MB) into the circulation, where they can be detected in peripheral blood draw.
- Unstable angina, as currently defined, is the clinical picture of ACS in the absence of both (1) ST-segment elevation on ECG and (2) elevated biomarker levels. These factors clearly differentiate unstable angina from NSTEMI and STEMI.
- The greatest consensus on the factors that make angina "unstable" include:
  - Anginal onset at rest (especially in patients who previously had only exertional angina)
  - Anginal symptoms do not resolve after

    - rest, if onset was with exertion
    - abortive therapy, such as sublingual nitroglycerin
    - 20 minutes
  - "crescendo" pattern of symptoms or change in usual anginal pattern
  - Multiple episodes within 24 hours
  - Association with signs of heart failure
- Most cases of ACS occur as a result of fracture or frank rupture of atherosclerotic plaque in an epicardial artery, but unstable angina also may result from "demand" ischemia, in which blood flow through a stenotic coronary artery is insufficient to meet increased myocardial oxygen demands (such as in exercise or physiologic stress). In the latter case, the plaque causing the stenosis need not be fractured or ruptured.



Normal coronary anatomy. [Achenbach S. Normal coronary anatomy. In: Budoff MJ, Achenbach S, Narula J, Braunwald E, editors. Atlas of cardiovascular computed tomography. Philadelphia: Current Medicine; 2007.] *Caption from original*

- Atherosclerosis, which is most often at the foundation of unstable angina, is a product of diverse inherited and acquired conditions, including:
  - Family history
  - Hyperlipidemia
  - Hypertension
  - Diabetes mellitus
  - Tobacco abuse



Atherosclerosis risk factors and intervention targets. [Thorbjornsdottir P, Thorgeirsson G, Kotwal GJ, Arason GJ. Control of inflammation with complement control agents to prevent atherosclerosis. In: Suri JS, Kathuria C, Molinari F, editors. Atherosclerosis disease management. New York: Springer; 2011. p. 633-75. Book https://doi.org/10.1007/978-1-4419-7222-4; Chapter: 20; Chapter https://doi.org/10.1007/978-1-4419-7222-4_20, 2011-01-01] *Caption adapted from original*

Risk factors	No. of patients
Individual	
Smoking	6
Hypertension	11
Hypercholesterolemia	9
Diabetes mellitus	4
Clusters	
Smoking and hypercholesterolemia	1
Hypertension and hypercholesterolemia[a]	4
Hypertension and diabetes	2
Smoking, hypertension and hypercholesterolemia	1
Smoking, hypertension, hypercholesterolemia and diabetes	2

[a] Hypertension was defined as a diastolic arterial pressure >95 mm Hg and hypercholesterolemia >6 mmol/l

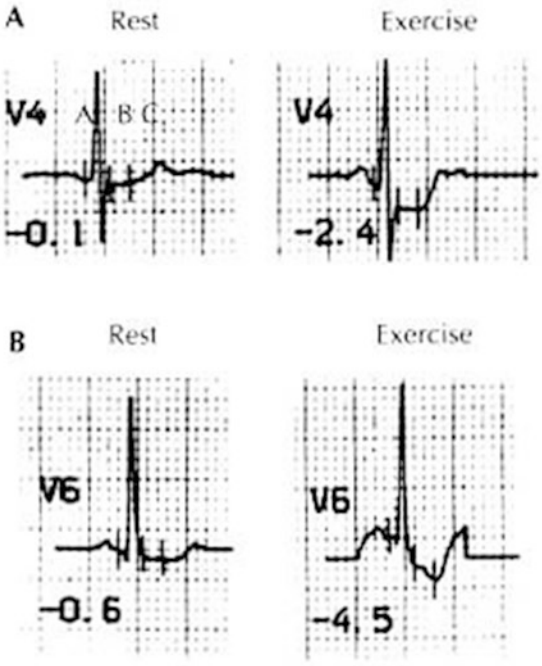
Main known risk factors for atherosclerosis in 16 patients studied. [Watt S, Aesch B, Lanotte P, Tranquart F, Quentin R. Viral and bacterial DNA in carotid atherosclerotic lesions. Eur J Clin Microbiol Infect Dis. 2003 Feb;22(2):99-105. https://doi.org/10.1007/s10096-002-0867-1, 2003-02-01] *Caption adapted from original*

- See pathophysiology discussions under NSTEMI and STEMI for details of the thromboinflammatory processes underlying ACS resulting from a breach of an atherosclerotic plaque.
- Besides atherothrombosis and demand across a critical stenosis, unstable angina may result from a variety of much rarer etiologic considerations, including
    - Pure arterial spasm (which may be precipitated by sympathomimetic agents such as cocaine or methamphetamine)
    - Arteritis
        - Lupus
        - Takayasu disease
        - Kawasaki disease

Presentation

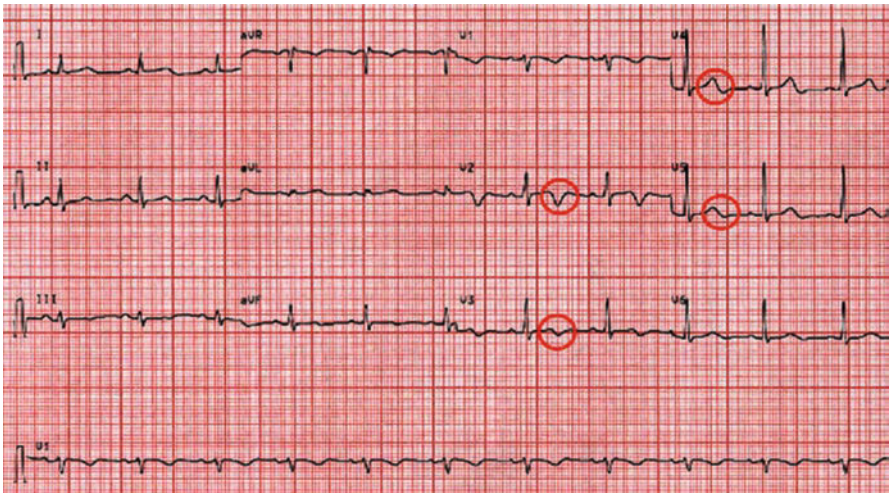
Typical/"Classic"

- Pressure-like chest pain starting substernally and radiating toward the left shoulder or left jaw.
- Pain is classically associated with diaphoresis, dyspnea, and nausea.
- Pain often accompanied by tachycardia; blood pressure is variable, with very high and very low presenting blood pressures associated with poorer prognosis.
- Pain often starts with exertion; may be improved with rest or with use of nitroglycerin. May also start at rest and often persists > 20 minutes prior to presentation.
- Pain unchanged with movement, positioning, or deep breathing.
- In describing pain, patient may hold clenched fist over chest ("Levine sign").
- Notable for absence of specific, diagnostic ECG findings:
    - Persistent ST-segment elevation is ABSENT
    - ST-segment depression confers a higher risk for poor outcomes but IS NOT diagnostic of NSTEMI.
        - Particularly high risk when depression is "dynamic"—that is, present when patient is experiencing pain and resolved when that pain is relieved



A, Example of ischemic horizontal ST-segment depression. The J-point (B) is depressed 0.3 mm relative to the PQ junction (A), and ST-80 (C) is depressed 0.1 mm at rest. During exercise, the J-point and ST-80 are depressed 2.4 mm. The reported net difference in ST-80 depression would be 2.3 mm. B, Example of downsloping ST-segment depression. The second patient reveals 0.6-mm ST-80 depression at rest, which worsens with exercise, resulting in J-point depression of 2.5 mm and ST-80 depression of 4.5 mm during exercise. The reported net difference in ST-80 depression would be 3.9 mm. [Chaitman B. Exercise electrocardiographic stress testing. In: Beller G, editor. Chronic ischemic heart disease. Philadelphia: Current Medicine; 1995. Chapter 2. (Braunwald E, editor. Atlas of heart diseases; vol. 5.) ISBN: 1-878132-29-6, 2002-01-23] *Caption adapted from original*

- T-wave inversion confers a higher risk in patients with symptoms of ACS but IS NOT diagnostic of unstable angina or NSTEMI.



Electrocardiogram with T-wave inversions in leads V1 to V4. [From article: Triptans and troponin: a case report. Orphanet J Rare Dis. 2009 Jun 18;4: 15. https://doi.org/10.1186/1750-1172-4-15, at http://link.springer.com/article/10.1186/1750-1172-4-15; by Claudia R Weder, Markus Schneemann, © Weder and Schneemann. 2009; licensee BioMed Central Ltd.; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

Atypical

- Unstable angina has been diagnosed in patients with virtually any complaint localized above the umbilicus.
- "Anginal equivalents" listed above include different distributions of pain (e.g., epigastric, jaw, neck, back) and some presentations that are not painful at all (e.g., palpitations, nausea, syncope).
  - Patients with ACS who present without chest pain as their chief complaint frequently experience delays in diagnosis and therefore delays in treatment.
  - Atypical presentations are more common in women, in elderly people, and in diabetics.
- The absence of an elevated troponin level is required for the diagnosis of unstable angina, by current definitions.

Primary Differential Considerations

- Primary differential considerations include pain mimics to angina and are diverse, including life-threatening and more benign causes:
  - Aortic dissection
  - Pulmonary embolism
  - Peptic and esophageal disease, hiatal hernia
  - Costochondritis
  - Pneumonia
  - Pneumothorax
  - Pleurisy
  - Anxiety and panic disorders
  - Biliary colic
  - Herpes zoster

	Helpful clinical features
Cardiovascular	
Angina	Retrosternal chest pressure, squeezing, heaviness. Associated with exertion or emotional stress, relieved by rest or nitroglycerin. Usually between 2 and 20 min in duration.
Aortic stenosis	Similar features as for angina, but with late-peaking systolic murmur radiating to carotids. May be associated with syncope or signs of left heart failure.
Pericarditis	Sharp, retrosternal, pleuritic chest pain lasting hours to days. May be associated with friction rub and may be alleviated by leaning forward.
Aortic dissection	Sudden onset of tearing, ripping chest pain radiating to back. Associated with underlying hypertension.
Pulmonary embolism	Ipsilateral pleuritic pain associated with dyspnea, tachycardia, possible cor pulmonale. May have irritative cough or hemoptysis or present with syncope. Usually sudden onset.
Pulmonary	
Pneumonia/ pleuritis/pleural effusion	Pleuritic pain, lateralizing to side of infection/ inflammation. May be associated with fevers, dyspnea, cough. Exam with pleural rub, consolidation, or dullness to percussion.
Asthma/COPD exacerbation	Chest "tightness" associated with more prominent findings of dyspnea, tachypnea and diffuse wheezing.
Spontaneous pneumothorax	Sudden onset of pleuritic pain. Unilateral and associated with dyspnea. More common in thin, young males or patients with emphysematous disease. Decreased breath sounds and hyperresonance on side of pneumothorax.
Chest wall	
Muscle spasm/ strain	Associated with prior increased physical activity/ weight lifting. Pain variable in character but usually reproducible with palpation.

	Helpful clinical features
Costochondritis	Sharp, sudden onset pain that is short in duration. May be reproducible with palpation.
Herpes zoster	Sharp, burning, superficial neuropathic pain. May have allodynia, vesicular rash on exam. Unilateral dermatomal distribution.
Rib fracture	Prior trauma or known metastatic disease of bone. Point tenderness over affected rib(s). Pain is usually pleuritic.
Cervical/thoracic nerve root compression	Intermittent neuropathic pain often associated with neck movement or position. Usually unilateral.
Gastrointestinal	
Mediastinitis/ esophageal rupture	Often preceded by esophageal procedure or forceful vomiting. Pt. may have fever, associated septic shock. Symptoms vary from burning chest discomfort to severe dyspnea.
Esophageal reflux	Burning pain, often associated with nausea, belching. Usually worse at night and after large meals. Alleviated by antacids.
Esophageal spasm	Sudden onset, sharp, retrosternal pain. May be relieved by nitroglycerine and exacerbated by cold liquids. Sometimes associated with dysphagia.
Pancreatitis	Sharp epigastric pain, usually constant and prolonged. Exacerbated by food and often associated with nausea/vomiting. Alcohol and gallstones are risk factors.
Peptic ulcer	Sharp or burning epigastric pain. Often relieved by food or antacids. May be associated with occult GI bleeding or massive acute blood loss.
Psychogenic	
Anxiety/panic disorder	May be unable to distinguish from anginal pain, but usually has atypical features such as prolonged duration and no exertional component. Should be a diagnosis of exclusion at initial workup.

Differential diagnosis of acute chest pain. [McClintic BR, Rosenblatt RL. Approach to the patient with chest pain. In: Bisognano JD, Beck R, Connell R, editors. Manual

of outpatient cardiology. London: Springer; 2012. p. 349-71. Book https://doi.org/10.1007/978-0-85729-944-4; Chapter: 13; Chapter https://doi.org/10.1007/978-0-85729-944-4_13, 2012-01-01] *Caption from original*

History and Physical Exam

Findings That Confirm Diagnosis

- None

Factors That Suggest Diagnosis

- Nature and history of symptoms with presence of risk factors

Factors That Exclude Diagnosis

- An elevated troponin level is inconsistent with the diagnosis of unstable angina.

Ancillary Studies

Laboratory

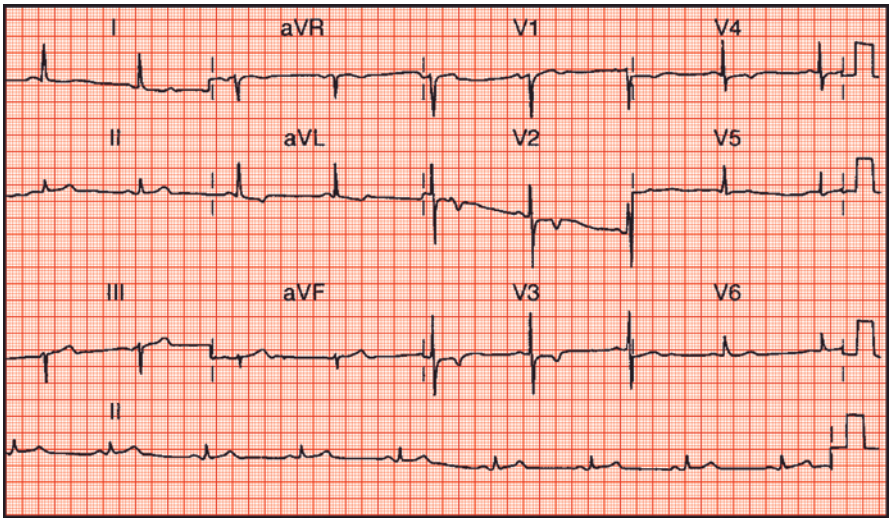
- CBC: no diagnostic findings.
- Electrolytes: no diagnostic findings.
- Renal function: no diagnostic findings, but renal insufficiency/failure is a risk factor for ACS and may complicate treatment.
- Coagulation studies: no diagnostic findings but should be performed before initiation of therapy.
- Cardiac enzymes: lack of elevation in troponin (I or T) levels is required to differentiate unstable angina from myocardial infarction.
    - Time course is critical.
        - Depending on specific troponin assay and volume of muscle infarcted, generally takes about 6 hours after onset of symptoms for troponin levels to rise.

- A negative troponin within 6 hours of reliable onset time of symptoms is not particularly helpful.
  - If onset time unclear, start at time of presentation.
  - Patients may be given the *clinical* diagnosis of unstable angina and then be "upgraded" to NSTEMI if a subsequent troponin assay shows an elevated level.
- Positive troponin is *always* helpful, but use caution in interpreting levels in patients with renal insufficiency.

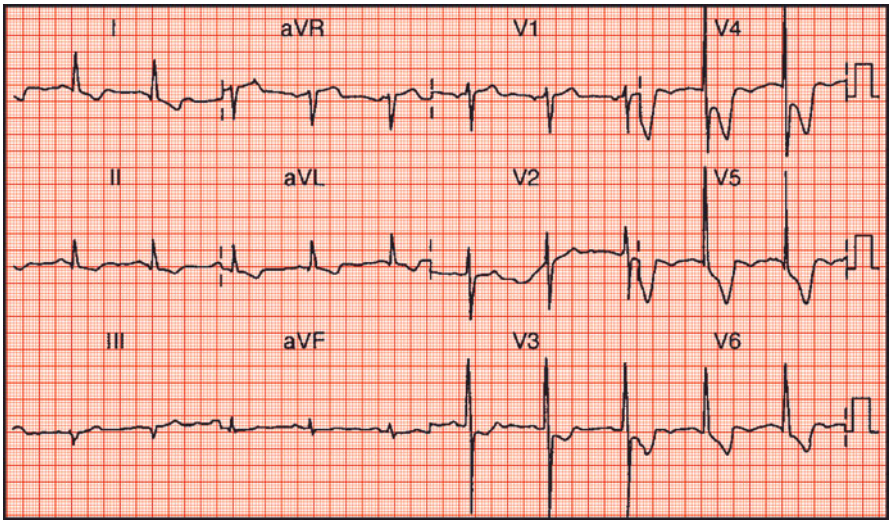
- BNP levels may offer some prognostic significance.

Electrocardiography

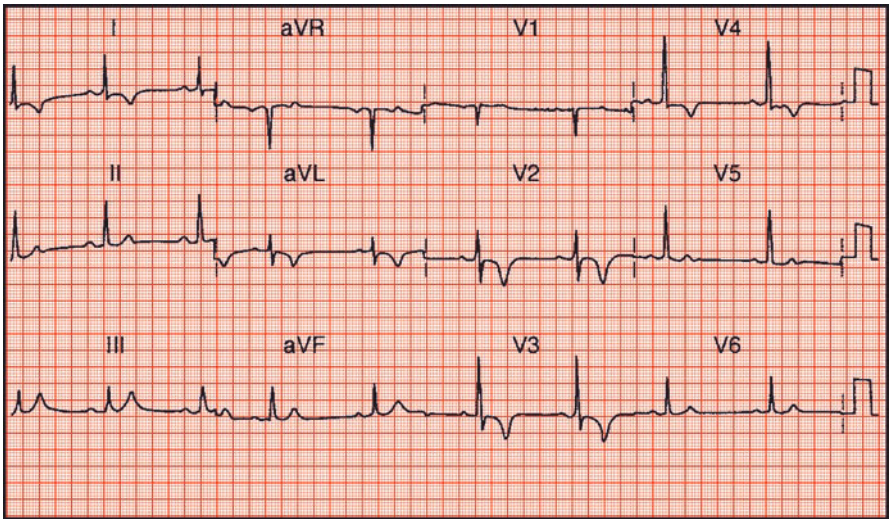
- No diagnostic findings, although both ST-segment depression and T-wave inversion confer a poorer prognosis in the setting of unstable angina.



This 57-year-old patient presented with unstable angina, ischemic changes (T wave inversions) are noted in the anteroseptal leads (aVL, V2, V3, V4) (SM; 13/3/93). [Peters N, Gatzoulis MA, Vecht R. ECG diagnosis in clinical practice. London: Springer; 2009. Chapter 2, Ischaemic (coronary) heart disease; p. 11-66.] *Caption from original*



Unstable angina with marked anterolateral ischemic changes. Cardiac catheterization showed critical mainstem stenosis. The patient underwent surgery on the same day (MK; 5/12/95). [Peters N, Gatzoulis MA, Vecht R. ECG diagnosis in clinical practice. London: Springer; 2009. Chapter 2, Ischaemic (coronary) heart disease; p. 11-66.] *Caption from original*



This 86-year-old man presented with severe unstable angina. His cardiac enzyme levels were not elevated. He was treated medically (PR; 16/4/95) [Peters N, Gatzoulis MA, Vecht R. ECG diagnosis in clinical practice. London: Springer; 2009. Chapter 2, Ischaemic (coronary) heart disease; p. 11-66.] *Caption from original*

- According to national quality standards in the United States, ECG should be obtained within 10 minutes of arrival at an emergency department.

Imaging

- No diagnostic findings for ACS on chest x-ray (CXR).
- Findings of heart failure (cardiomegaly, pulmonary congestion) on CXR portend a poorer prognosis in unstable angina.

Frontal chest radiograph reveals typical features of pulmonary interstitial edema in a patient with congestive heart failure, manifested by peribronchial cuffing, indistinctness of the pulmonary vessels, and Kerley B lines. Note the cephalization or redistribution of the pulmonary vasculature and mild cardiomegaly. [Boiselle PM, Dass C, Steiner RM. Radiologic imaging in the critically ill patient. In: Criner GJ, Barnette RE, D'Alonzo GE, editors. Critical care study guide. 2nd ed. New York: Springer; 2010. p. 181-207. Risk Scoring

TIMI risk score may be helpful in establishing short-term prognosis, which helps drive intensity of therapy.

- Age ≥65 years
- History of known CAD (documented prior coronary artery stenosis >50%)
- ≥3 conventional cardiac risk factors (age, male sex, family history, hyperlipidemia, diabetes mellitus, smoking, obesity)
- Use of aspirin in the past 7 days
- ST-segment deviation (persistent depression or transient elevation)
- Increased cardiac biomarkers (troponins)
- ≥2 anginal events in the preceding 24 h

TIMI = Thrombosis in Myocardial Infarction; CAD = coronary artery disease

Score = sum of number of above characteristics

TIMI = Thrombosis in Myocardial Infarction; CAD = coronary artery disease

Score = sum of number of above characteristics

TIMI risk score for unstable angina and NSTEMI. [Stillman AE, Oudkerk M, Ackerman M, Becker CR, Buszman PE, Feyter PJ, Hoffmann U, Keadey MT, Marano R, Lipton MJ, Raff GL, Reddy GP, Rees MR, Rubin GD, Schoepf UJ, Tarulli G, Beek EJR, Wexler L, White CS. Use of multidetector computed tomography for the assessment of acute chest pain: a consensus statement of the North American Society of Cardiac Imaging and the European Society of Cardiac Radiology. Int J Cardiovasc Imaging. 2007 Aug;23(4):415-27. https://doi.org/10.1007/s10554-007-9226-8, 2007-07-12] *Caption adapted from original*

Value	TIMI risk score[a] (95% CI)	Modified TIMI risk score[b] (95% CI)
Sensitivity	53.7 (44.9–62.3)	58.1 (49.8–66.4)
Specificity	75.2 (72.1–78.2)	82.6 (80.0–85.2)
Negative predictive value	90.6 (88.2–927)	92.2 (90.2–94.1)
Positive predictive value	26.6 (21.5–32.3)	35.9 (29.6–42.2)

[a] Using a cut point of 3 (less than 3 vs. 3 or greater)

[b] Using a cut point of 2 (less than 2 vs. 2 or greater)

A summary of the TIMI risk score and modified TIMI risk scores as predictors of 30-day myocardial infarction/revascularization/death. [Jaffery Z, Hudson MP, Jacobsen G, Nowak R, McCord J. Modified Thrombolysis in Myocardial Infarction (TIMI) risk score to risk stratify patients in the emergency department with possible acute coronary syndrome. J Thromb Thrombolysis. 2007 Oct;24(2):137-44. https://doi.org/10.1007/s11239-007-0013-0, 2007-08-02] *Caption adapted from original*

Special Populations

Age

- Risk for coronary artery disease that causes angina increases with age, starting at age 40 in men and at menopause in women.
  - Age is a risk factor for mortality from all types of ACS.
  - Likelihood of atypical presentation with unstable angina increases with age.

Comorbidities

- Hypertension, diabetes, and renal failure are important comorbidities in ACS risk and prognosis.
- Diabetes is associated with the likelihood of atypical presentation with unstable angina.
- Obesity is a weaker predictor of unstable angina risk.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- ECG must be performed as soon as the diagnosis of ACS is even considered. By definition, in unstable angina, there will not be persistent ST-segment elevation.

Mimics

- All differential considerations are listed under Primary Differential Considerations.
  - Of these, only aortic dissection and pulmonary embolism are also life threatening.

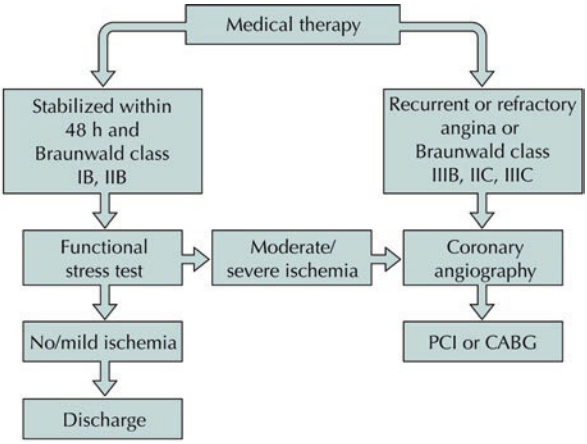
Time-Dependent Interventions

- Stabilization of the unstable angina patient is time-sensitive.
- Derangements in blood pressure should be addressed immediately: hypertension results in increased myocardial oxygen demand, and hypotension reduces blood supply to the myocardium.

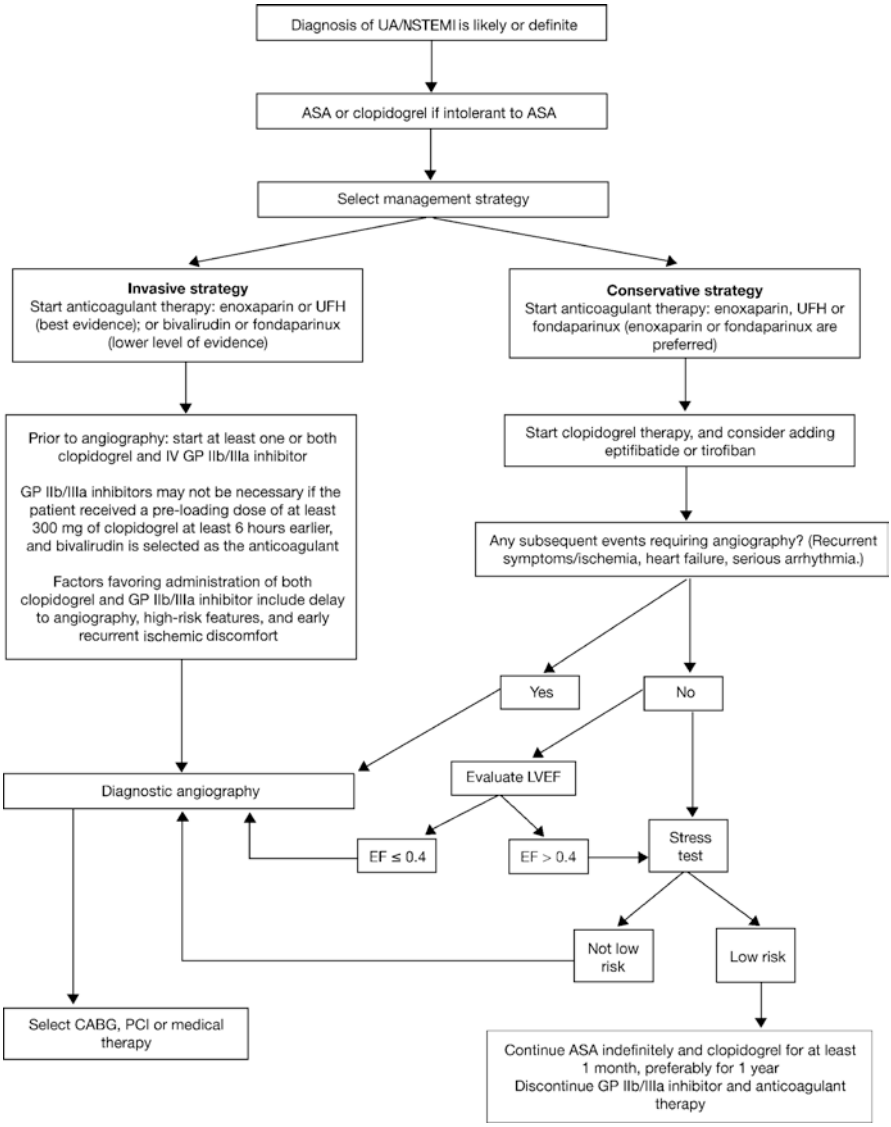
- Current guidelines call for diagnostic angiography in 24–48 hours to establish preferred course of management.
- Unless contraindicated (allergy, active bleeding), 324–325 mg aspirin should be administered immediately upon suspicion of an ACS.
- Anticoagulation therapy should be initiated upon determination of the diagnosis of unstable angina or when there is high suspicion in high-risk patients.
- Airway and oxygenation should be monitored and supported as necessary.
- Patients with a diagnosis of unstable angina should be on continuous cardiac monitoring to evaluate for dangerous arrhythmias.
- Consider early initiation of dual antiplatelet therapy (aspirin plus an ADP receptor antagonist—ticagrelor or clopidogrel).

Overall Principles of Treatment

- Immediate stabilization of the patient with control of blood pressure, pulse rate, and pain is critical. The patient with unstable angina only rarely requires resuscitation, intubation, and intensive support.
- Medical management with anticoagulation and antiplatelet therapy is important.
  - Bleeding risk should also be assessed so that the risk of treatment-related hemorrhage can be minimized.
- The higher the patient's risk, the more disproportionately s/he benefits from aggressive therapy.



Treatment for unstable angina [Prasad A, Holmes D, Kleiman N. Use of percutaneous coronary intervention in unstable angina and acute myocardial infarction. In: Califf RM, editor. Acute myocardial infarction and other acute ischemic syndromes. 2nd ed. Philadelphia: Current Medicine; 2001. Chapter 7. (Braunwald E, editor. Atlas of heart diseases; vol. 8.)]



Algorithm for the initial management of patients with UA/NSTEMI with an invasive or conservative treatment strategy. Abbreviations: ASA, aspirin; CABG, coronary artery-bypass grafting; EF, ejection fraction; GP, glycoprotein; IV, intravenous; LVEF, left ventricular ejection fraction; PCI, percutaneous coronary intervention; UA/NSTEMI, unstable angina/non-ST-elevation myocardial infarction; UFH, unfractionated heparin. [Cohen M. High-risk acute coronary syndrome patients with non-ST-elevation myocardial infarction: definition and treatment. Cardiovasc Drugs Ther. 2008 Oct;22(5):407-18. https://doi.org/10.1007/s10557-008-6120-0, 2008-09-04] *Caption adapted from original*

Disease Course

- The expected mortality rate associated with unstable angina alone is not clear, owing to differences in the definition of the disease. Mortality in NSTEMI—the other component of NSTE-ACS—is 6–10 %, depending on the population studied, over 6 months.

Chapter 5
Acute Pericarditis

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Acute pericarditis

Incidence/Epidemiology

- Acute pericarditis is the admitting diagnosis in 0.1 % of hospital admissions. Acute pericarditis accounts for 1 % of cases of ST-segment elevation seen in the emergency department.
- Acute pericarditis occurs more commonly in men than in women. There are no known geographic predilections. There is a very rare familial form (Mulibrey nanism)

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_5

Differential Diagnosis

- Acute pericarditis has many causes (see Pathophysiology and Etiology below), and often the differential exploration focuses on determining an etiology for the disease. This involves a search for co-morbidities as diverse as malignancy, renal failure, recent myocardial infarction, adverse effects of certain drugs, and collagen vascular diseases. Because the primary clinical manifestation of acute pericarditis is chest pain, the differential is broad.

Pathophysiology and Etiology

- The pathophysiology of acute pericarditis, regardless of etiology, is inflammation of the pericardium, a double (serous and parietal) membrane separated normally by 15-50 mL of fluid that is an ultrafiltrate of plasma.
- The function of the pericardium is to prevent sudden overdistention of the cardiac chambers and to help maintain the anatomic position of the heart and great vessels. By definition, acute pericarditis is present and symptomatic for less than 6 weeks; pericarditis for 6 weeks to 6 months is termed subacute, and beyond 6 months, chronic.
    - This inflammation may result from a myriad of potential causes:
        - Infectious:
            - Viral (Coxsackie, echovirus, adenovirus, HIV)
            - Tuberculous
            - Pyogenic (pneumococcal, streptococcal, staphylococcal)
            - Fungal (histoplasmosis, coccidioidomycosis, blastomycosis, *Candida*)
        - Noninfectious:
            - Post–myocardial infarction (Dressler's syndrome)
            - Uremia/renal failure
            - Neoplastic (primary or metastatic [lung, breast, lymphoma, Hodgkins])
            - Myxedema
            - Trauma (penetrating or nonpenetrating)
            - Aortic dissection into pericardium
            - Post–radiation therapy
            - Rheumatic fever
            - Collagen vascular disease (lupus, rheumatoid arthritis, scleroderma, Wegener's granulomatosis)
            - Drug-induced (procainamide, hydralazine, INH, phenytoin, doxorubicin, rifampin, methyldopa)
            - Idiopathic (most common)

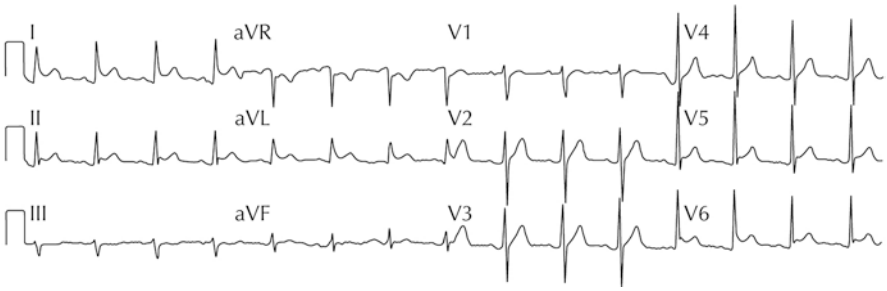
Presentation

Typical/"Classic"

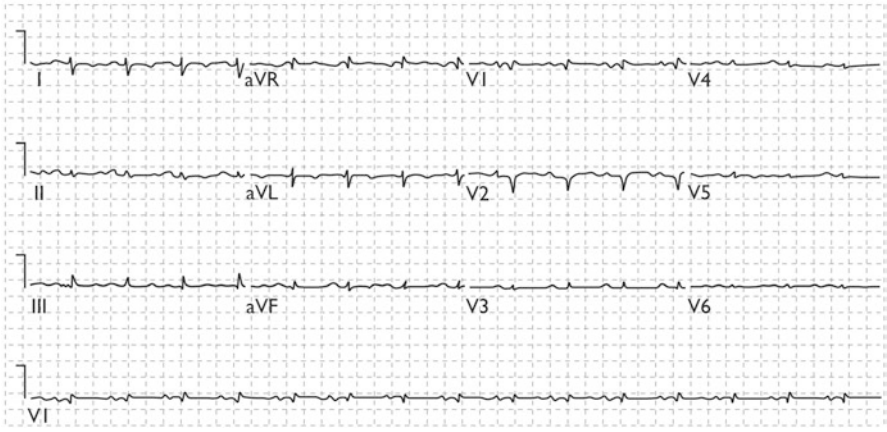
- Chest pain and a pericardial friction rub are most the common findings.

http://www.easyauscultation.com/acute-pericarditis
[Acute Pericarditis Page; Easy Auscultation; copyright 2015, MedEdu LLC]

- On electrocardiography, there are electrical changes suggesting acute pericarditis, and if there is also an effusion there is generalized low voltage.



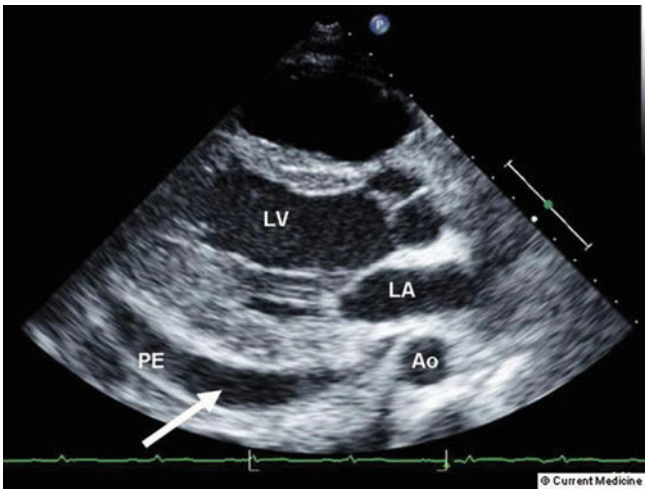
ECG finding in acute pericarditis [Oh J, Espinosa R. Pericardial disease. In: Vannan MA, Lang RM, Rakowski H, Tajik AJ, editors. Atlas of echocardiography. Philadelphia: Current Medicine; 2005 (Braunwald E, editor. Atlas of heart diseases; vol. 16).] *Caption from original*



Typical amyloid ECG with diffuse low voltage [Wellens H, Subramaniam K. The electrocardiogram in heart failure. In: Shivkumar K, Weiss JN, Fonarow GC, Narula J, editors. Atlas of electrophysiology in heart failure. Philadelphia: Current

Medicine; 2005 (Braunwald E, editor. Atlas of heart diseases; vol. 15).] *Caption from original*

- On echocardiogram, an effusion may be visible but is not required for a diagnosis of acute pericarditis.



Echocardiogram of pericardial effusion. Arrow indicates descending thoracic aorta. [Aurigemma G, Tighe D, Oh J, Espinoza R. Pericardial disease and cardiac masses. In: Solomon SD, editor. Atlas of echocardiography. 2nd ed. Philadelphia: Current Medicine; 2008.] *Caption adapted from original*

In: Solomon SD, editor. Atlas of echocardiography. 2nd ed. Philadelphia: Current Medicine; 2008.] *Caption adapted from original*

- If the effusion is large (>250 mL), the heart takes on a "water bottle" appearance on plain chest x-ray.

Chest X-ray in pericardial effusion: water bottle shaped heart. [Tissot C, Phelps CM, Cruz EM, Miyamoto SD. Pericardial diseases. In: Munoz R, Morell V, Cruz E, Vetterly C, editors. Critical care of children with heart disease. London: Springer; 2010. p. 521-41. https://doi.org/10.1007/978-1-84882-262-7_47; 2009-01-01] *Caption from original*

- Cardiac tamponade may develop, and the patient may have pulsus paradoxus.

http://www.youtube.com/watch?feature=player_embedded&v=jTsjCZ9QxW8
Stanford 25 video on pulsus paradoxus. Provides definition, guidance on testing, sound clip.

- The pain is often severe. It is most often substernal and left-sided. It often radiates to the back and to the trapezius ridge.

Trapezius ridge: the lower border of trapezius, 1; the rhomboids, 2. [Birch R. Surgical disorders of the peripheral nerves. London: Springer; 2010. Chapter 5, Clinical aspects of nerve injury; p. 145-90] *Caption adapted from original*

- The pain is often pleuritic in nature, so it is aggravated by deep inspiration, cough, and lying down as opposed to sitting up.
- The friction rub is the most important physical sign of acute pericarditis. It is often described as "scratching" or "grating," and it may be evanescent. It is best heard with the diaphragm of the stethoscope along the lower left sternal border, with the patient sitting up, during exhalation.
- The classic ECG findings of acute pericarditis are diffuse, mild ST-segment elevation across the precordium. Depression of the PQ segment is common. With large effusions, the overall voltage on the ECG is reduced. Occasionally, atrial fibrillation occurs with acute pericarditis. The ST-segment elevation associated with acute pericarditis can be differentiated from simple early repolarization, and from left ventricular hypertrophy with strain, by considering the ratio of the amplitude of ST segment to the amplitude of the T wave in leads I, V4, V5, and V6.

Atypical

- The most common form of pericarditis is idiopathic, and the diagnosis is one of exclusion. Patients with acute pericarditis and no effusion may present with chest pain and no audible friction rub, with limited to no ECG changes. In this case, acute pericarditis is just one of many differential considerations in the chest pain syndrome presentation. As in other etiologies of chest pain syndrome, the pain may occur in non-substernal locations.

- Pain may be mostly absent in slowly developing pericarditis (neoplastic, uremic, postradiation). Worsening exercise intolerance may be a clue to the diagnosis in these patients.

Primary Differential Considerations

- The initial differential elements to be considered in a patient with a presentation consistent with acute pericarditis are angina, aortic dissection, pulmonary embolism, and distal esophageal pain.

History and Physical Exam

Findings That Confirm Diagnosis

- A full classic presentation (substernal and/or left-sided pleuritic chest pain, a friction rub, and diffuse mild ST-segment elevation on ECG) should be considered confirmatory and should prompt a search for an etiology other than idiopathic.

Factors That Suggest Diagnosis

- Any of the classic findings in isolation should elevate acute pericarditis in the differential diagnosis of the chest pain patient.
- Onset of pain within 2–4 days of acute myocardial infarction (Dressler's syndrome) or after thoracic surgery should elevate acute pericarditis in the differential diagnosis of the chest pain patient.
- A presentation consistent with both acute pericarditis and an apparent cause of pericarditis (such as uremia, myxedema, acute infection, immunocompromise, collagen vascular disease, post chest irradiation) should elevate acute pericarditis in the differential diagnosis of the chest pain patient.
- Uremic pericarditis is most often seen in patients on hemodialysis (HD). A history of HD therefore is suggestive of the diagnosis. It should be noted that chest pain is often minimal or absent in uremic pericarditis, but a friction rub is common.

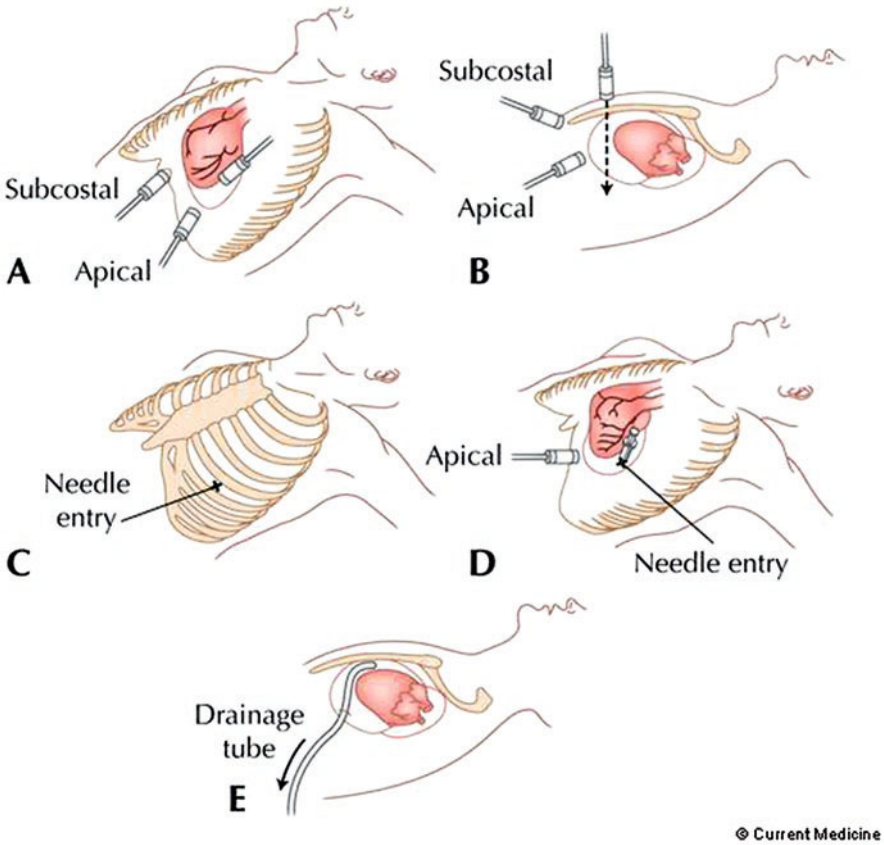
Factors That Exclude Diagnosis

- A normal echocardiogram excludes pericardial effusion and tamponade but not acute pericarditis.

Ancillary Studies

Laboratory

- Lab tests should include CBC; serum electrolyte, blood urea nitrogen (BUN), and creatinine levels; and erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP) levels. In the evaluation of chest pain syndrome, cardiac biomarker measurements are often indicated.
- The ESR and CRP levels are elevated in acute pericarditis, consistent with the underlying inflammation. These tests also are abnormal in patients with collagen vascular diseases, which may be an etiology of acute pericarditis.
- Other laboratory tests may be pertinent to the evaluation of the etiology of the pericarditis:
  - Assessment of renal function in possible uremic pericarditis
  - Assessment of thyroid function in possible myxedema
  - An antistreptolysin O (ASO) titer is indicated if rheumatic fever is suspected.
  - If a pericardial effusion is sampled via pericardiocentesis, the fluid should be tested for cell count, glucose and protein, and culture growth. Other specialized tests may be needed, and fluid should be retained for “unusual” requests by consultants.



Echocardiographically guided pericardiocentesis procedure [Aurigemma G, Tighe D, Oh J, Espinoza R. Pericardial disease and cardiac masses. In: Solomon SD, editor. Atlas of echocardiography. 2nd ed. Philadelphia: Current Medicine; 2008.] *Caption from original*

https://www.youtube.com/watch?v=y0-K2RcThi0

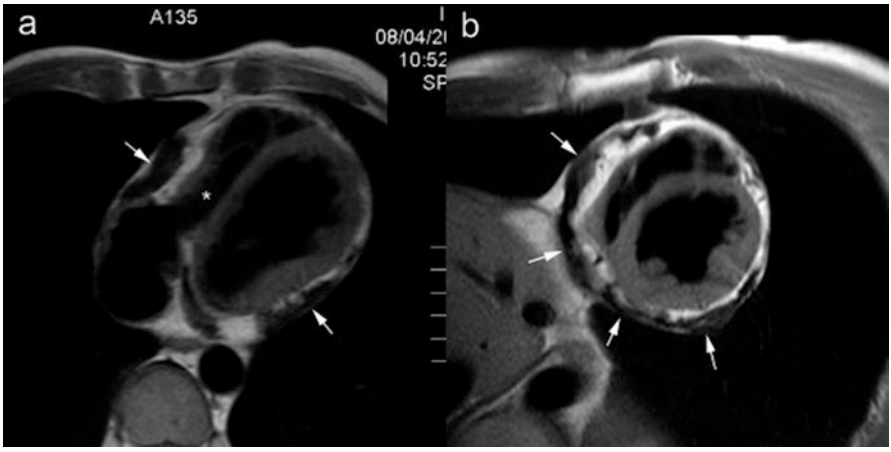
Video from MD Anderson Cancer Center explaining the anterior chest approach to pericardiocentesis.

Imaging

- There are no diagnostic imaging findings of acute pericarditis. When a pericardial effusion is present, transthoracic echocardiography will demonstrate an echo-free space between the visceral and parietal layers of the pericardium.
- Echocardiography should be performed in all cases of pericarditis, because any form of pericardial inflammation may induce pericardial effusion. It is important to note that in the absence of effusion, the pericardium may have a normal appearance in pericarditis.
- With large effusions, a "swinging heart" may be seen on echocardiography, as the heart "floats" in the effusion fluid.

https://www.youtube.com/watch?feature=player_embedded&v=huXuWp_eOKQ
Brief clip of cardiac tamponade with swinging heart echocardiogram.

- Plain chest radiographs are usually normal in acute pericarditis. If there is an effusion of 250 mL or more fluid, the cardiac silhouette will take on an enlarged, "water bottle" appearance.
- Smaller effusions may be detected by MRI, which can also assess the thickness of the pericardium (normal, 4 mm). In acute pericarditis, the pericardium may be globally or locally thickened.



Classic presentation of constrictive pericarditis on T1-weighted fast spin-echo CMR, axial view (a), and short-axis view (b) [From article: Cardiovascular magnetic resonance in pericardial diseases. J Cardiovasc Magn Reson. 2009; 11(1):14. https://doi.org/10.1186/1532-429X-11-14, at http://link.springer.com/article/10.1186%2F1532-429X-11-14; by Jan Bogaert, Marco Francone, © Bogaert and Francone; licensee BioMed Central Ltd. 2009; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

Special Populations

Age

- Acute pericarditis is more common in adults than in children, but adolescents are more commonly affected than young adults
- The most common presenting complaint in children with pericarditis is chest pain, accompanied by the typical findings seen in patients of any age.
- In children, the clear majority of cases are viral in etiology, since autoimmune diseases usually present no earlier than late adolescence.

Co-morbidities

- Review of the etiologies of acute pericarditis will indicate co-morbidities of interest. Uremia, malignancy, and immunocompromise are the most worrisome of these.

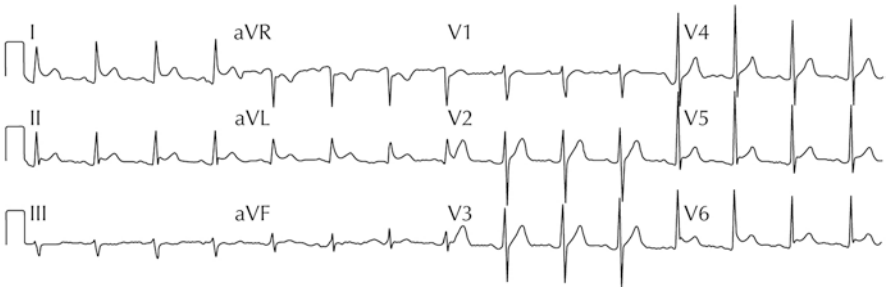
Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step. In patients with hemodynamic compromise, an echocardiogram should be performed early to assess for effusion, or even tamponade, and to measure the pumping ability of the heart.
- Acute pericarditis is one of the few diagnoses in which an ESR and CRP are actually very helpful.

Mimics

- The entire constellation of diagnoses that underlies chest pain syndrome can mimic the pain and overall presentation of acute pericarditis.
- Because acute pericarditis is often associated with diffuse ST-segment elevation on ECG, acute coronary syndrome must be always considered as an alternative diagnosis. PR-segment depression usually is also seen in patients with acute pericarditis who have ST-segment elevation.



ECG finding in acute pericarditis [Oh J, Espinosa R. Pericardial disease. In: Vannan MA, Lang RM, Rakowski H, Tajik AJ, editors. Atlas of echocardiography. Philadelphia: Current Medicine; 2005 (Braunwald E, editor. Atlas of heart diseases; vol. 16).] *Caption from original*

Time-Dependent Interventions

- Time-dependent interventions in acute pericarditis are necessary only when cardiac function is compromised, which is usually the case only when there is a large pericardial effusion. In such patients, pericardiocentesis may be a life-saving procedure.

Overall Principles of Treatment

- Because acute pericarditis is an inflammatory disease, the primary treatment in idiopathic pericarditis comprises anti-inflammatory agents (such as corticosteroids [e.g., prednisone] and nonsteroidal anti-inflammatory drugs [NSAIDs]). Resistant cases may require a surgical pericardiectomy, pericardiotomy, or pericardial window.
- Patients with an identified underlying cause of their pericarditis generally benefit from better control/specific treatment of the disease.

Disease Course

- Idiopathic pericarditis generally resolves within 1-2 weeks with anti-inflammatory therapy. The recurrence rate may reach 33 %.
- The course of secondary pericarditis typically follows control of the underlying disease.

Chapter 6
Anomalous Coronary Arteries

Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

- Anomalous Left Coronary Artery from the Pulmonary Artery (ALCAPA)
- Also known as Bland-White-Garland Syndrome

Incidence/Epidemiology

- A rare but serious congenital anomaly.
- Usually an isolated cardiac anomaly.
- If unaddressed, mortality rates reach 90 % in the first year of life.

Differential Diagnosis

- Dilated cardiomyopathy
- Myocarditis

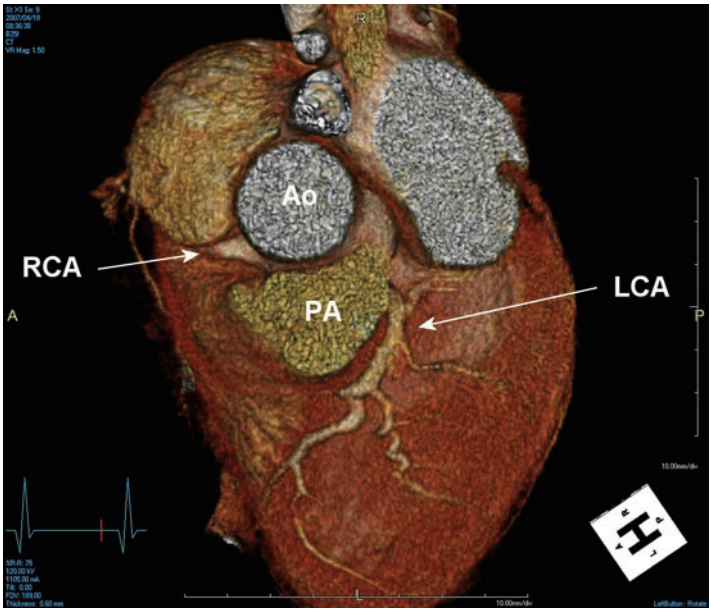
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_6

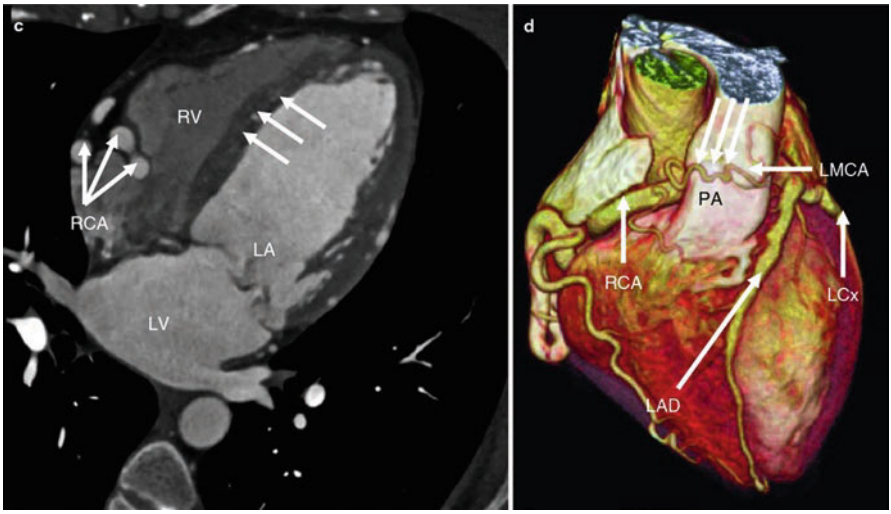
- Coronary artery fistula
- Severe mitral regurgitation

Pathophysiology and Etiology

- After birth, pulmonary pressures decrease, as does pulmonary arterial oxygen content.
- As a result of this, the left ventricular musculature is underperfused and underoxygenated.
- This is often accompanied by varying degrees of mitral insufficiency.



Three-dimensional image of patient. In this cranial view of the heart, the left coronary artery (LCA) can be seen to originate from the pulmonary artery (PA), a condition known as ALCAPA. The right coronary artery (RCA) has a normal origin from the right coronary cusp of the aorta (Ao) [de Jonge GJ, van Ooijen PMA, Piers LH, Dikkers R, Tio RA, Willems TP, van den Heuvel AFM, Zijlstra F, Oudkerk M. Visualization of anomalous coronary arteries on dual-source computed tomography. European Radiology. 2008 Nov;18(11):2425–32.] *Caption adapted from original*



Anomalous pulmonary origin of left main coronary artery (LMCA) from the main pulmonary artery (MPA) also known as ALCAPA or Bland–White–Garland syndrome. Panels (a) and (b) are multiplanar reformats demonstrating the takeoff of the LMCA from the MPA. Panels (c) and (d) illustrate the very large and tortuous right coronary artery (RCA), which provides oxygenated myocardial blood supply for the whole myocardium via an extensive collateral circulation to the branches of the left coronary circulation, and seen best in panel (c and d) and shown by the arrows. Note the flow of blood from the left coronary artery to the MPA. Aoasc ascending aorta, LA left atrium, LAA left atrial appendage, LAD left anterior descending artery, LCx left circumflex artery, LV left ventricle, RA right atrium, RV right ventricle, SVC superior vena cava [Mazur W, Siegel MJ, Miszalski-Jamka T, Pelberg R. Coronary Artery Anomalies. CT Atlas of Adult Congenital Heart Disease [Internet]. London: Springer London; 2013 [cited 2016 May 31]. p. 183–202. Available from: http://link.springer.com/10.1007/978-1-4471-5088-6_16] *Caption from original*

Presentation

Typical/"Classic"

Typical signs and symptoms of ALCAPA appear in the first two months of life and include:

- Abnormal heart rhythm
- Enlarged heart
- Heart murmur (rare)

- Rapid pulse
- Crying or sweating during feeding ("splanchnic steal")
- Pale skin
- Poor feeding, poor weight gain
- Rapid breathing
- Sweating
- Symptoms of pain or distress in the baby (often mistaken for colic)

Atypical

- Poor feeding and fussiness in infant, at first attributed to colic.
- Occasionally ALCAPA does not present until adolescence or early adulthood.

Primary Differential Considerations

- Dilated cardiomyopathy due to other causes, such as myocarditis, should be considered.

History and Physical Exam

Findings That Confirm Diagnosis

- The combination of respiratory distress, diaphoresis, and pallor, accompanied by ECG findings consistent with myocardial ischemia, will point the clinician toward making the diagnosis.
- Auscultation may demonstrate a systolic murmur consistent with mitral valve regurgitation.

http://www.easyauscultation.com/mitral-regurgitation

Mitral regurgitation audio. [Mitral Regurgitation Page; Easy Auscultation; www.easyauscultation.com/mitral-regurgitation; copyright 2015, MedEdu LLC]

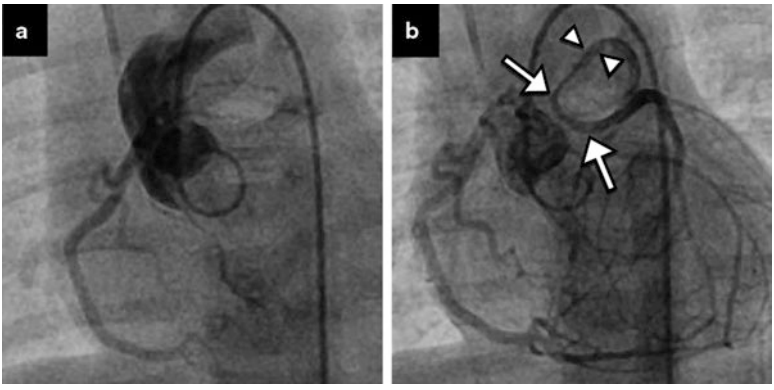
- In severe cases, signs of congestive heart failure (CHF) will be present, including tachycardia, tachypnea, gallop, poor perfusion, and signs of right sided failure (late).

Factors That Suggest Diagnosis

- ANY infant or child who presents with diaphoresis during feedings should be considered a candidate for a full cardiac workup.

Factors That Exclude Diagnosis

- ALCAPA cannot be excluded in symptomatic patients based on history and physical alone. Coronary angiography is required.

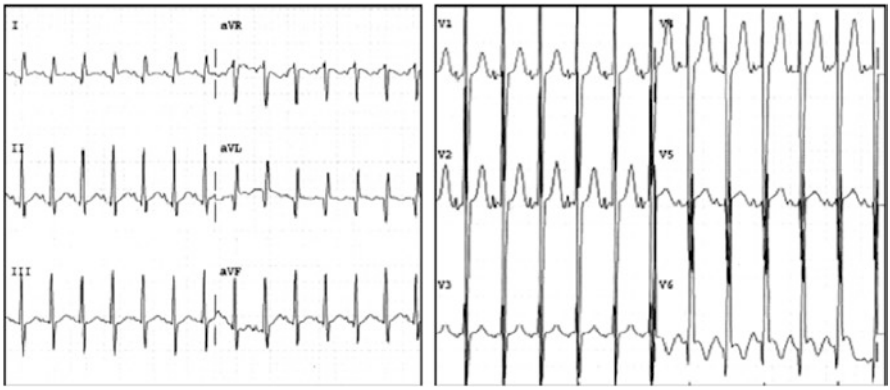


Still images (a, b) from the patient's digital subtraction angiogram (DSA). Injection of the aortic root demonstrates an enlarged and tortuous RCA with several epicardial collateral vessels; no sign of the LCA during early phase of injection (a). There is retrograde filling of the ALCAPA (arrows) (b) via multiple small collaterals from the right coronary system. There is retrograde flow of contrast through the ALCAPA and into the PA (arrowheads) [Day K, Avery R, Oliva I, Jokerst C. Coronary CTA appearance of anomalous left coronary artery arising from the pulmonary artery with Intramural Aortic Route. The International Journal of Cardiovascular Imaging. 2014 Feb;30(2):241–3.] Available from http://springerimages.com/Images/MedicineAndPublicHealth/1-10.1007_s10554-013-0334-3-1. *Caption from original*

Ancillary Studies

Electrocardiography

- In most cases, a pattern consistent with an anterolateral infarct with abnormal deep (>3 mm) and wide (>30 msec) q waves is observed in leads I, aVL, V_5, and V_6.



Typical electrocardiogram in anomalous left coronary artery arising from the pulmonary artery (ALCAPA) syndrome: Q waves in I and avL with prominent Q waves in V6 [Tissot C, da Cruz EM, Miyamoto S. Cardiac Failure. In: Munoz R, Morell V, Cruz E, Vetterly C, editors. Critical Care of Children with Heart Disease [Internet]. London: Springer London; 2009 [cited 2016 Jul 28]. p. 557–72. Available from: http://link.springer.com/10.1007/978-1-84882-262-7_49] *Caption from original*

Cardiac Enzymes

- Unfortunately, laboratory tests are not definitive.

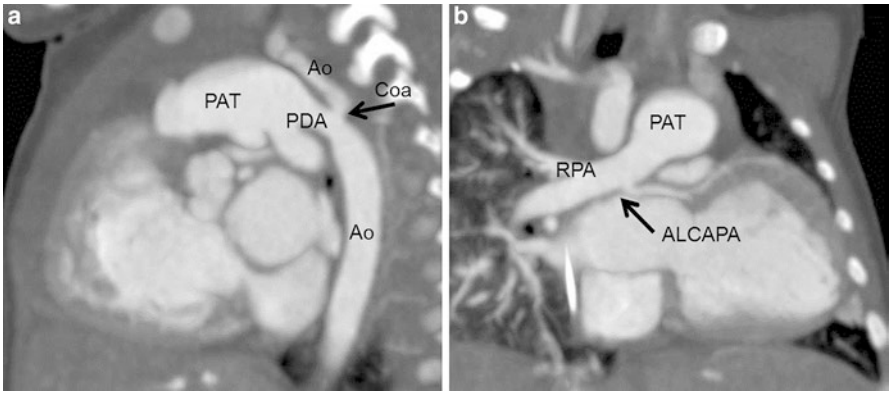
Special Populations

Age

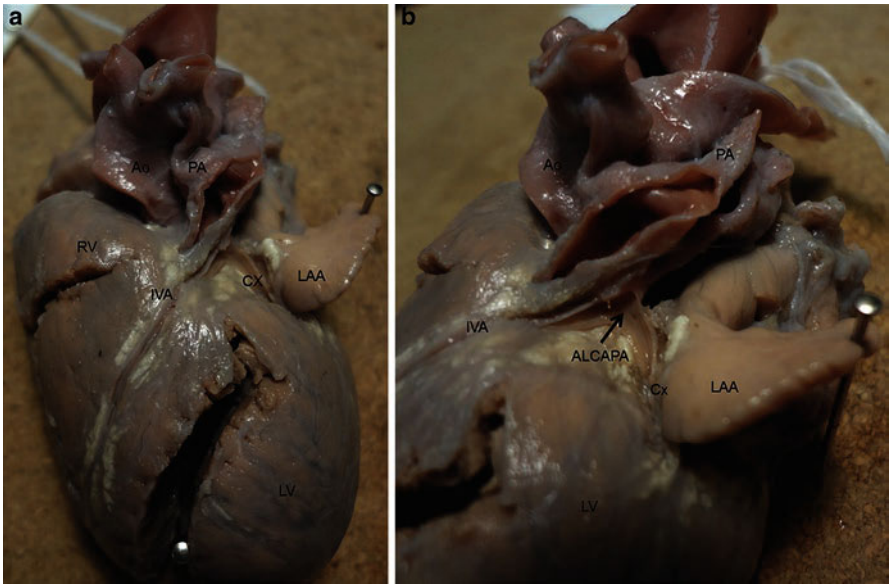
- ALCAPA is almost exclusively a pediatric disease, with only very rare presentations in adolescence or early adulthood.

Co-morbidities

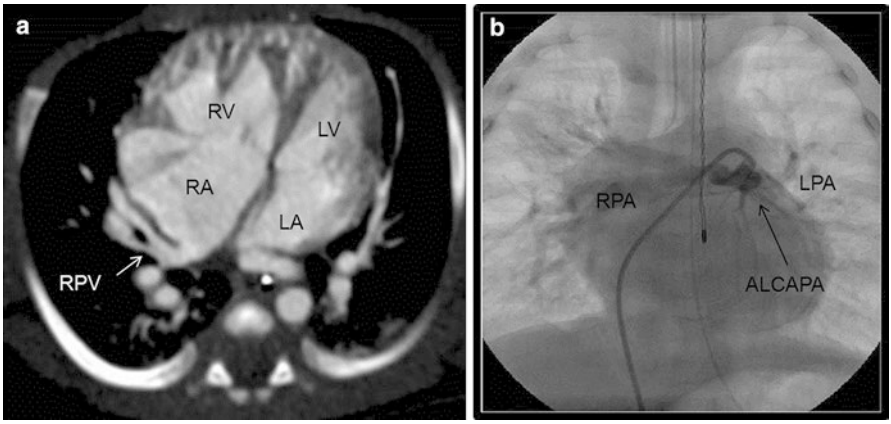
- ALCAPA may occur with other congenital malformations.
- When ALCAPA coexists with other congenital malformations, particularly those associated with pulmonary hypertension, the initial presentation can be quite confusing and is often misinterpreted.



Computer tomographic (CT) images of aortic coarctation and anomalous left coronary artery connected to the pulmonary artery (ALCAPA). a Sagittal CT image showing an aortic coarctation (CoA, black arrow) bypassed by a large persistent arterial duct (PDA). The horizontal aortic arch is hypoplastic. b Coronal CT image with the anomalous left coronary artery (ALCAPA, black arrow) connected to the right pulmonary artery (RPA), a rather rare anatomic variant. PAT pulmonary artery trunk [Laux D, Bertail C, Bajolle F, Houyel L, Boudjemline Y, Bonnet D. Anomalous Left Coronary Artery Connected to the Pulmonary Artery Associated With Other Cardiac Defects: A Difficult Joint Diagnosis. Pediatric Cardiology. 2014 Oct;35(7):1198–205.] Available from http://springerimages.com/Images/MedicineAndPublicHealth/1-10.1007_s00246-014-0916-4-0. *Caption adapted from original*



Macroscopic views of a heart with tetralogy of Fallot and pulmonary atresia associated with anomalous left coronary artery connected to the pulmonary artery (ALCAPA). **a** Frontal view of the heart in anatomic position with the apex to the left: The right (RV) and left (LV) ventricles have been opened, but the interior cannot be seen. The trunk of the pulmonary artery (PA) has been opened to confirm valvular atresia (not shown). The left coronary artery with its division in the infundibular anterior descending artery (IVA) and the circumflex (Cx) artery can be seen connecting to the PA. **b** A lateral, close-up view of the same heart with the opened ALCAPA and its two branches. LAA left atrial appendage, Ao aorta [Laux D, Bertail C, Bajolle F, Houyel L, Boudjemline Y, Bonnet D. Anomalous Left Coronary Artery Connected to the Pulmonary Artery Associated With Other Cardiac Defects: A Difficult Joint Diagnosis. Pediatric Cardiology. 2014 Oct;35(7):1198–205.] Available from http://springerimages.com/Images/MedicineAndPublicHealth/1-10.1007_s00246-014-0916-4-1. *Caption adapted from original*



Computed tomography (CT) scan and cardiac catheter image of patient 9 with divided left atrium, partial anomalous pulmonary venous connection, and anomalous left coronary artery connecting to the pulmonary artery (ALCAPA).**a** Four-chamber view of the patient's heart on an axial CT image: The right pulmonary veins (RPVs) connect to the right atrium (RA). **b** Left coronary artery abnormally connecting to the pulmonary trunk (ALCAPA, black arrow) in the same patient shown by anterograde injection of contrast agent into the pulmonary trunk during cardiac catheterization (frontal view). RV right ventricle, LA left atrium, LV left ventricle, RPA right pulmonary artery, LPA left pulmonary artery [Laux D, Bertail C, Bajolle F, Houyel L, Boudjemline Y, Bonnet D. Anomalous Left Coronary Artery Connected to the Pulmonary Artery Associated With Other Cardiac Defects: A Difficult Joint Diagnosis. Pediatric Cardiology. 2014 Oct;35(7):1198–205.] Available from http://springerimages.com/Images/MedicineAndPublicHealth/1-10.1007_s00246-014-0916-4-2. *Caption from original*

Pitfalls in Diagnosis

Critical Steps Not to Miss

- The most important step in making the diagnosis of ALCAPA is to accept the fact that there is a congenital anomaly that will present *exactly* like the adult form of ischemic heart disease.

Mimics

- As previously mentioned, the feeding difficulties in these infants will often be misinterpreted as colic or some form of dietary intolerance.

Time-Dependent Interventions

- Immediate consultation with a Pediatric Cardiologist is recommended
- Focus is on diagnosis, not treatment; time-dependent interventions are limited.

Overall Principles of Treatment

- In cases that present with CHF, supplemental oxygen is indicated.
- The use of diuretics may be beneficial, but should be applied *only* after consultation with a Pediatric Cardiologist.

Disease Course

- The prognosis is excellent if surgical correction is carried out.

Chapter 7
Anxiety

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Anxiety, anxiety disorder, panic disorder, panic attacks

Incidence/Epidemiology

- Anxiety disorder is a very common psychiatric condition. It often manifests through physical symptoms; chest pain +/- dyspnea/hyperventilation +/- palpitations is a common presentation of anxiety disorder.
- There is no good estimate of the incidence of anxiety as a cause of chest pain that prompts medical evaluation.
- Around 25 % of individuals are thought to experience at least one panic attack in their lifetimes.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_7

Differential Diagnosis

- Presentation can be quite dramatic. The differential considerations for chest pain due to anxiety therefore include immediate life threats such as pulmonary embolism, acute coronary syndrome, and aortic dissection. Less severe differential considerations include pneumonia and pneumothorax, which can cause pleuritic pain; and chest wall pain.

Pathophysiology and Etiology

- Current thinking is that anxiety and panic result from an imbalance in CNS neurotransmitters.
- The diagnosis of anxiety as an etiology for chest pain that prompts medical evaluation should be made only after more serious causes have been evaluated and reasonably excluded.

Presentation

Typical/"Classic"

- The classic presentation of anxiety- or panic-related chest pain is:
  - Acute onset
  - Associated with dyspnea (the patient may confuse hyperventilation with dyspnea)
  - Associated with diaphoresis
  - Trembling or shaking
  - Fear of dying
  - Sense of loss of control
  - Nausea

Atypical

- Patients with anxiety or panic disorder may present with myriad complaints. Chest pain is common among these, but many other features may be present.

Primary Differential Considerations

- The differential diagnosis of acute anxiety is broad and includes both medical and psychiatric considerations.
- Medical:
  - Because acute anxiety may mimic acute somatic disease, one must consider such immediate life threats as acute myocardial infarction, aortic dissection, arrhythmias, pulmonary embolism, pneumothorax, or stroke.
  - Other concerns include hypo- and hyperglycemia, poisoning and drug abuse, delirium tremens, and encephalopathy.
- Psychiatric:
  - Acute anxiety may be confused with acute psychosis, conversion disorders, dissociative disorders, schizoaffective disorder, and Tourette's syndrome.

History and Physical Exam

Findings That Confirm Diagnosis

- History and physical examination are not diagnostic for anxiety.

Factors That Suggest Diagnosis

- Symptoms are out of proportion with physical findings.
- Patient-reported dyspnea is found on exam to be hyperventilation.

Video overview of the causes and treatment of hyperventilation
https://www.youtube.com/watch?v=p97HeXx0vN0

- History of anxiety or panic disorder.
- Young age and/or lack of risk factors for more serious conditions.
- Choking sensation accompanying chest pain.
- Current substance abuse.

Factors That Exclude Diagnosis

- There are no history or physical findings that conclusively exclude anxiety as a cause of chest pain.

Ancillary Studies

Laboratory

- There are no diagnostic laboratory studies for anxiety.
- Laboratory tests target suspected underlying disease.

Imaging

- There are no diagnostic imaging studies for anxiety.

Special Populations

Age and Gender

- The epidemiology of anxiety and panic disorder does not indicate any consistent patterns by age or gender. It may begin at a young age.
- Anxiety disorders are the most common psychiatric disturbances in childhood, usually representing negative outcomes of naturally occurring fears associated with childhood development.
- The literature describes multiple forms of anxiety disorders in children, including social anxiety, agoraphobia, panic attacks, separation anxiety, and specific phobias.

Co-morbidities

- It is important to consider and evaluate for the presence of serious underlying disease or psychiatric stress that could prompt situation anxiety, such as:
  - Recent death of a loved one
  - Recent relationship stress
  - Recent diagnosis of serious disease
- Other psychiatric issues may be discovered upon questioning.
- Substance abuse issues may be discovered upon questioning.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Because there are differential considerations that are immediate life threats, evaluation for acute coronary syndrome, pulmonary embolism, and pneumonia should be considered early.

Mimics

- The entire constellation of diagnoses that underlies chest pain syndrome can mimic or cause the pain and overall presentation of anxiety.

Time-Dependent Interventions

- Other than excluding life threats, there are no time-dependent interventions for chest pain deemed due to anxiety or panic disorder.
- Patients who also express suicidal or homicidal ideation should be promptly evaluated in an emergency care setting.

Overall Principles of Treatment

- Treatment of the acute symptoms of chest pain caused by panic or anxiety disorder may include:
  - Reassurance and support
  - Benzodiazepines
  - Monitoring while the effects of acute substance abuse diminish

Disease Course

- The course of patients with anxiety or panic disorder may vary widely, from no further episodes to debilitating psychiatric illness that limits or precludes productive engagement with society.

Chapter 8
Aortic Regurgitation

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Aortic Regurgitation

- Aortic Insufficiency

Incidence/Epidemiology

- The most common causes of aortic regurgitation (AR) in the developed world are congenital bicuspid aortic valve and aortic root enlargement from diseases such as Marfan's syndrome.
- In the developing world, the most common cause of aortic regurgitation is rheumatic heart disease.
- The prevalence of aortic regurgitation increases with age, with about a 2 % prevalence of moderate to severe AR in men over 70, and about a 2.5 % prevalence of moderate to severe AR in women over 70.

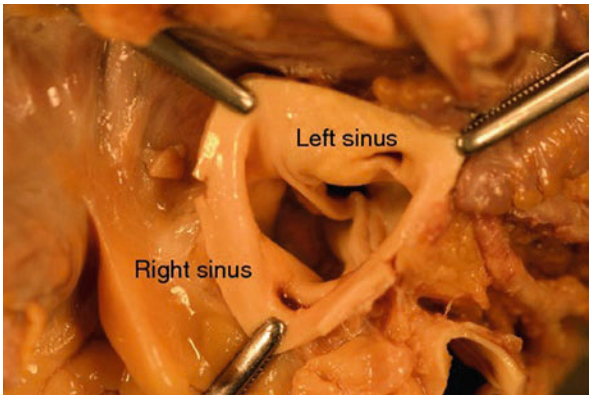
- Aortic regurgitation may result from either primary aortic valvular disease or aortic root disease.
- Primary valve disease. There are multiple causes of primary valve disease that may result in aortic regurgitation. The final common pathophysiologic pathway involves some deformity/disease of the valve leaflets that prevents normal systolic opening and/or diastolic closure. Usually these processes cause fibrosis, scarring, and hypertrophy of the valve leaflets. The causes of primary valve disease include:
    - Rheumatic valve disease, which is usually associated with concomitant mitral valve disease.
    - Congenital bicuspid aortic valve, which more commonly results in aortic stenosis, but may also develop into aortic regurgitation.



Bicuspid aortic valve. The origin of the coronary arteries can be appreciated in each of the sinuses. BAV was found during autopsy of a 41-year-old male who died from ischaemic heart disease [Suárez-Mier MP, Morentin B, Cobo M, Castedo E, García-Pavía P. Pathology of the Heart Valves. In: Lucena JS, García-Pavía P, Suarez-Mier MP, Alonso-Pulpon LA, editors. Clinico-Pathological Atlas of Cardiovascular Diseases [Internet]. Cham: Springer International Publishing; 2015 [cited 2016 Apr 4]. p. 171–200. Available from: http://link.springer.com/10.1007/978-3-319-11146-9_7] *Caption from original*

- Membranous, subaortic stenosis
- Infective endocarditis
- Syphilis
- Ankylosing spondylitis
- Ventricular septal defect
- Non-penetrating chest trauma
- Prior use of fenfluramine-phentermine

- Primary aortic root disease. Aortic root disease occurs with any process that causes widening and dilatation of the aortic root. This causes separation of the aortic valve leaflets and prevents normal opening and closing of the valve. Aortic root disease may result from:
  - Marfan's disease
  - Idiopathic
  - Annuloaortic ectasia
  - Osteogenesis imperfecta
  - Severe hypertension
  - Retrograde dissection of the aorta to the aortic root
  - Syphilitic aortitis
  - Ankylosing spondylitis

- Hemodynamic consequences. When the aortic valve does not close completely during diastole, regurgitant blood will flow back from the aorta into the left ventricle. This increases the total stroke volume of the left ventricle because in addition to normal blood flow from the left atrium, regurgitant blood flow from the aorta also fills the left ventricle during diastole. This results in an increased left ventricular end diastolic volume (LVEDV), or increased preload. Initially, the heart compensates for the volume increase with left ventricular (LV) dilatation and subsequent hypertrophy, maintaining a near-normal cardiac output and blood pressure. Eventually, however, the left ventricle can no longer dilate or hypertrophy any further, and the end-diastolic volume continues to increase, leading then to a decrease in stroke volume and forward flow. Initially, these changes manifest as exertional dyspnea and fatigue, as the cardiac output can be maintained during rest but not with exertion. These processes may take many years to develop, and there is generally a long asymptomatic period. It may take 15–20 years for symptoms to develop. This is typical, chronic aortic regurgitation.
- In some cases (especially with endocarditis, dissection, trauma) significant aortic regurgitation may develop acutely. In this situation, the left ventricle cannot handle the massive increase in LVEDV to sufficiently maintain stroke volume, and pulmonary edema or cardiogenic shock develops quickly.

Presentation

Typical/"Classic"

- Aortic regurgitation is generally a chronic, slowly progressive disease and may be asymptomatic for many (typically 15–20) years.
- Early complaints are somewhat nonspecific but may include:
- An unusual awareness of the heart beating, especially when lying down and on the left side. In these positions, the left ventricle becomes closer to the chest wall.
    - Persistent sinus tachycardia.
    - Palpitations with frequent ectopy. Ectopic beats may become even more uncomfortable than usual, as there is even more LV filling during the compensatory pause, so the eventual beat feels even "stronger" than usual.
    - Noticing that the head "bobs" with the heart beat when sitting quietly.
    - Chest pain, either exertional or nocturnal, often accompanied by severe diaphoresis and not significantly alleviated by sublingual nitroglycerin.
- The typical presentation is one of slowly worsening exertional dyspnea, associated with the typical diastolic murmur of aortic regurgitation. Often, the diastolic murmur is the first manifestation appreciated on routine examination, which then leads to the diagnosis.

Atypical

- The atypical presentation of aortic regurgitation is the acute presentation of pulmonary edema or cardiogenic shock.

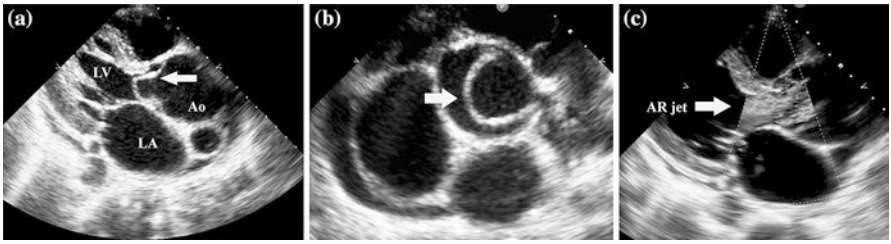
Primary Differential Considerations

- The differential diagnosis of AR is basically limited to other valve disorders, acute coronary syndrome, very proximal aortic dissection, and infective endocarditis.

History and Physical Exam

Findings That Confirm Diagnosis

- A consistent history and physical examination should be confirmed with a transthoracic echocardiogram.

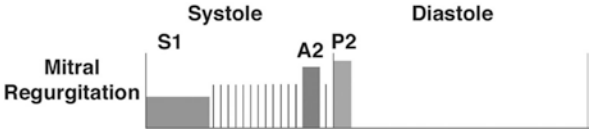


Transthoracic echocardiogram a parasternal long-axis view showing the dissection flap prolapsing into the LVOT (arrow), b parasternal short axis view showing a circular dissection flap (arrow) and c colour Doppler image showing severe aortic regurgitation (arrow). LVOT left ventricular outflow tract, LV left ventricle, LA left atria, Ao aorta, AR aortic regurgitation [Rajesh GN, Sajeer K, Anishkumar N, Sajeev CG, Krishnan MN. Intimo-intimal intussusception–circumferential aortic dissection: a rare mechanism of severe acute aortic regurgitation. Journal of Echocardiography. 2014 Sep;12(3):118–9.] *Caption from original*

Factors That Suggest Diagnosis

- Auscultatory findings.
  - Typical auscultatory findings can strongly suggest the diagnosis of aortic regurgitation.
  - The aortic closure sound (A2) may be soft or absent.
  - The classic murmur of chronic aortic regurgitation is a blowing, high-pitched, decrescendo, diastolic murmur, heard best in the third intercostal space along the left sternal border with the patient sitting up, leaning forward, at end expiration. There is little correlation between the intensity of the murmur and the degree of regurgitation. However, as the degree of regurgitation becomes greater, the duration of the murmur will increase and eventually become holosystolic. The murmur is usually accentuated by maneuvers that increase systemic vascular resistance, such as sustained handgrip, and squatting. The murmur decreases with Valsalva maneuver.

http://www.easyauscultation.com/cases-listing-details?caseID=124
The classic murmur of chronic aortic regurgitation. [Aortic Regurgitation (Decrescendo Diastolic Murmur); Easy Auscultation; www.easyauscultation.com; copyright 2014, MedEdu LLC]



Caused by an insufficiency of the mitral valve, the mitral regurgitation murmur is a systolic murmur best heard over the mitral auscultation area. A2 = aortic valve closure; P2 = pulmonic valve closure; S1 = first heart sound [Bojanov G. Blood Pressure, Heart Tones, and Diagnoses. In: Iaizzo PA, editor. Handbook of Cardiac Anatomy, Physiology, and Devices [Internet]. Totowa, NJ: Humana Press; 2009 [cited 2016 Apr 4]. p. 243–55. Available from: http://link.springer.com/10.1007/978-1-60327-372-5_16] *Caption from original*

- There is often an associated midsystolic ejection murmur, heard best at the base of the heart, that radiates into the carotids.
- The Austin Flint murmur is sometimes heard in severe, chronic AR. It is a soft-pitched, rumbling, mid- to late diastolic murmur, heard best at the apex. It is caused by turbulence from the interaction of the usual antegrade blood flow from the left atrium and the retrograde flow from the aorta. This turbulence may result in displacement of the mitral valve leaflets.

https://www.youtube.com/watch?v=y5CcncRHl38
Video of the Austin Flint murmur.

- Acute AR is associated with a softening of S1 due to the early closure of the mitral valve from the acutely increased LV end-diastolic volume. Often a soft, short, early diastolic murmur also is present.

- Many physical examination findings are associated with chronic, severe AR:
  - Widened pulse pressure. AR is often associated with systolic hypertension and a low diastolic pressure. A clue to disease progression is diastolic blood pressure that seems to increase over time, a result of the worsening regurgitant flow leading to increased end-diastolic volume. As the diastolic pressure approaches the LVEDV, they will eventually become equal and then rise, as the diastolic pressure cannot be below the LVEDV.
  - de Musset's sign: head bobbing with the heartbeat.
  - Corrigan (water hammer) pulse. The pulse is palpated with a forceful, rapid rise, and then quickly dissipates.

https://www.youtube.com/watch?v=OR19BOodAVI
Video demonstrating Corrigan's pulse in aortic regurgitation.

  - Quincke's pulse (capillary pulsations). While holding pressure at the tip of the nail, one can see pulsations of the skin at the nail bed; may also be seen at the lips.

https://www.youtube.com/watch?v=9m_0RAQDFHM
Video demonstrating Quincke's pulse

  - Traube's sign. A "pistol-shot" sound heard over the femoral artery.
  - Duroziez's sign. A back-and-forth bruit heard over the femoral artery after light compression with the head of the stethoscope.

Factors That Exclude Diagnosis

- A normal echocardiogram excludes aortic regurgitation.

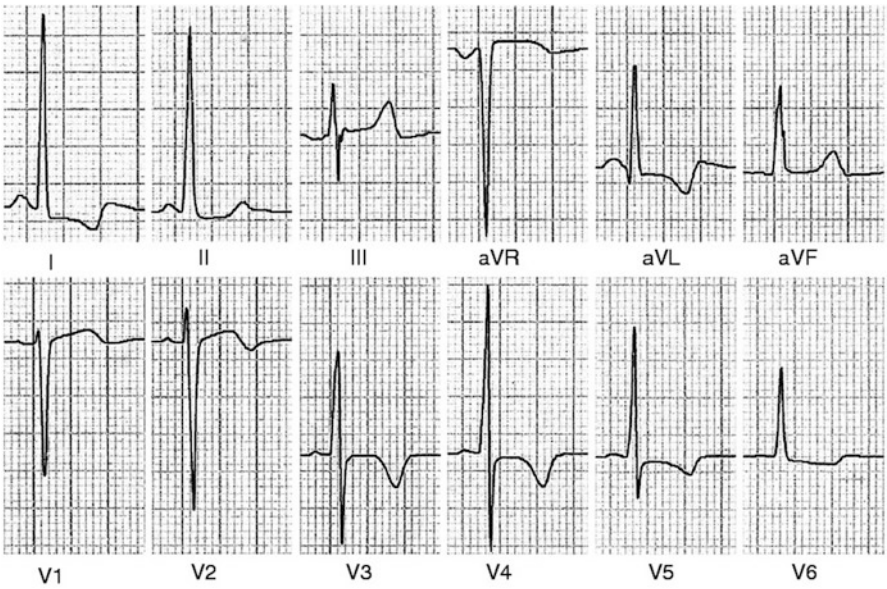
Ancillary Studies

Laboratory

- Lab tests for patients with these nonspecific but questionably cardiac complaints should include a CBC, complete metabolic panel, cardiac biomarkers, and a B-type natriuretic peptide.

Electrocardiography

- The ECG in chronic, severe aortic regurgitation often shows LV hypertrophy with an associated strain pattern. This is usually seen as large-voltage QRS complexes with ST depression and T-wave inversions in the inferolateral leads.

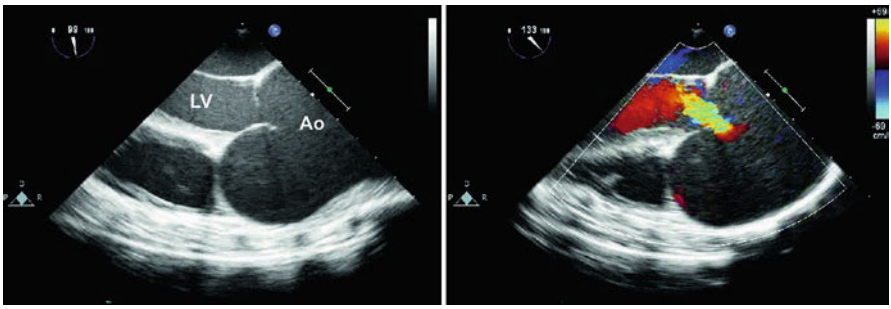


Electrocardiograph (ECG) in a patient with hypertrophic cardiomyopathy (HCM) showing left ventricular (LV) hypertrophy and T-wave inversion [Merlo M, Cocciolo A, Brun F, Sinagra G. Hypertrophic Cardiomyopathy: Clinical Assessment and Differential Diagnosis. In: Pinamonti B, Sinagra G, editors. Clinical Echocardiography and Other Imaging Techniques in Cardiomyopathies [Internet]. Cham: Springer International Publishing; 2014 [cited 2016 Apr 4]. p. 85–94. Available from: http://link.springer.com/10.1007/978-3-319-06019-4_9] *Caption from original*

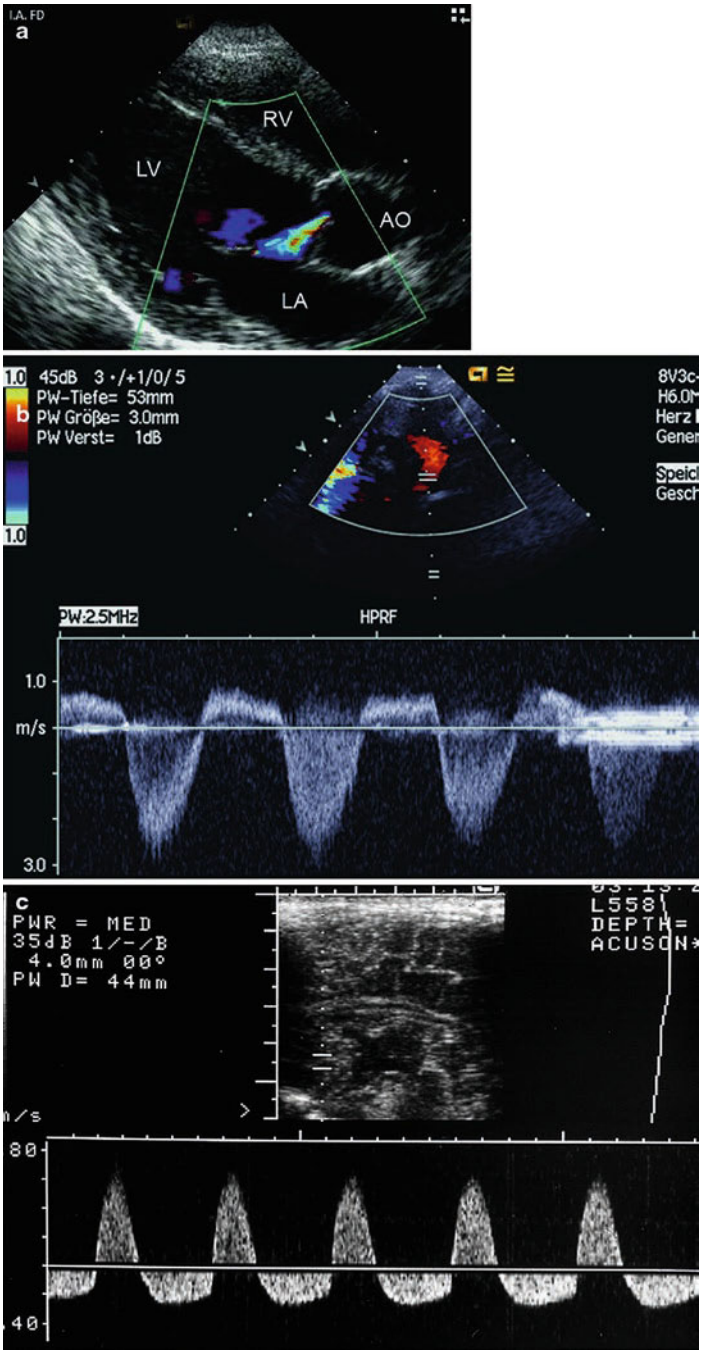
Imaging

- A transthoracic echocardiogram is the diagnostic study of choice in the diagnosis and evaluation of aortic regurgitation. It can document the presence of aortic regurgitation, quantify the regurgitant flow, and define the cause of aortic regurgitation.
- A chest x-ray may be normal, but also may show cardiomegaly associated with LV hypertrophy. In acute aortic regurgitation, the chest x-ray may be consistent with pulmonary edema.

- Cardiac catheterization and angiography may be useful if all other imaging modalities (echo, cardiac MRI) are inconclusive, as well as for preoperative evaluation of aortic regurgitation. Before valve replacement surgery, coronary angiography is often performed to evaluate for concurrent coronary artery disease.



Markedly dilated aortic root as seen from the mid esophageal aortic valve long axis view without color mapping (left panel) and with color mapping, showing central aortic regurgitation (right panel). Ao aorta, LV left ventricle [Lopez L, Ventura R, Choueiter NF. Outflow Tract Anomalies. In: Wong PC, Miller-Hance WC, editors. Transesophageal Echocardiography for Congenital Heart Disease. London: Springer-Verlag London; 2014. p. 283-305. https://doi.org/10.1007/978-1-84800-064-3_11] *Caption from original*



(a) Colour flow imaging of aortic insufficiency. Diastolic flow in the left ventricular outflow tract shown in the parasternal long axis view. The picture shows mild

diastolic backflow from the aorta into the left ventricular outflow tract. AO aorta, LA left atrium, LV left ventricle, RV right ventricle. (b) Flow measurement in the aortic arch in severe aortic regurgitation. Colour Doppler shows retrograde flow in the aortic arch which is displayed red. Pulsed Doppler shows diastolic backflow displayed above the baseline. (c) Flow measurement in the anterior cerebral artery in a patient with severe aortic regurgitation. Diastolic backflow caused by severe aortic regurgitation [Deeg K-H. Cardiovascular Diseases Which Influence the Flow in the Extracardial Arteries. In: Deeg K-H, Rupprecht T, Hofbeck M, authors. Doppler Sonography in Infancy and Childhood [Internet]. Cham: Springer International Publishing; 2015 [cited 2016 Apr 4]. p. 679–730. Available from: http://link.springer.com/10.1007/978-3-319-03506-2_15] *Caption from original*

Special Populations

Age

- Aortic regurgitation is more common in middle-aged and older adults, especially because the latent period before the appearance of symptoms may be two decades.
- Aortic regurgitation may be seen in children, in whom it is usually associated with either severe aortic stenosis or a ventricular septal defect. Most cases in children are mild and asymptomatic, and need only be followed with serial exams and echocardiography.

Co-morbidities

- Aortic regurgitation may be diagnosed in relatively healthy patients but also may present in the setting of numerous other cardiovascular diseases and risks.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step. In patients with hemodynamic compromise, an echocardiogram should be performed early to assess all hemodynamic parameters and determine the need for urgent operative intervention.

Mimics

- The entire constellation of diagnoses that underlies dyspnea, chest pain, and other valvular diseases can mimic the presentation of aortic regurgitation.

Time-Dependent Interventions

- Time-dependent interventions in aortic regurgitation are necessary only when acute aortic regurgitation is considered and cardiac and pulmonary function is compromised. In such patients, urgent valve replacement may be a lifesaving procedure.
- For chronic aortic regurgitation, there must be a well-planned and considered approach to operative intervention.

Overall Principles of Treatment

- Acute aortic regurgitation.
  - In acute aortic regurgitation, urgent valve replacement is indicated. Intravenous diuretics and vasodilators (such as sodium nitroprusside) may be helpful as a bridge to surgery.
  - In acute aortic regurgitation, intra-aortic balloon counterpulsation (IABP) is contraindicated, as it may worsen the regurgitation. Intravenous beta-blockers are relatively contraindicated, as they may decrease cardiac output even further.
- Chronic aortic regurgitation.
  - All patients diagnosed with aortic regurgitation, even those who are asymptomatic, must have their systolic blood pressure controlled. Aortic regurgitation is often associated with difficult-to-control systolic hypertension due to increased stroke volume. The goal should be less than 140 mm Hg. Most patients may benefit from vasodilator therapy with ACE inhibitors, dihydropyridine calcium channel blockers, or hydralazine.
  - Patients with early symptoms and mild dyspnea often also benefit from the addition of a diuretic.
  - Surgery with aortic valve replacement is indicated for all symptomatic patients with chronic aortic regurgitation.
  - The optimal time for surgery seems to be after the onset of LV dysfunction but before the development of symptoms. It is important to remember that patients with chronic AR do not become symptomatic until after LV dysfunction develops.

- Appropriately timed surgery often may restore normal LV function. However, surgery delayed for more than 1 year after the onset of LV dysfunction or symptoms often fails to restore normal LV function.
- If there are no indications for surgery, it is generally recommended that the patient be followed up with exams and echocardiograms every 3–6 months.
- Indications for operation in the asymptomatic patient include:
  - An LV ejection fraction <50 %
  - An LV end-systolic dimension < 55 mm or an end-diastolic dimension <75 mm
  - A regurgitant fraction ≥50 %
  - A regurgitant volume ≥ 60 mL

Disease Course

- Patients with AR may remain asymptomatic for decades, but many patients eventually require valve replacement surgery.
- Overall operative mortality is 3 %, but in the presence of prolonged LV dysfunction, mortality approaches 10 % and is then also associated with a late mortality approaching 5 % per year from LV failure.

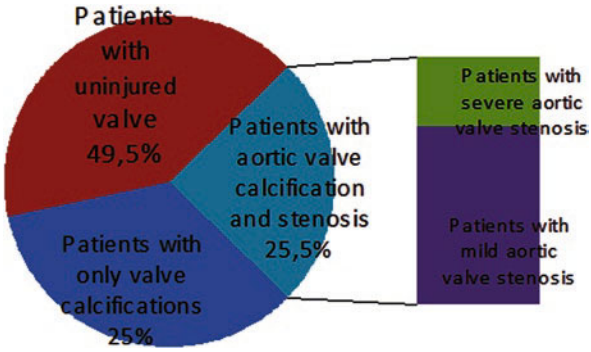
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_9

Differential Diagnosis

- The main issue to recognize is that the symptoms may be attributed to other disease processes, and aortic stenosis can be missed in the acute setting
- Other diagnostic considerations include supravalvular aortic stenosis, congenital subvalvular aortic stenosis, and hypertrophic obstructive cardiomyopathy.

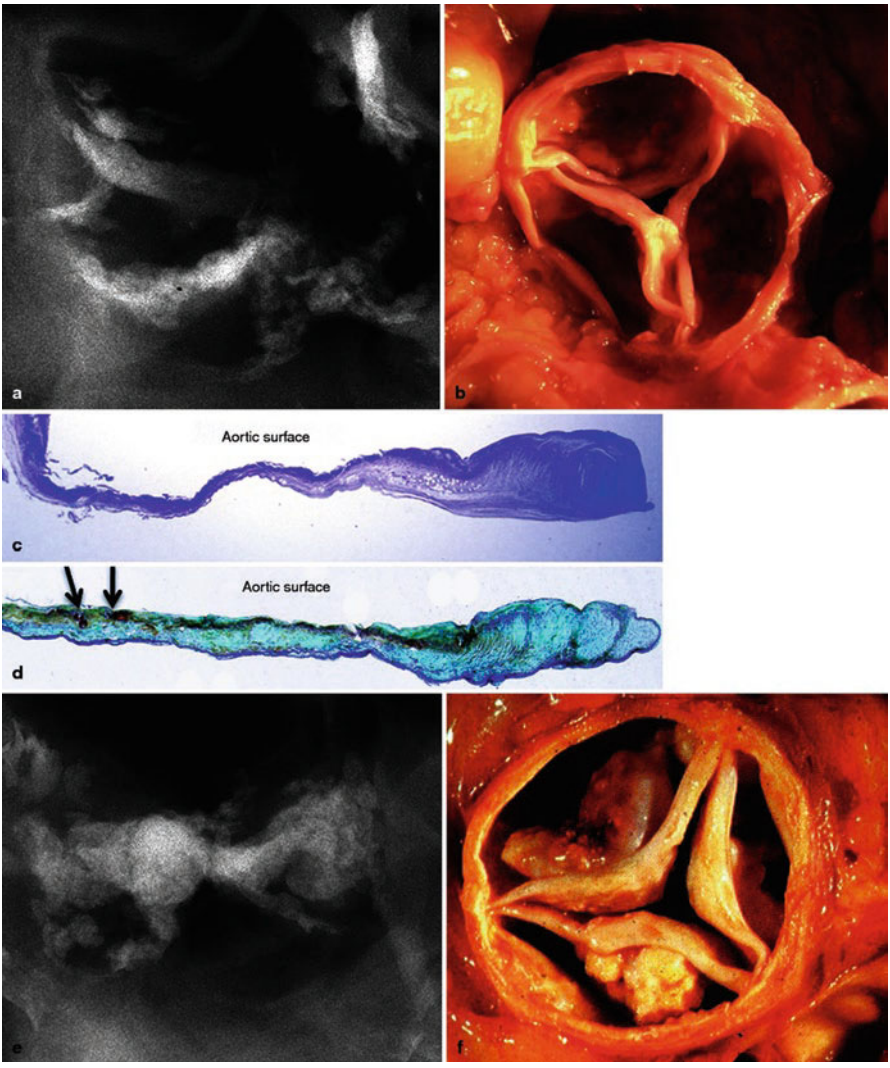
Pathophysiology and Etiology

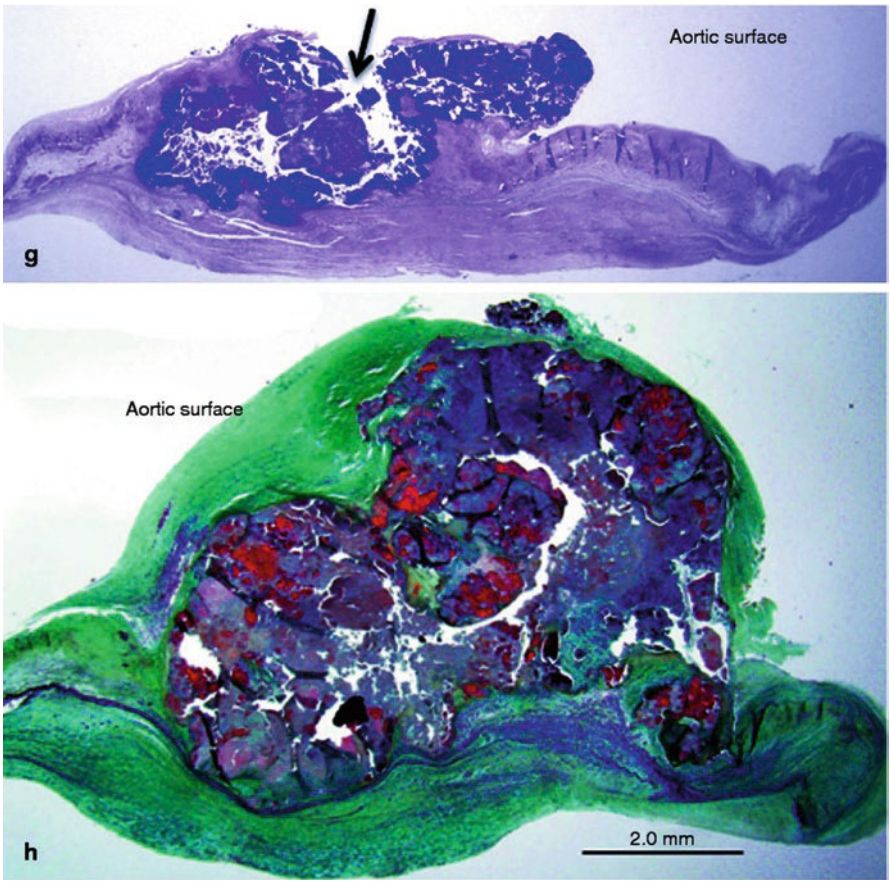
- Three primary causes of aortic stenosis:
  - Congenital (unicuspid/bicuspid valve) with superimposed calcification
  - Calcified disease of a trileaflet aortic valve
  - Rheumatic valve



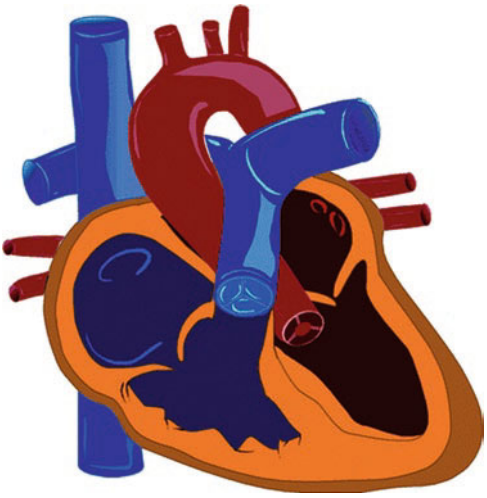
Distribution of population according to aortic valve degeneration. Patients with uninjured valve 49.5 %. Patients with aortic valve calcification and stenosis 25.5 %. Patients with only valve calcifications 25 %. [Fazio G, Caracciolo C, Barone R, D'angelo L, Di Maggio R, Vernuccio F, Siragusa S. An unknown cause of aortic valve stenosis: polycythemia vera. Journal of Thrombosis and Thrombolysis. 2013 Feb;35(2):282–5.] *Caption from original*

- Pathophysiology differs depending on the cause:
  - Calcified disease occurs when lipid accumulation triggers an inflammatory response by various mediators. There is local production of protein that promotes tissue calcification. Aortic stenosis occurs when the antegrade velocity across an abnormal valve is at least 2.6 m/sec.
  - Rheumatic valve disease causes fusion of the commissures between the leaflets leaving a small central opening.

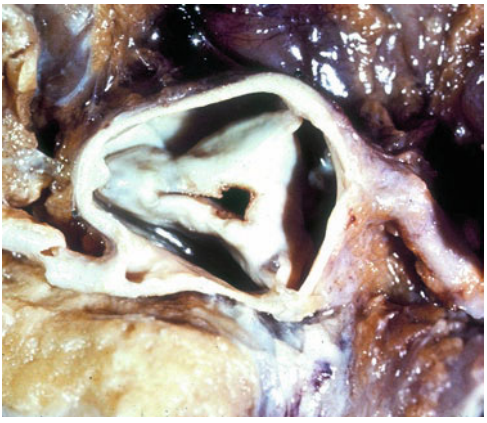




Two aortic valves seen at autopsy showing progression of calcific aortic stenosis. (a, b) Radiograph and gross image of aortic valve from an 83-year-old female. This valve shows mild calcification with small calcific deposits on aortic surface of cusps and sparing of the free edge. (c, d) Histologic sections of cusps showing fibrotic thickening and microscopic calcific deposits in the zona fibrosa (arrows). (e, f). Radiograph and gross image of stenotic aortic valve from an 82-year-old female. There is marked nodular calcification of the cusps with bulky deposits on the aortic surface. (g, h) Histologic sections of the cusps show calcific nodules superimposed on a fibrotic cusp with ulceration of the aortic surface (arrow). Note fibrotic thickening of the ventricular surface [Ladich E, Nakano M, Virmani R. Pathologic Findings in Aortic Stenosis. In: Min JK, Berman DS, Leipsic J, editors. Multimodality Imaging for Transcatheter Aortic Valve Replacement [Internet]. London: Springer London; 2014 [cited 2015 Aug 27]. p. 145–56. Available from: http://link.springer.com/10.1007/978-1-4471-2798-7_11] *Caption from original*



Aortic stenosis (AS). The aortic valve orifice is small; this may be a result of thickening of valve cusps, adhesion of cusp edges rendering separation between cusps during systole limited and/or due to small valve annulus [Holmes KW, McCarville MA. Aortic Stenosis. In: Abdulla R, editor. Heart Diseases in Children [Internet]. Boston, MA: Springer US; 2011 [cited 2015 Aug 27]. p. 149–58. Available from: http://link.springer.com/10.1007/978-1-4419-7994-0_11] *Caption from original*



Rheumatic heart disease: aortic stenosis. In this aortic valve, there is diffuse fibrosis of the three cusps and fusion of the three commissures, producing a narrow central orifice [Buja LM, Cheong B. Cardiovascular Pathology. In: Krueger GRF, Buja LM, editors. Atlas of Anatomic Pathology with Imaging [Internet]. London: Springer London; 2013 [cited 2015 Aug 27]. p. 43–104. Available from: http://link.springer.com/10.1007/978-1-4471-2846-5_2] *Caption from original*

Presentation

Typical/"Classic"

- Typically asymptomatic for a prolonged period of time. There is a wide degree of outflow obstruction that causes symptoms. On average, symptoms develop once the aortic valve area is < 1.0 cm^2. The typical symptoms are heart failure, syncope, and angina, but they reflect late disease.
- In earlier disease dyspnea on exertion, decreased exercise tolerance, dizziness, and exertional angina are more common findings.

Atypical

- Aortic stenosis can manifest as sudden cardiac death, atrial fibrillation, or endocarditis.

Primary Differential Considerations

History and Physical Exam

Findings that Confirm Diagnosis

- There is no single or combination of findings that is sensitive or specific enough to confirm the diagnosis of aortic stenosis.

Factors that Suggest Diagnosis

- The quality of the arterial pulse reflects degrees of obstruction. This is often described as "parvus and tardus," meaning the pulse is weak and increases slowly.
- There is a harsh systolic ejection murmur heard best at the second intercostal space on the right. The murmur can be transmitted to the carotid arteries.

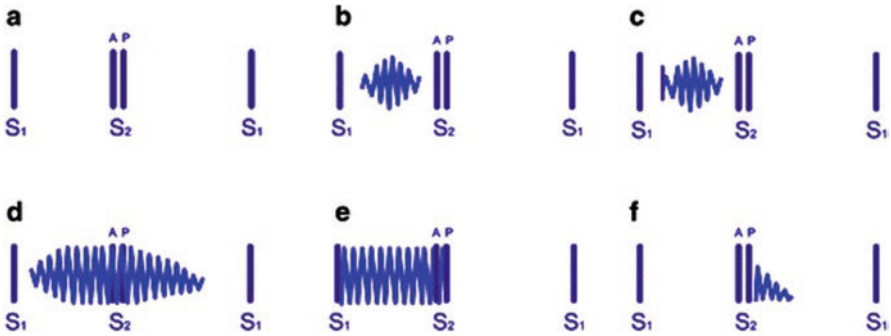
Aortic Stenosis (Diamond Shaped Systolic Murmur). [Aortic Stenosis (Diamond Shaped Systolic Murmur); Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

- The S2 heart sound can be paradoxically split with severe stenosis, and the S2 heart sound is soft.

http://www.easyauscultation.com/cases?coursecaseorder=3&courseid=31
Second Heart Sound – Splitting**.** [Second Heart Sound – Splitting; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]



Heart sounds and murmurs. (a) Normal heart sounds: once the ventricles start to contract at the onset of systole, the tricuspid and mitral valves close. Closure of the atrioventricular valves contributes to the first heart sound which tends to be single. Aortic and pulmonary valves open soon after S1; however, this is usually inaudible in the normal heart. Flow across the aortic and pulmonary valves follows, which is again usually inaudible in the normal heart. The aortic valve closes first, followed by the pulmonary valve; the delay in closure of the pulmonary valve gives the "splitting" character of the second heart sound. Diastole, similar to systole is quiet; during diastole, blood flows through the tricuspid and mitral valves into the right and left ventricles. (b) Systolic flow murmur: increased blood flow across the pulmonary or aortic valve causes turbulence of blood flow which produces a systolic flow murmur heard over the left or right upper sternal border, respectively. In atrial septal defect, increased blood flow across the pulmonary valve causes a systolic ejection murmur along the left upper sternal border. Severe anemia with increase in blood volume to compensate for decreased oxygen-carrying capacity causes turbulence of blood flow and consequently a murmur across both aortic and pulmonary valves. These murmurs are distinguished from those caused by stenosis of the pulmonary or aortic valves by lack of a systolic ejection click heard just before the systolic murmurs. (c) Pulmonary or aortic valve stenosis: flow across the pulmonary and aortic valves occurs during midsystole; therefore, pulmonary or aortic stenosis produces a systolic ejection murmur preceded by a systolic ejection click. These murmurs are loudest over the right upper sternal borders in aortic stenosis and the left upper sternal border in pulmonary stenosis. The systolic ejection click is caused

by the snap sound of opening of abnormal pulmonary or aortic valves. (d) Continuous murmur: a murmur heard over systole and most of diastole reflects abnormal shunting across a vascular structure connecting the systemic to pulmonary circulations, such as with patent ductus arteriosus. Murmur caused by PDA may be restricted to systole in children due to the soft and inaudible flow during diastole. (e) Early diastolic murmur: during early diastole, blood in the proximal portions of the pulmonary artery and aorta eject to the pulmonary and systemic circulations, respectively. Backward flow of blood into the right or left ventricles due to valve regurgitation will cause an early diastolic murmur. Aortic regurgitation is best heard over the mid or left sternal region. Pulmonary regurgitation is typically inaudible due to low pressures in the right heart and if heard may indicate pulmonary hypertension. (f) Mid-diastolic murmur: during mid-diastole blood flows from the atria to the respective ventricles. Excessive blood flow across the tricuspid valve, such as with atrial septal defect, or across the mitral valve such as with patent ductus arteriosus will cause a mid-diastolic murmur heard over the left lower sternal border in patients with atrial septal defect and at the apex in patients with patent ductus arteriosus [Thompson WR, Mehrotra SM. Cardiac History and Physical Examination. In: Abdulla R, editor. Heart Diseases in Children [Internet]. Boston, MA: Springer US; 2011 [cited 2015 Aug 27]. p. 3–16. 	Severity of AS		
	Mild	Moderate	Severe
Arterial pulse	Normal	Slowly rising	Parvus et tardus
Jugular venous pulse	Normal	Normal	Usually normal
Carotid thrill	±	±	±
Cardiac impulse	Normal	Heaving	Heaving, sustained
Precordial thrill	±	±	Palpable *a* wave
			Usually ++
Auscultation			
S_4	–	±	++
ESC	+	±	–
Peak of ESM	Early systole	Mid systole	Late systole
S_2	Normal	Normal or single	Single or paradoxic

Physical examination for aortic stenosis. The findings on physical examination in patients with mild aortic stenosis (AS) are an ejection systolic click (ESC) and ejection systolic murmur (ESM) that peak in early systole. The ESC may be absent if the valve is calcified or is rigid. These patients may have a carotid or precordial

thrill. Patients with severe AS display characteristic physical findings. The arterial pulse, which is best felt over the carotid or the suprasternal notch, shows a slowly rising pulse that takes longer to reach peak (parvus et tardus) (see). The jugular venous pulse is normal and a carotid thrill may be present. The cardiac impulse is left ventricular (LV) in type; it is heaving and sustained. Often a powerful presystolic wave (a wave) is felt. A precordial systolic thrill is often present. On auscultation, there is an S4gallop, the ESC is absent, the ESM peaks in late systole, and the S2 is single. S2 is at times paradoxic, but this usually occurs in the presence of associated left bundle branch block or LV failure. In addition, there is usually a faint diastolic murmur of minimal aortic regurgitation. In the presence of congestive heart failure, the jugular venous pressure is often increased, the LV is dilated, there is an S3, and the ESM may be very soft or absent. Frequently, a holosystolic murmur of mitral regurgitation is present. The findings on physical examination resemble those of heart failure from a variety of causes, eg, a cardiomyopathy, rather than AS. The physical findings in moderate AS are between those seen in mild and severe AS. [Rahimtoola S. Chapter 06. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. ISBN: 1-878132-30-X] *Caption from original*

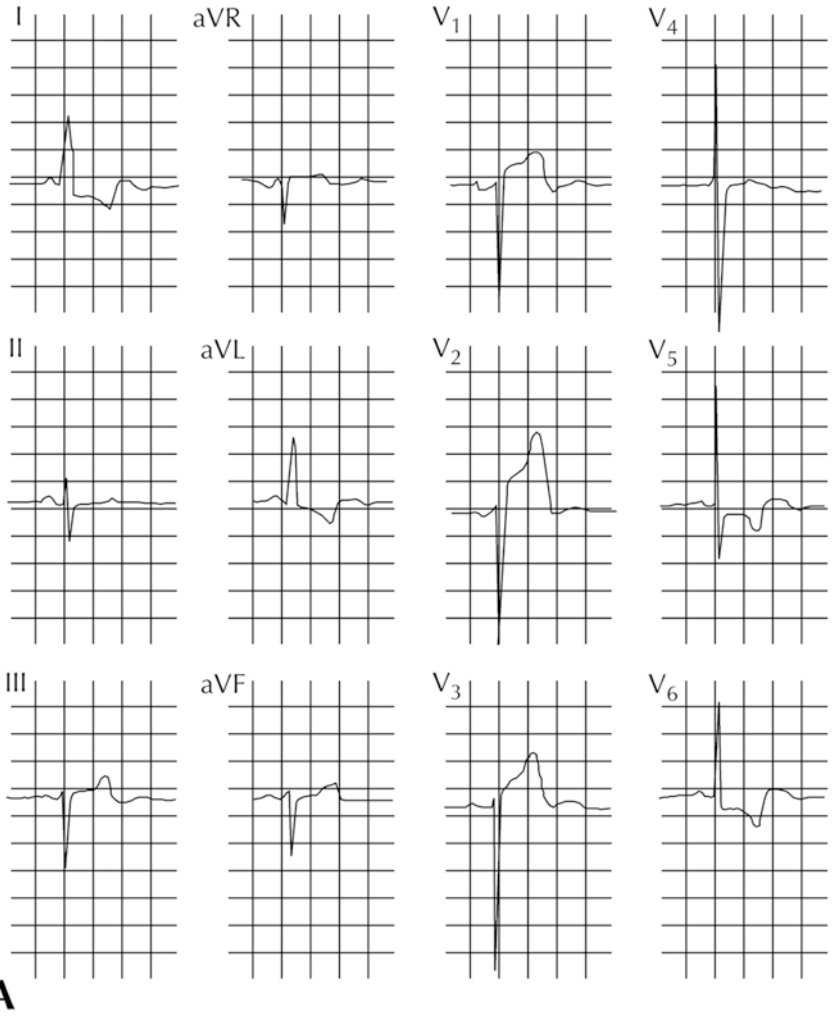
Factors that Exclude Diagnosis

- The presence of a normal split S2 heart sound most reliably excludes **severe** aortic stenosis in adults.

Ancillary Studies

Electrocardiography

- May see left ventricular hypertrophy, increased QRS voltage, ST-T wave changes that reflect subendocardial ischemia and left atrial hypertrophy. Atrial fibrillation is common in adults with aortic stenosis.



Electrocardiographic data in aortic stenosis. Electrocardiograph (ECG), chest radiographic, left ventricular (LV) and ascending aorta pressure pulses, LV diastolic pulmonary artery wedge (PAW) pressure pulses, and hemodynamic-LV function data. This 61-year-old man had recent onset of symptoms of mild shortness of breath on exertion. A, The ECG shows voltage criteria for LV hypertrophy and ST depression with T-wave inversion in leads I, aVL, V5, and V6. ECG standardization is 1 mV=10 mm. [Rahimtoola S. Chapter 06. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. ISBN: 1-878132-30-X] *Caption adapted from original*

Imaging

- Chest radiography is usually normal.However, a rounding of the left ventricular apex may be seen, suggesting left ventricular hypertrophy or the calcification of the aortic leaflets and aortic root, but this is a rare finding

Chest radiographic diagnosis of aortic stenosis. Chest radiography (posteroanterior view) shows an increased heart size (cardiothoracic ratio, 0.53) and normal pulmonary vasculature. The cardiac silhouette is typical for LV hypertrophy associated with severe AS. Calcification of the aortic valve would be best appreciated in the lateral view of the chest. [Rahimtoola S. Chapter 06. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. ISBN: 1-878132-30-X] *Caption adapted from original*

- Echocardiography is the most reliable way to evaluate aortic stenosis.
- Some findings include the finding of a bicuspid valve, thickened and calcified aortic leaflets, possible left ventricular hypertrophy, and probable concurrent aortic regurgitation.
- Echocardiography has reduced the need for cardiac catheterization with hemodynamic measurements.

Special Populations

Age

- Severe isolated aortic stenosis is primarily a disease of older patients
- Aortic stenosis in infancy will often present with signs of CHF, with accompanying growth failure.
- AS in older children is usually asymptomatic.

Co-Morbidities

- Patients with aortic stenosis have an increased risk of bleeding. The increased risk appears to be due to an acquired Von Willebrand syndrome.

Pitfalls in Diagnosis

Critical Steps Not to Miss

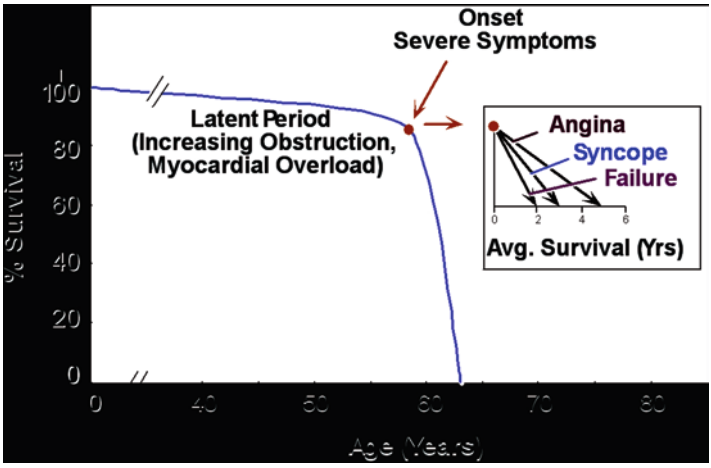
- Once symptoms develop, prompt surgical intervention is needed to increase survival owing to the high risk of sudden death.

Mimics

- Symptoms may be attributed to other diseases, such as coronary artery disease or congestive heart failure, with the diagnosis of aortic stenosis being made only later in the work-up.

Time Dependent Interventions

- Once symptoms develop, even mild symptos, surgery is needed because without a valve replacement the survival rate is only 2 to 3 years.



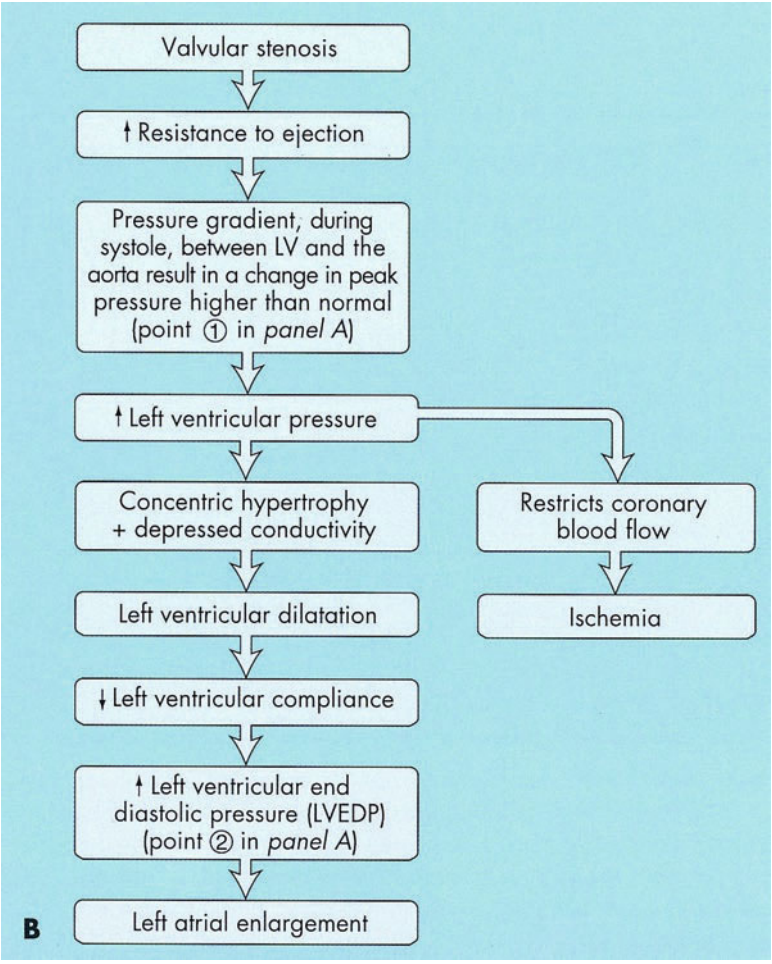
Classic survival curve aortic stenosis. [Ross J, Braunwald E. Aortic Stenosis. Circulation. 1968 Jul 1;38(1S5):V-61-V-67. Reprinted with permission.]

- Symptomatic patients with severe aortic stenosis alone or
  - Undergoing coronary artery bypass surgery
  - Undergoing surgery on the aorta or other heart valves
- Patients with moderate aortic stenosis and
  - Undergoing coronary artery bypass surgery
  - Undergoing surgery on the aorta
  - Undergoing surgery on other heart valves
- Asymptomatic patients with severe aortic stenosis and left ventricular systolic dysfunction typified by
  - Abnormal response to exercise (e.g., hypotension)
  - Ventricular tachycardia
  - Marked or excessive left ventricular hypertrophy (> 15 mm)
  - Valve area $< 0.6\ cm^2$
  - Prevention of sudden death without the findings listed

Aortic valve replacement in aortic stenosis (Bonow RO, Carabello BA, Kanu C, et al. ACC/AHA guidelines for the management of patients with valvular heart disease. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation 2006;114:e84–231.) [John R, Liao KK. Heart Valve Disease. In: Iaizzo PA, editor. Handbook of Cardiac Anatomy, Physiology, and Devices [Internet]. Totowa, NJ: Humana Press; 2009 [cited 2015 Aug 28]. p. 527–49. Available from: http://link.springer.com/10.1007/978-1-60327-372-5_31] *Caption from original*

Overall Principles of Treatment

- After repair of aortic stenosis, quality of life and survival generally return to those expected for age and comorbidity burden.



Aortic stenosis. The primary hemodynamic abnormality in aortic stenosis is obstruction to left ventricular outflow, which results in a pressure gradient (B) (which can be estimated by Doppler echocardiography) between the left ventricle (LV) and the aorta, leading to left ventricular hypertrophy. Loss of atrial contraction and contribution to ventricular filling may result in clinical deterioration. The increased left ventricular size necessitates an increase in myocardial oxygen demand, and intraventricular wall pressure may exceed coronary artery perfusion pressure, causing myocardial ischemia even in the absence of coronary artery disease. Cardinal signs

are exertional dyspnea (inability to increase cardiac output and elevated pulmonary capillary pressure), angina pectoris, and exertional syncope (caused by decreased arterial pressure associated with vasodilatation in the exercising muscles or arrhythmias). Care must be taken to avoid intravascular volume depletion [Mulligan M, Cousins M. Chapter 4. In: Lichtor JL, editor. Preoperative preparation and intraoperative monitoring. Philadelphia: Current Medicine; 1997. (Miller RD, editor. Atlas of anesthesia; vol. 3)] *Caption adapted from original*

Disease Course

- After the onset of symptoms, patients with severe aortic stenosis have a survival rate as low as 50% at two years and 20% at five years without aortic valve replacement.

Chapter 10
Aspiration

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Aspiration; Aspiration Pneumonia; Aspiration Pneumonitis; Chemical Pneumonitis

Incidence/Epidemiology

- About half of all healthy adults aspirate to some degree during sleep, but this is usually not clinically significant. Healthy people have physiologic defenses (such as cough and glottic closure) against aspiration that helps to limit the damage that can be caused.
- Aspiration becomes clinically significant when the patient has some underlying condition that compromises the usual defenses.
- Up to 15 % of cases of typical community-acquired pneumonia (CAP) are due to aspiration of pathogenic bacteria from the oro-pharyngeal cavity and the stomach. The incidence increases with age, and up to 20 % of CAP in the elderly is from aspiration.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_10

- It is felt that the majority of hospital- and nursing home-acquired pneumonias are due to aspiration.
- Factors that can increase the risk of aspiration include: decreased level of consciousness; neurologic disorders that affect swallowing; mechanical disruption of the oro-pharynx, epiglottis, trachea, and esophagus, such as endotracheal intubation; nasogastric feeding tubes; tracheostomy, etc.

Differential Diagnosis

- Aspiration, especially aspiration of gastric contents causing aspiration pneumonitis, can present as acute shortness of breath with both tachypnea and hypoxia. As such, the differential is broad, and contains all the usual causes of acute dyspnea and respiratory compromise, such as ACS, pulmonary embolism, and pulmonary edema/CHF, among others.
- Aspiration pneumonia may present as typical CAP or HAP, with fever and cough with purulent sputum, but can also present sub-acutely when caused predominately by anaerobes.

Pathophysiology and Etiology

- Aspiration results in three broad clinical syndromes, often presenting with overlapping features:
  - Aspiration pneumonitis (chemical pneumonitis)
  - Bacterial Infection causing pneumonia, empyema, and/or pulmonary abscess
  - Airway obstruction from larger, solid matter
- The pathophysiology starts similarly in all syndromes. They are caused by the abnormal entry of endogenous secretions, fluids, and/or particulate matter into the lower airway.
- Aspiration/Chemical Pneumonitis. In this syndrome, there is aspiration of materials that have a direct, toxic effect on the lower airways and lung tissue. The best-known and studied substance is gastric acid, and serves as the pathophysiologic model for all other substances.
  - The airways and lungs are relatively resistant to injury. For clinically significant issues to result, there needs to be a large amount of aspirate (generally more than 25 ml in an adult), and the pH must be below 2.5.
  - When this condition is met, rapid physiologic changes occur (within 3 minutes), including atelectasis, peribronchial hemorrhage, pulmonary edema, and rapid death of bronchial epithelial cells.
  - After 4 hours, the alveolar spaces will become filled with an inflammatory exudate composed of inflammatory cells, fibrin, and desquamated tissue.

  - Within 2 days there will be hyaline membrane formation, and the lungs will be edematous and hemorrhagic with consolidation of the alveolar spaces.
  - Lungs that have been injured by acid or other directly toxic materials are more susceptible to subsequent bacterial infection.
- Bacterial Infection/Aspiration Pneumonia. The bacteria that cause aspiration pneumonia generally originate in the upper airways or stomach.
  - Classically, oral anaerobes (*Peptostreptococcus*, *Fusobacterium nucleatum*, *Prevotells*, and *Bacteroides* spp.) and streptococci caused aspiration pneumonia.
  - More recently, hospital- and healthcare-acquired aspiration pneumonia has been associated with more virulent organisms, such as Staphylococcus aureus, Pseudomonas aeruginosa, and gram-negative bacilli.
- Airway obstruction. Airway obstruction may result from either fluids or solid material aspiration.
  - The ingestion of fluids that are not directly toxic to lung tissue (saline, barium, etc.) can initiate a reflex airway closure, such as in drowning.
  - Solid objects cause differing levels of obstruction based upon their size relative to the airways.
  - Most foreign body aspirations occur in children between the ages of one and three.
  - Large objects can obstruct at the larynx, proximal trachea, tracheal bifurcation, or main stem bronchus. They cause nearly immediate respiratory distress, inability to talk, and cyanosis. Unless removed quickly, they can rapidly lead to death.
  - Smaller objects cause local atelectasis, and the patient will have a cough or focal wheezing.

Presentation

Typical/"Classic"

- Aspiration/Chemical Pneumonitis:
  - Acute onset of symptoms with profound dyspnea, and associated hypoxemia.
  - Often seen in the setting of known risk-factors for aspiration.
- Bacterial Infection. Presentation is variable, and depends upon the causative organisms and the overall health status of the affected patient.
  - Most patients present somewhat acutely with the typical symptoms of pneumonia, fever, productive cough, and dyspnea, especially when the infection is due to organisms other than anaerobes (such as Staph, Strep, Pseudomonas, etc.).

- Infections from anaerobic organisms often present more slowly, over days and weeks. There is often necrotic-smelling sputum, and a notable lack of rigors. Most patients with anaerobic aspiration pneumonia will have an easily recognized risk factor for aspiration, and poor dental health.

- Airway Obstruction.
  - Large particle airway obstruction causes acute respiratory compromise and failure, with severe dyspnea, inability to talk, hypoxia/cyanosis, and rapid cardiovascular collapse if not removed.
  - Small particle airway obstruction can present in a more subtle fashion, with an indolent, irritative cough, associated with dyspnea that is sometimes present only with exertion.

Atypical

- There is a wide-spectrum of clinical presentations and syndromes for aspiration. As above, aspiration syndromes typically present acutely, but depending upon many factors, may be sub-acute or indolent. Also, as noted above, atypical presentations occur especially with aspiration pneumonia caused by anaerobic organisms, airway obstruction caused by small particles, or aspiration pneumonitis caused by small volume, higher pH substances.

Primary Differential Considerations

- Differential considerations for aspiration include:
  - Respiratory Distress Syndrome
  - Other respiratory failure
  - Status asthmaticus
  - Circulatory shock
  - RSV infection in children

History and Physical Exam

Findings That Confirm Diagnosis

- A witnessed aspiration event, followed by the typical clinical syndrome of aspiration pneumonitis, confirms the diagnosis.

Factors That Suggest Diagnosis

- A patient who presents with community- or hospital-acquired pneumonia, has risk factors for aspiration, and/or has infiltrates in the dependent lung zones (lower lobes if aspiration occurred in the upright position, or superior segments of the lower lobes and/or posterior segment of the upper lobes if aspiration occurred in the supine position) should be further evaluated for aspiration and swallowing difficulties.

Factors That Exclude Diagnosis

- Finding another cause for the dyspnea/respiratory distress makes aspiration unlikely.

Ancillary Studies

Laboratory

- Laboratory abnormalities in aspiration pneumonitis are usually non-specific. There may be a moderately elevated white blood cell count. Patients may be hypoxic with a respiratory acidosis on blood gas analysis, especially in the acute setting when they are tachypneic.
- Patients with bacterial pneumonia caused by aspiration will usually have laboratory findings of acute infection with a leukocytosis with bandemia and/or a leftward shift. These patients may also be hypoxic.
    - Sputum culture has a limited role in aspiration pneumonia. Most infections are polymicrobial, and many of the causative organisms are difficult to culture. Coughed sputum samples are not useful for culture, as the normal flora of the mouth and upper airway contaminates them.
- Laboratory studies are not helpful in the diagnosis of airway obstruction from particulate matter.

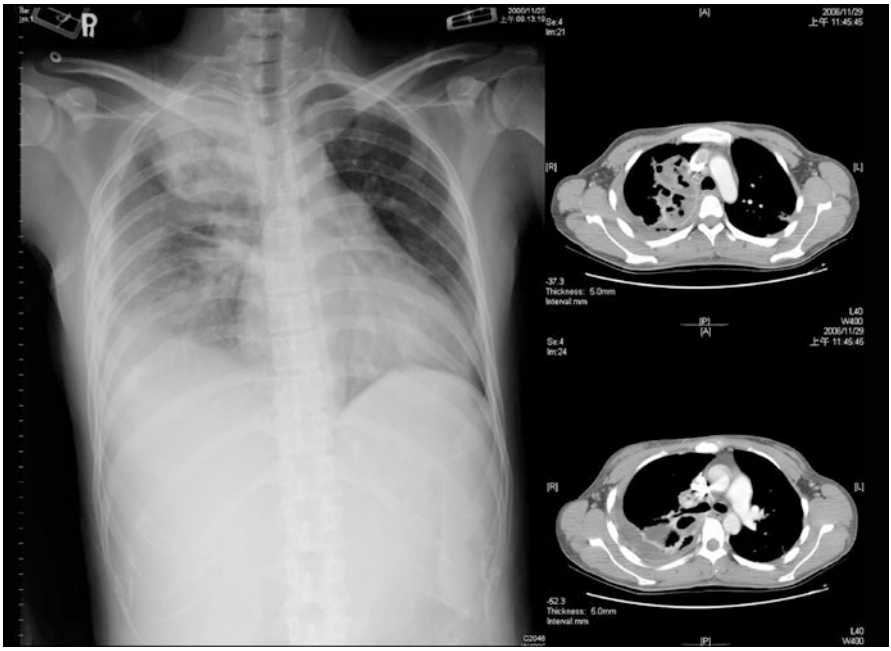
Imaging

- CXR findings in aspiration pneumonitis typically appear about 2 hours after an aspiration event. Typically, there are infiltrates in the dependent lung zones. These are the lower lobes when the patient was in an upright position during the aspiration event, and the superior segments of the lower lobes and posterior segments of the upper lobes if the patient was in the supine position during the aspiration event. Over time, if the disease progresses, the CXR may show evidence of ARDS with diffuse, fluffy infiltrates.

Aspiration pneumonia with infection: image progression. **a** Several hours after aspiration of gastric content, there are patchy infiltrates at both lung bases medially. **b** Three days after aspiration, the consolidation has increased in density and extent. At this phase, aspiration pneumonitis should be improving. This suggests secondary infection. **c** Four days after aspiration, computed tomography reveals dense consolidation in the posterior and lateral basal segments of both lower lobes. This degree of consolidation is more than one usually sees with uncomplicated aspiration pneumonitis. [Goodman LR. Imaging the Intensive Care Patient. In: Hodler J, von Schulthess GK, Zollikofer CL, editors. Diseases of the Heart and Chest, Including Breast 2011–2014 [Internet]. Milano: Springer Milan; 2011 [cited 2015 May 22]. p. 66–9. Available from: http://link.springer.com/10.1007/978-88-470-1938-6_10] *Caption adapted from original*

- The CXR in aspiration pneumonia caused by bacteria will also typically reveal an infiltrate in one or more of the dependent lung zones.
- Patients with pneumonia caused by anaerobic bacteria can have more indolent presentation and may develop either lung abscess or empyema that can be revealed on the CXR.

The chest radiograph and computed tomography scan showed pleural empyema without lung abscess. [From article: Lung abscess predicts the surgical outcome in patients with pleural empyema. Journal of Cardiothoracic Surgery. 2010;5(1):88. https://doi.org/10.1186/1749-8090-5-88, at http://link.springer.com/article/10.1186%2F1749-8090-5-88; by Hung-Che Huang, Heng-Chung Chen, Hsin-Yuan Fang, Yi-Chieh Lin, Chin-Yen Wu, Ching-Yuan Cheng, © Huang et al; licensee BioMed Central Ltd. 2010; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*



The chest radiograph and computed tomography showed pleural empyema with lung abscess. [From article: Lung abscess predicts the surgical outcome in patients with pleural empyema. - Airway obstruction from aspirated, large objects must be diagnosed prior to CXR, as the patients are in extremis and need rapid treatment. When the object is smaller, and the presentation not as severe or obvious, a CXR may be helpful. Many objects that are aspirated are biologic and radiolucent (peanuts, vegetables, other food objects), and some are radiodense (teeth, buttons, batteries, etc.). If the object itself is not visualized on the x-ray, there may be atelectasis with an elevated hemidiaphragm, and other signs of lung-volume loss.

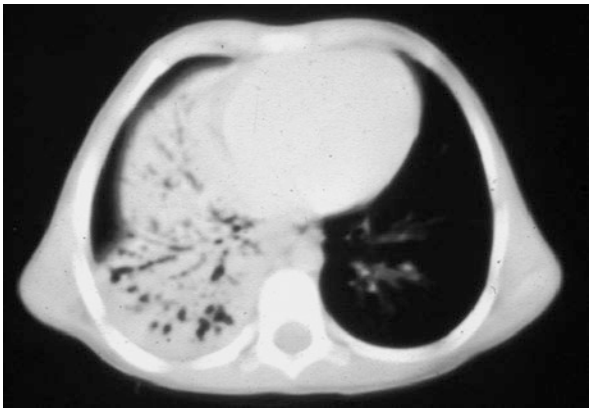
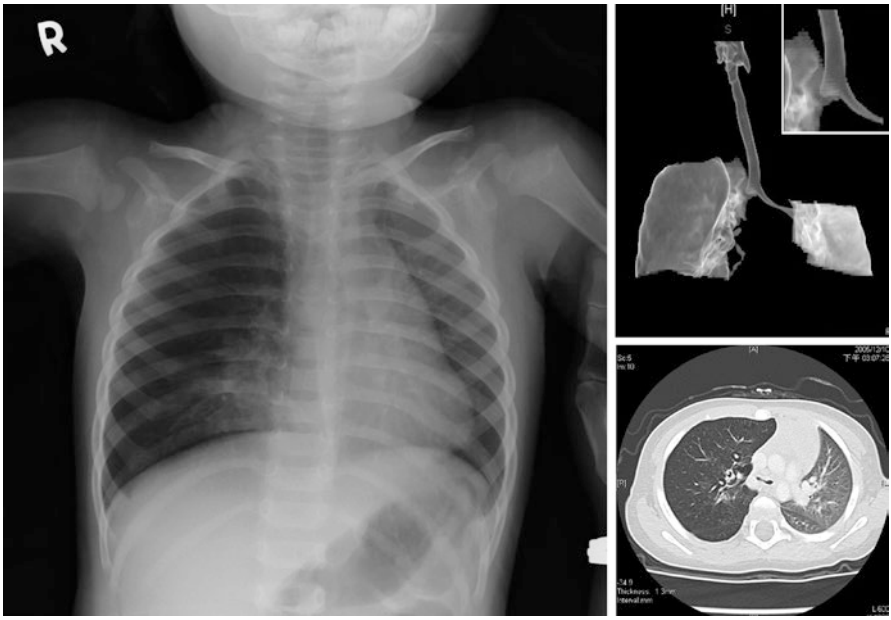
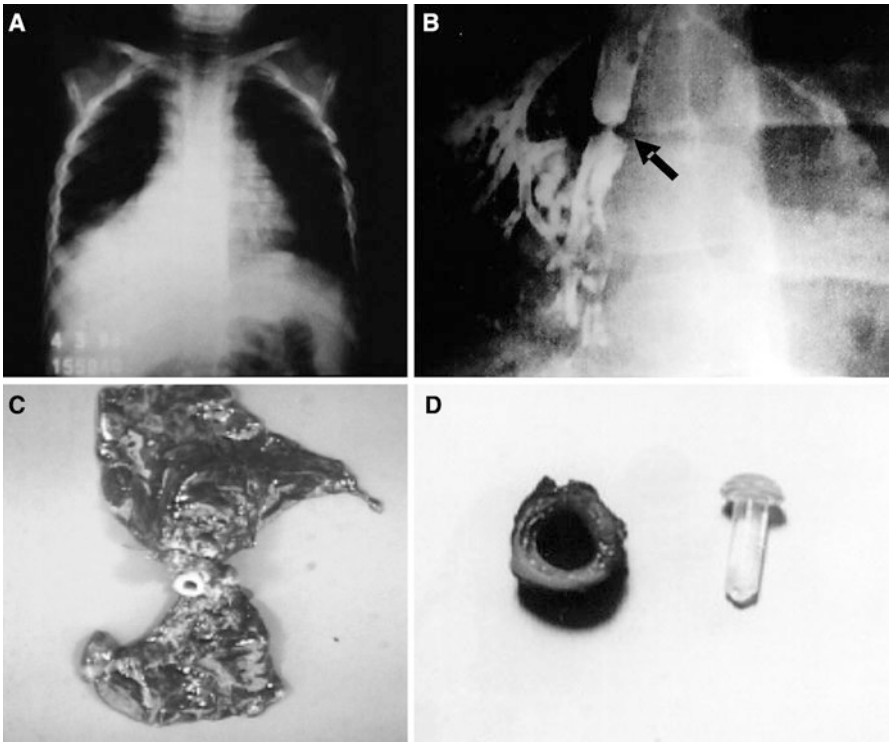
Frontal chest radiograph of a child with foreign body aspiration. The left lung is large and hyperlucent with less vessels due to air trapping caused by partial obstruction of the left main bronchus. Note the mediastinal shift to the right. [Soto G, Moënne K. Classic Chest Radiology Findings, Pearls and Pitfalls. In: Garcia-Peña P, Guillerman RP, editors. Pediatric Chest Imaging [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2013 [cited 2015 May 22]. p. 13–30. Available from: http://link.springer.com/10.1007/174_2013_905] *Caption from original*



Axial CT of the lower chest in a case of chronic foreign body aspiration into the right intermediate bronchus, causing collapse and bronchiectasis in the right middle lobe and right lower lobe. [Koplewitz BZ, Bar-Ziv J. Foreign Body Aspiration: Imaging Aspects. In: Garcia-Peña P, Guillerman RP, editors. Pediatric Chest Imaging [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2015 May 22]. p. 305–26. Available from: http://link.springer.com/10.1007/174_2013_952] *Caption from original*



Plain chest radiograph showing a nearly left total opacity with ipsilateral mediastinal shift caused by foreign body aspiration. Three-dimensional chest computed tomography showing a nearly total occlusion in the right main bronchus [Huang H-J, Fang H-Y, Chen H-C, Wu C-Y, Cheng C-Y, Chang C-L. Three-dimensional computed tomography for detection of tracheobronchial foreign body aspiration in children. Pediatric Surgery International. 2008 Feb;24(2):157–60.] *Caption from original*



a Thorax X-ray showing atelectasis of the inferior and middle lobe of the right lung in a child with recurrent pneumonia for 2 years. b Bronchography showing stenosis of the intermediate segment, the foreign body cannot be seen. c Removed inferior and middle destroyed lobes. d Foreign body and blocked bronchus. When saw the foreign body, the mother said that it was part of a toy that had disappeared 2 years earlier [Cataneo AJM, Cataneo DC, Ruiz RL. Management of tracheobronchial foreign body in children. Pediatric Surgery International. 2008 Feb;24(2):151–6.] *Caption from original*

Special Populations

Age

- Aspiration pneumonitis is more common in the elderly, especially those with neurologic and other swallowing difficulties.
- Aspiration of objects is more common among children between the ages of one and three.
- Gastroesophogeal reflux (GER) is common in infancy, resulting in vomiting, albeit without complications.

- The diagnosis of gastroesophogeal reflux disease (GERD) applies when reflux events are associated with pathologic outcomes or debilitating symptoms.
- Concomitant aspiration events are rarely seen in infants with GERD, except in patients with swallowing disorders, e.g., neurological impairment scenarios.

Co-morbidities

- There are multiple co-morbidities that increase the risk of all types of aspiration. These include:
  - Reduced consciousness, which depresses the gag and glottic closure reflexes and can be brought on by causes such as alcohol and drug intoxication, and hepatic failure.
  - Prior stroke or neuromuscular disorder that impairs the ability to swallow.
  - Other neurologic conditions such as stroke, head injury, and dementia.
  - Mechanical instrumentation of the upper airway, such as endotracheal intubation, tracheostomy, nasogastric tube feedings, and upper endoscopy.
  - Periodontal disease.
  - General anesthesia and procedural sedation.
  - Gastroesophageal reflux, esophageal dysmotility.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step. Patients presenting with respiratory compromise need all appropriate supportive care until a diagnosis can be established.
- CXR should be performed early, but findings may be delayed by several hours.
- Patients who are felt to have a syndrome-consistent aspiration should have their swallowing function evaluated.

Mimics

- Many conditions can cause acute dyspnea and respiratory compromise, including ACS, pulmonary embolism, pneumothorax, pulmonary edema/CHF, among others.

Time-Dependent Interventions

- Airway obstruction with a large object causing complete airway obstruction is a medical emergency and can be fatal within minutes if not recognized and treated appropriately.
- Aspiration pneumonia from bacterial infection can present with acute respiratory compromise, so the rapid support of ventilatory function and administration of empiric antibiotics for likely pathogens is necessary.
- A witnessed aspiration event should be treated urgently with airway suctioning to remove as much fluid and solid matter as possible, and ventilatory and respiratory function should be supported.

Overall Principles of Treatment

- Aspiration pneumonitis.
  - As noted above, a patient with a witnessed or presumed acute aspiration event should have tracheal suctioning, administration of supplemental oxygen, and all respiratory and ventilator necessary.
  - The use of glucocorticoids is controversial. There are no good data supporting their use in aspiration pneumonitis.
  - Empiric or prophylactic antibiotics are commonly given in aspiration pneumonitis. Chemically injured lungs are at an increased risk for developing bacterial superinfection in the coming days, but there is no good evidence that prophylactic antibiotics administration prevents these infections. It is appropriate to administer antibiotics if the diagnosis is in doubt and bacterial pneumonia remains on the differential.
- Bacterial Aspiration Pneumonia.
  - Antibiotics are necessary in the treatment of aspiration pneumonia due to bacteria.
  - Most of these infections are polymicrobial, and include anaerobes. As such, most patients will be treated (at least initially), with a combination of antibiotics.
  - Clindamycin is the antibiotic of choice to cover anaerobes. Metronidazole should not be used alone, as it has a failure rate of up to 50% when used as monotherapy.
  - Clindamycin can be combined with either amoxicillin or penicillin.
  - When the patient has a hospital- or healthcare-acquired aspiration pneumonia, it is important to consider both gram positive organisms, such as Staph and strep, and the aerobic gram negative bacilli as causes. These patients should be broadly covered with an antibiotic or combination of antibiotics, to cover the gram-positives and negatives. This usually includes vancomycin

with either a carbapenem or piperacillin/tazobactam. These regimens will also cover most pathogenic anaerobes.

- Airway obstruction from large objects needs to be relieved immediately. The preferred method is the Heimlich maneuver. If unsuccessful, a surgical airway may need to be secured.
  - Smaller objects can often be removed by bronchoscopy.

Disease Course

- Aspiration pneumonitis. The course varies considerably based upon the patient's underlying medical condition and the cause of the aspiration. The majority of patients will recover rapidly. A small percentage will go on to develop ARDS and/or bacterial superinfection. There is a significant mortality associated with both of these complications.
- Patients with bacterial aspiration pneumonia often recover fully, but when the predominant pathogens are anaerobic bacteria, a small percentage can go on to develop pulmonary abscess or empyema as complications of the primary infection. The incidence of these complications has been decreasing.
- All patients who suffer from aspiration need to be evaluated for the primary cause of their aspiration, or they remain at risk for further episodes.
- Most patients who have an airway obstruction recover uneventfully if the obstruction is relieved in a timely manner.

Chapter 11
Asthma

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Asthma

Incidence/Epidemiology

- Approximately 235 million people, worldwide, are affected by asthma.
- Approximately 250,000 people die of asthma each year.
- Rates vary between countries with prevalence between 1 % and 18 %.
- There is some racial predilection (for example, asthma severity and asthma mortality is higher in US blacks than US whites). This may be more socioeconomic than clinical,

[a] Results presented as weighted average annual estimate

[b] Behavioral Risk Factor Surveillance System participants who answered "No" to the question "Were you ever told by a doctor or other health professional that you had asthma?"

[c] Behavioral Risk Factor Surveillance System participants who answered "Yes" to the question "Were you ever told by a doctor or other health professional that you had asthma?" and "No" to the question "Do you still have asthma?"

[d] Behavioral Risk Factor Surveillance System participants who answered "Yes" to the questions "Were you ever told by a doctor or other health professional that you had asthma?" and "Do you still have asthma?"

[e] Asthma Call-back Survey participants who described current employment status as "employed full-time" or "employed part-time" or responded "yes" to the question "Have you ever been employed outside the home?"

[f] "No" to all of the following five questions: "Were you ever told by a doctor or other health professional that your asthma was related to any job you ever had?", "Was your asthma caused by chemicals, smoke, fumes, or dust in your current job?", "Was your asthma caused by chemicals, smoke, fumes, or dust in any previous job you ever had?", "Is your asthma made worse by chemicals, smoke, fumes, or dust in your current job?", and "Was your asthma made worse by chemicals, smoke, fumes, or dust in any previous job you ever had?"

[g] "No" response to the question "Were you ever told by a doctor or other health professional that your asthma was related to any job you ever had?" and "Yes" responses to any of the following four questions: "Was your asthma caused by chemicals, smoke, fumes, or dust in your current job?", "Was your asthma caused by chemicals, smoke, fumes, or dust in any previous job you ever had?", "Is your asthma made worse by chemicals, smoke, fumes, or dust in your current job?", and "Was your asthma made worse by chemicals, smoke, fumes, or dust in any previous job you ever had?"

[h] "Yes" to the question "Were you ever told by a doctor or other health professional that your asthma was related to any job you ever had?"

Estimated proportion of individuals with poor health-related quality of life among select population groups, Behavioral Risk Factor Surveillance System and Asthma Call-back Survey, 38 states and District of Columbia, 2006–2009 [Knoeller GE, Mazurek JM, Moorman JE. Health-related quality of life among adults with work-related asthma in the United States. Quality of Life Research. 2013 May;22(4): 771–80.] *Caption from original*

- Asthma is the most common chronic disease in childhood.
- Asthma occurs more frequently in boys before puberty and in girls after puberty.

Differential Diagnosis

- See chart, but includes:
  - Airway foreign body
  - Bronchitis with bronchospasm
  - Pneumonia with bronchospasm
  - Congestive heart failure
  - Bronchiolitis
  - Chronic obstructive pulmonary disease
  - Cystic fibrosis

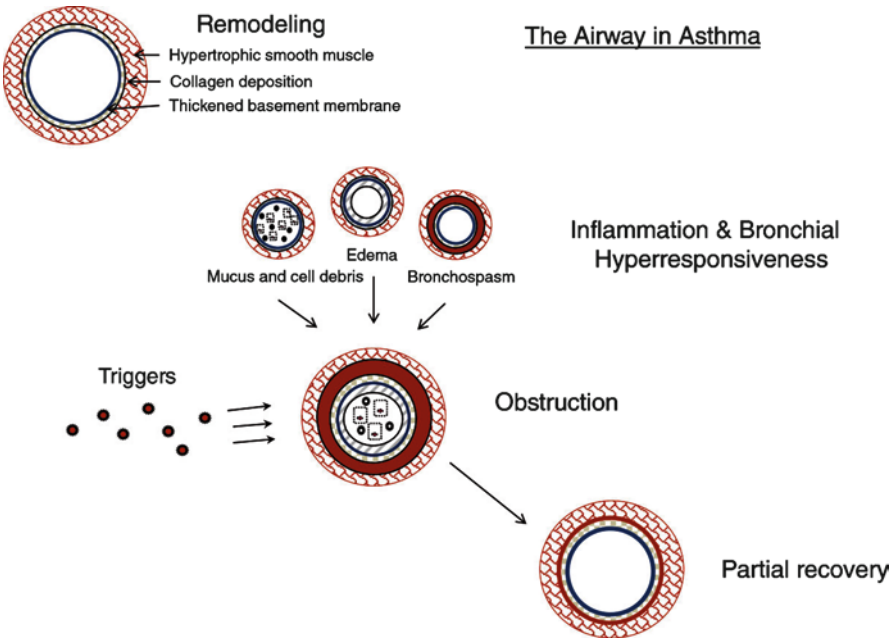
- Pulmonary embolism
- Tracheomalacia
- Vocal cord dysfunction

Chronic bronchitis	Vocal cord dysfunction
Emphysema	Congestive heart failure
Cystic fibrosis	Pulmonary embolism
Viral bronchiolitis	Eosinophilic pneumonia
Bronchial stenosis	Drug-induced cough
Mechanical airway obstruction	β-Blockers
Aspirated foreign body	Angiotensin-converting enzyme inhibitors
Endobronchial tumor	Systemic vasculitis
Superior vena cava syndrome	Carcinoid syndrome
Substernal thyroid	Allergic bronchopulmonary aspergillosis

Differential diagnosis of asthma [Holgate S, Sewell J, Payne KD. Chapter 01. In: Crapo J, editor. Bone's atlas of pulmonary and critical care medicine. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-211-7] *Caption adapted from original*

Pathophysiology and Etiology

- An inflammatory process of the airways that results in periodic, at least partially reversible airflow obstruction.
- Bronchial hyperresponsiveness.
- Family history may be pertinent for asthma diagnosis.
- Many cells and cellular elements contribute to asthma, including:
  - Neutrophils
  - Mast cells
  - Eosinophils
  - Macrophages
  - Activated T lymphocytes
  - Epithelial cells
- Many asthma triggers exist, including:
  - Environmental allergens: dust mites, molds, animal dander, cockroach allergens, fungi, etc.
  - Viral respiratory tract infections
  - Hyperventilation
  - Gastroesophageal reflux disease
  - Environmental pollutants, e.g., tobacco smoke
  - Obesity
  - Hypersensitivity to nonsteroidal anti-inflammatory drugs (NSAID)



Pathophysiology of asthma at steady state and during an exacerbation. The airways of asthmatic individuals are characterized by pathological changes, including thickened basement membrane, collagen deposition and hypertrophic smooth muscle, collectively called 'airway remodeling'. Inflammation is triggered by a variety of factors, including allergens and respiratory viruses. These factors also induce hyperreactive responses in the asthmatic airways, associated with mucus and cell debris released into the lumen, oedema and bronchoconstriction, leading to airway obstruction and related acute exacerbations. Although pathophysiological changes related to asthma are generally reversible, recovery may be partial. [From article: Research needs in allergy: an EAACI position paper, in collaboration with EFA. Clinical and Translational Allergy. 2012;2(1):21.; https://doi.org/10.1186/2045-7022-2-21, at http://link.springer.com/article/10.1186%2F2045-7022-2-21/fulltext.html; by Nikolaos G Papadopoulos, Ioana Agache, Sevim Bavbek, et al., © Papadopoulos et al.; licensee BioMed Central Ltd. 2012; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

Presentation

Typical/"Classic"

- Wheezing, coughing, shortness of breath, chest tightness, tachypnea, tachycardia, respiratory distress, altered mental status.

Atypical

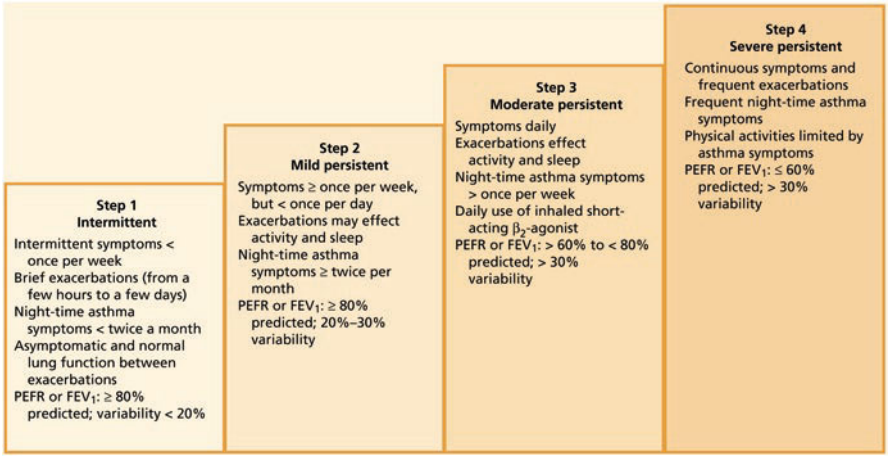
- Cough-variant asthma, nonasthmatic eosinophilic bronchitis, and atopic cough.
  - Approximately 30 % of cough variant asthma that go untreated will result in progression to asthma

Primary Differential Considerations

- Vocal cord dysfunction
- Allergic and environmental asthma
- Tracheal and bronchial lesions
- Foreign bodies
- Pulmonary migraine
- Congestive heart failure
- Diffuse panbronchiolitis
- Aortic arch anomalies
- Sinus disease
- Gastroesophageal reflux
- Pulmonary embolism
- Cystic fibrosis
- Eosinophilia count >8 %, consider allergic bronchoplumonary aspergillosis, Churg-Strauss syndrome, or eosinophilic pneumonia

History and Physical Exam

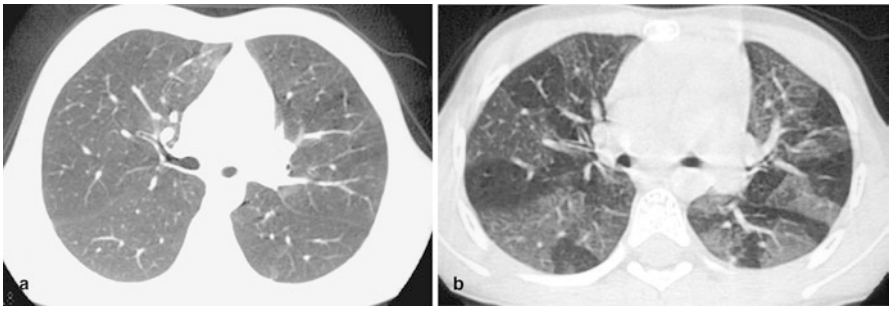
- Categories of asthma severity are determined by the following factors:
  - Reported symptoms over the previous 2 – 4 weeks
  - Current level of lung function: FEV_1, FEV_1 (FVC values)
  - Number of exacerbations requiring oral glucocorticoids per year
- Asthma Severity categories:
  - Intermittent
  - Mild persistent
  - Moderate persistent
  - Severe persistent
- Family history of asthma is often common for diagnoses of asthma, allergies, eczema, and/or nasal polyps.
- Social history is frequently helpful to ascertain for environmental smoke exposure. As mentioned under Incidence/Epidemiology, lower socioeconomic status may be associated with more severe asthma.



Classification of asthma severity. Severity of asthma is classified into four groups according to symptoms and lung function measurements. This method of classification is important because therapy for asthma takes a stepwise approach according to the disease severity. Generally patients have poor perception of the severity of their asthma because they tend to adapt their lifestyle to accommodate their symptoms. This in turn leads to poor control of the disease as well as poor quality of life. Classifying the disease in this stepwise fashion allows the targeting of therapy according to the severity of the disease. FEV1—forced expiratory volume in 1 second; PEFR—peak expiratory flow rate. [Gnanakumaran G, Holgate S. Asthma in Adults. In: Lieberman P, Blaiss M, editors. Atlas of Allergic Diseases, 2e. Philadelphia: Current Medicine; 2005] *Caption from original*

Findings That Confirm Diagnosis

- Arterial blood gases and pulse oximetry for severity and response to treatment.
- Eosinophil counts >4 %, absence is not exclusionary.
- Spirometry before and after short-acting bronchodilator.
- Bronchoprovocation test.
- High-resolution computed tomography (HRCT).



Expiratory HRCT technique. A 9-year-old girl with suspected asthma. a Normal inspiratory HRCT scan. b Expiratory HRCT shows visible differences in lung attenuation (mosaic pattern) due to obstructive small airway disease, which proved to be asthma. Air-trapping is better depicted on expiratory scans [Garcia-Peña P, Lucaya J. HRCT in children: technique and indications. European Radiology Supplements. 2004 Mar 1;14(4):L13–30.] *Caption from original*

Factors That Suggest Diagnosis

- Serum immunoglobulin E levels greater than 100 IU frequently an allergic reaction, may not be asthma but other conditions.
- Elevated blood eosinophils.
- Non-specific IgE >150IU.
- Family history.
- Allergies.

Factors That Exclude Diagnosis

- Laboratory assessments and studies are usually used to exclude other diagnoses.

Evaluation of Exacerbations

- Pulse oximetry: Inability to maintain pulse ox between above 92% suggests impending respiratory failure.
- PEFR or FEV_1 measurement: PEFR is effort-dependent but can be used to compare severity of exacerbation and response to therapy to previous care episodes. FEV_1 is more accurate but is often logistically challenging to obtain in the acute setting

Ancillary Studies

Laboratory

- ABG: progression of severity is typically hyperoxemia → hypoxemia → hypercarbia.
- Pulse oximetry.
- WBC: may be high due to stress release and/or to concomitant infection.

Electrocardiography

- Indicated in patients at risk for cardiac disease, dysrhythmias, myocardial ischemia.
- Transient ST-T wave changes in severe asthma.
- Tachycardia typical.

Imaging

- Chest x-ray is not necessary unless there is suspicion of pneumonia, pneumothorax or pneumomediastinum, foreign body aspiration, comorbid illness, diabetes, AIDS, renal failure, or cancer.

Other Studies

- Peak Flow
- Spirometry
- Lung function study
- Provocative testing
- Diffusing capacity for carbon monoxide (DLco)
- Allergy testing

Special Populations

Age

Pediatrics

- Asthma is not an uncommon cause of chest pain in children.
- Severity classification in children is key.
  - Even children with mild asthma can have severe exacerbations.
  - Controller medications are based on the severity of the symptoms and exacerbation.
- Nonspecific symptoms in infants or young children may have a history of recurrent bronchitis, bronchiolitis, or pneumonia.
- Review for family history or allergy and medical history of early injury to airway.
- Infants are vulnerable to respiratory failure.

Drug name (trade name)	Category	Components (scientific names)	Pediatric indication[a]
Accolate	Leukotriene receptor antagonist	Zafirlukast	5 years and older
Advair Diskus	Combination (ICS + LABA)	Fluticasone propionate Salmeterol xinafoate	4 years and older
Advair HFA	Combination (ICS + LABA)	Fluticasone propionate Salmeterol xinafoate	12 years and older
Albuterol oral syrup	SABA	Albuterol sulfate	2 years and older
Alvesco	Inhaled ICS	Ciclesonide	12 years and older
Asmanex Twisthaler	Inhaled ICS	Mometasone furoate	4 years and older
Atrovent HFA	Anticholinergic	Ipratropium bromide	Not established
Dulera	Combination (ICS + LABA)	Mometasone furoate Formoterol fumarate dihydrate	12 years and older
Foradil	LABA	Formoterol fumarate	5 years and older
Intal inhaler	Anti-inflammatory	Cromolyn	Discontinued in USA, available still in other countries
Intal nebulization solution	Anti-inflammatory	Cromolyn	2 years and older
Pro-Air HFA	SABA	Albuterol sulfate	4 years and older
Proventil HFA	SABA	Albuterol sulfate	4 years and older
Pulmicort Flexhaler	Inhaled ICS	Budesonide	6 years and older

Seretide MDI	Combination (ICS + LABA)	Fluticasone propionate Salmeterol xinafoate	4 years and older (Australia)
Serevent Accuhaler	LABA	Salmeterol xinafoate	4 years and older (Australia)
Serevent Diskus	LABA	Salmeterol xinafoate	4 years and older (USA)
Serevent Inhaler	LABA	Salmeterol xinafoate	4 years and older (Australia)
Singulair	Leukotriene receptor antagonist	Montelukast	12 months and older (for asthma)
Spiriva HFA	Anticholinergic	Tiotropium bromide	Not indicated in children
Symbicort HFA	Combination (ICS + LABA)	Budesonide Formoterol fumarate dihydrate	12 years and older
Tilade CFC free	Anti-inflammatory	Nedocromil sodium	2 years and older
Ventolin HFA	SABA	Albuterol sulfate	4 years and older
Xolair	Monoclonal anti-IgE	Omalizumab	12 years and older
Xopenex HFA	SABA	Levalbuterol tartrate	4 years and older
Xopenex nebulization solution	SABA	Levalbuterol HCl	6 years and older
Zyflo	Leukotriene receptor antagonist	Zileuton	12 years and older

[a] These are current pediatric age indications by the FDA or corresponding regulatory agency if drug is available elsewhere

Pediatric indications for asthma drugs [Chang C. Asthma in Children and Adolescents: A Comprehensive Approach to Diagnosis and Management. Clinical Reviews in Allergy & Immunology. 2012 Aug;43(1-2):98–137.] *Caption from original*

- The management of an acute asthmatic in a child is not substantially different than that utilized for the adult patient.
- Inhaled anticholinergics in children should be utilized as recue medications. Early administration of steroids is effective and recommended in all cases.
- The use of chest radiographs in pediatric asthma should be reserved for infants or children who present with wheezing for the first time.
- Children are more likely to have cough-variant asthma, in which coughing is a more predominant presenting symptom than wheezing. The cough generally responds to bronchodilator therapy.

Elderly

- The elderly have high prevalence of other obstructive lung disease. The elderly may have increased sensitivity to adverse effects of β_2-agonists and inhaled corticosteroids.

Pregnancy

- Treat asthma aggressively during pregnancy. The National Asthma Education and Prevention Program Working Group Report on Managing Asthma During Pregnancy: Recommendations for Pharmacologic Treatment (2004; U.S. Department of Health and Human Services) can be found at the following link:http://www.nhlbi.nih.gov/health-pro/guidelines/archive/asthma-management-pregnancy-guidelines

Co-morbidities

- Rhinitis and rhinosinusitis management
- Allergic sensitivity and allergen exposure
- Psychological dysfunction
- Paradoxical vocal cord dysfunction
- Asymptomatic gastroesophageal reflux
- Obstructive sleep apnea
- Connective tissue disease
- Dermatologic conditions
- Immunologic and hematologic disease
- Metabolic disorders
- Obesity
- Obstructive lung disease
- Pregnancy
- Respiratory infection

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Altered mental status may signal respiratory failure.
- Correct use of medications such as inhalers and nebulizers.
- Monitor peak flows to assess severity and response to treatment.

Mimics

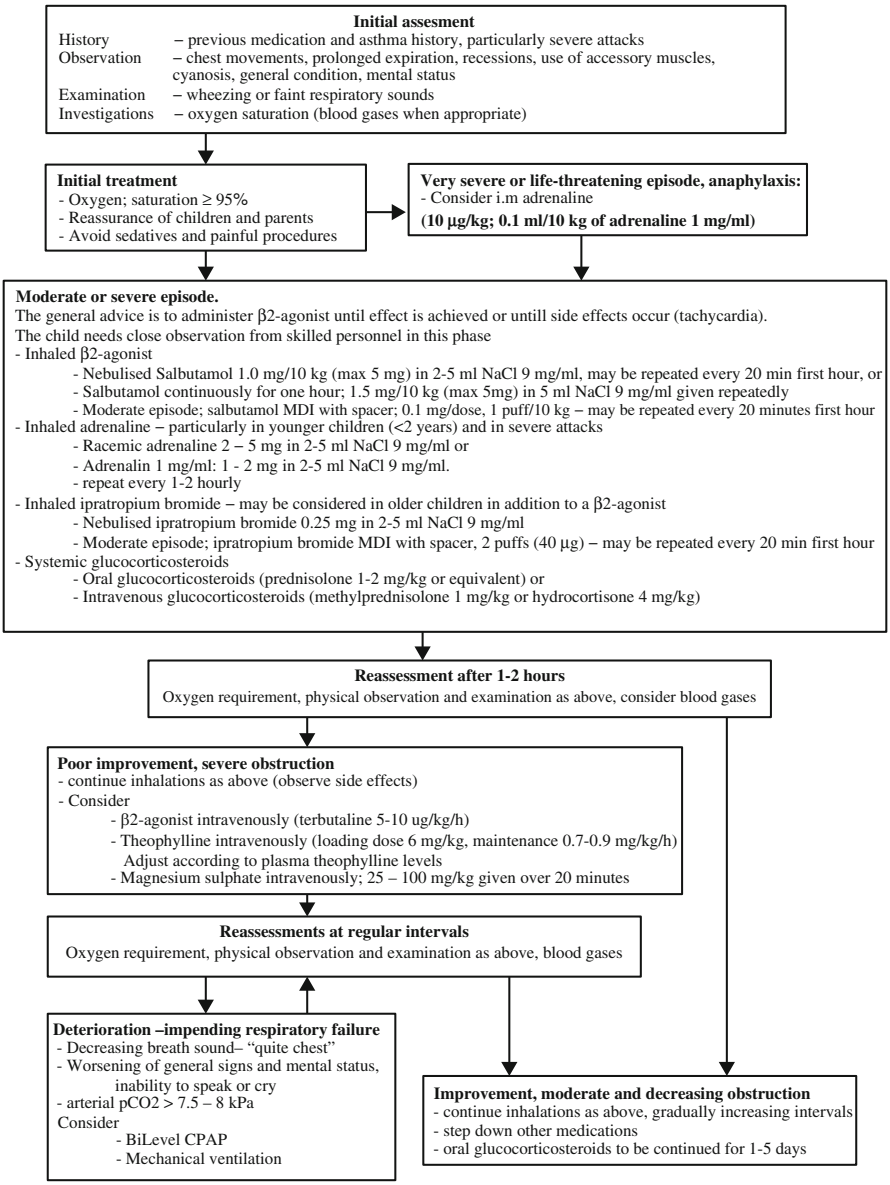
- Sinusitis
- Myocardial ischemia
- Gastrointestinal reflux
- Congestive heart failure
- Not all wheezing in infants and young children is asthma

Time-Dependent Interventions

- Immediate initiation of inhaled β_2- adrenergic agonist.
- Nebulized treatment.
- Supplemental oxygen.
- Administration of subcutaneous epinephrine unless concerned about coronary artery disease or hypertension.
- Intubation in respiratory failure.
- Corticoteroids should be given early, as they require 4–6 hours to show benefit.

Overall Principles of Treatment

- Treatment is based on asthma severity.
- Routine monitoring of symptoms and lung function.
- Patient education is essential.
- Recognize and control trigger factors (environmental factors).
- Controlling comorbid conditions that contribute to asthma severity.
- Pharmacologic therapy.
- Reduction of personal impairment and reduction of risk.
- Preventative approach with regularly scheduled check-ups and family/patient education.
- Awareness, recognition, and treatment of these atypical asthmas is important.
- Many base their management of asthma in children upon the National Asthma Education and Prevention Program (NAEPP) Expert panel guidelines (http://www.nhlbi.nih.gov/health-pro/guidelines/current/asthma-guidelines/full-report).



Acute exacerbation treatment: Treatment algorithm for children with moderate or severe asthma exacerbations. [From article: Emergency presentation and management of acute severe asthma in children. Disease Course

- By definition, asthma is characterized by *reversible* airflow obstruction, which means the impact of asthma on quality of life varies, from year to year, sometimes from season to season, or even day to day. There is little consensus on factors that determine disease progression versus disease stabilization.
- There is much interindividual variation is the course of asthma, and fatal exacerbations sometimes occur but are clearly unusual.
- With good control, asthmatics lead relatively normal and functional lives and have a normal lifespan. Poorer control is associated with impaired quality of life, more unscheduled healthcare visits, and more common hospitalization.

Chapter 12
Atrial Fibrillation

Charles V. Pollack, Jr., Melissa Platt, and Victoria G. Riese

Name and Synonyms

Atrial Fibrillation (AF)

Incidence/Epidemiology

- The most common cardiac arrhythmia
  - Affects 4 % of individuals older than 60 years and 8 % of those older than 80 years.
- It is more prevalent in men, and prevalence increases with age.
- In developed countries, hypertension and coronary artery disease are the most common underlying disorders.
- Rheumatic heart disease is associated with a higher incidence of AF, but this is much less common than in the past. Other causes of mitral valve disease also may lead to AF.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_12

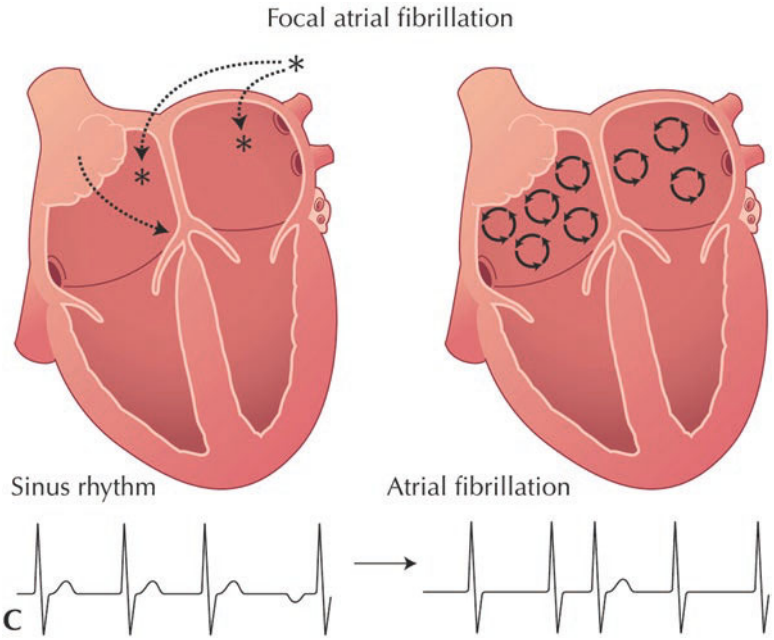
- Classified as follows:
  - Paroxysmal AF: terminates spontaneously or with intervention within 7 days of onset.
  - Persistent AF: does not terminate within 7 days.
  - Permanent AF: persists for a year or longer.
  - "Lone" AF: does not occur with any other clinical or echocardiographic cardiac problems; usually occurs in patients younger than 50.

Differential Diagnosis

- Atrial flutter
- Multifocal atrial tachycardia
- Supraventricular tachycardia

Pathophysiology and Etiology

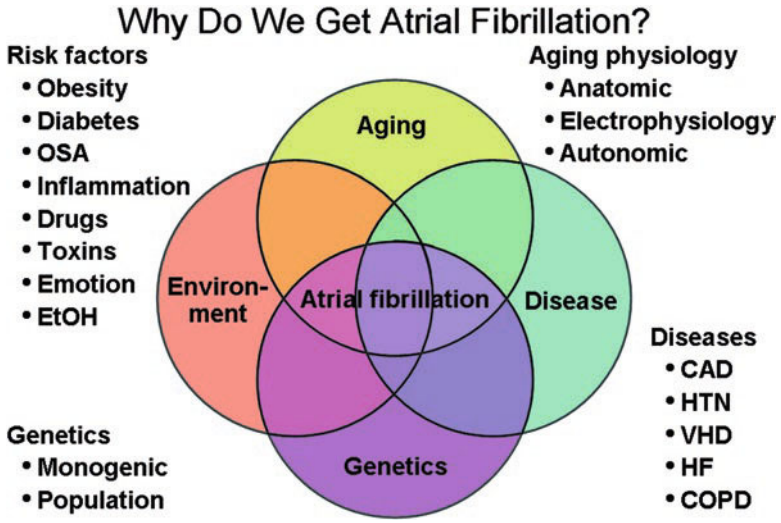
- Instead of being coordinated, atrial contractions are irregular, disorganized, chaotic, and very rapid.
- This electrical malfunction may result in:
  - Tachypalpitations, often described by patients as a "fluttering" or "butterflies" in the chest.
  - Inadequate "topping off" of the ventricular volume prior to ventricular systole, which may result in fatigue, dizziness, or heart failure.
- Because the cardiac cycle of atrial systole followed by ventricular systole is disrupted by the lack of regularity of impulses through the atrioventricular node, the ventricles beat irregularly and often beat faster than normal.
  - This "irregularly irregular" rhythm is classified as showing a "controlled" ventricular response (rate <100 bpm) or "rapid" ventricular response (rate ≥100 bpm).
- The precise mechanism that causes AF is not completely understood, but AF often is seen concomitantly with other heart and metabolic diseases, including:
  - Congestive heart failure
  - Coronary artery disease
  - Valvular heart disease
  - Hypertension
  - Hyperthyroidism
- Acute alcohol abuse, especially in binges, may cause AF ("holiday heart").



Focal atrial premature complexes usually originating from pulmonary veins can initiate AF. Ablation of these arrhythmogenic focal triggers can restore rhythm. This finding opens an exciting era in electrophysiology with the possibility of curing AF by ablation. [Grogin HR. Supraventricular tachycardia. In: Scheinman M, editor. Arrhythmias: electrophysiologic principles. Philadelphia: Current Medicine; 1996. Chapter 5 (Braunwald E, editor. Atlas of heart diseases; vol. 9).] *Caption adapted from original*

Atrial Fibrillation	
Common causes	Heart failure
	Hypertension
	Cardiac ischemia
	Myocardial infarction
	Mitral valve disease
	Pneumonia
	Hyperthyroidism
	Alcohol
	Postoperative AF
Rare causes	Cardiomyopathy
	Constrictive pericarditis
	Sick sinus syndrome
	Bronchial carcinoma
	Atrial myxoma
	Endocarditis
	Haemochromatosis
	Sarcoidosis

Causes of Atrial Fibrillation. [From article: Reversible atrial fibrillation secondary to a mega-oesophagus. BMC Ear Nose Throat Disord. 2006 Dec 13;6(1):15. https://doi.org/10.1186/1472-6815-6-15, at http://link.springer.com/article/10.1186%2F1472-6815-6-15; by Tahwinder Upile, Waseem Jerjes, Mohammed El Maaytah, Sandeep Singh, Colin Hopper, Jaspal Mahil, © Upile et al; licensee BioMed Central Ltd. 2006; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*



Atrial fibrillation is a multifactorial condition resulting from an interaction between cardiovascular disease effects, aging, genetics, and environmental factors. *CAD* coronary artery disease, *COPD* chronic obstructive pulmonary disease, *EtOH* alcohol use, *HF* heart failure, *HTN* hypertension, *OSA* obstructive sleep apnea, *VHD* valvular heart disease [Eleid MF, Cha Y-M, Shen W-K. Atrial fibrillation and heart failure: rate versus rhythm control. In: Bartunek J, Vanderheyden M, editors. Translational approach to heart failure [Internet]. New York: Springer; 2013 [cited 2015 Aug 13]. p. 129–44. Available from: http://link.springer.com/10.1007/978-1-4614-7345-9_6] *Caption from original*

Presentation

Typical/"Classic"

- Not all patients with AF have symptoms, but the risk of thromboembolic complications is the same, regardless.

- Typical symptoms include palpitations, tachycardia, fatigue, weakness, dizziness, lightheadedness, reduced exercise capacity, and dyspnea.

Atypical

- The first presentation of AF may be a thromboembolic complication, such as stroke or mesenteric ischemia.
- AF may present as anginal pain.
- Some patients, particularly those who are elderly, may not notice the palpitations (particularly if the ventricular rate is less than 100 bpm) and may present with completely unrelated complaints.

Primary Differential Considerations

- Atrial flutter
- Multifocal atrial tachycardia
- Supraventricular tachycardia
- Premature atrial contractions
- Premature ventricular contractions

History and Physical Exam

Findings That Confirm Diagnosis

- Although an "irregularly irregular" pulse is suggestive of AF, this also may be associated with other arrhythmias, and an ECG is required to differentiate among them.

Factors That Suggest Diagnosis

- Irregularly irregular pulse on examination
- Palpitations plus dyspnea
- Palpitations plus syncope or near-syncope
- Palpitations and generalized weakness
- Palpitations and hypotension
- Unexplained dyspnea, syncope, generalized weakness, or hypotension
- Acute ischemic stroke

Factors That Exclude Diagnosis

- ECG showing a normal sinus rhythm excludes AF "in the moment," but does not exclude paroxysmal AF.

Ancillary Studies

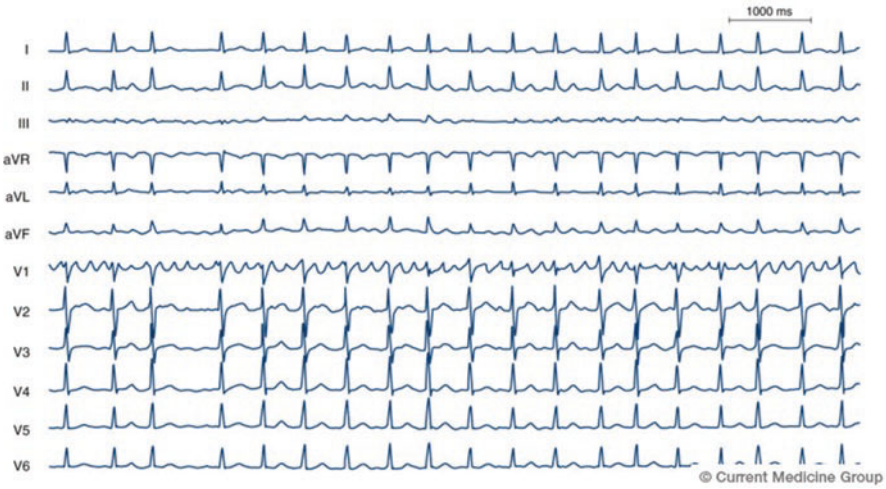
Laboratory

- Often obtained in search for underlying disorders or other associated disorders:
  - B-type natriuretic peptide (BNP)
  - Troponin
  - Electrolytes
  - Blood glucose
  - Thyroid-stimulating hormone (TSH)
  - Toxicology

Electrocardiography

- ECG is necessary to make the diagnosis.
- Irregular rate with an atrial rate greater than 300 bpm
- Ventricular rate may be slow, normal, or fast.
- Absent or erratic P waves are noted.
- PR interval is absent.
- QRS may be normal but may be widened if conduction delay is present.

Atrial fibrillation. Atrial fibrillation is characterized by the absence of P waves, which are replaced by irregular f waves or no sign of atrial activity. The QRS complexes may be normal or irregular and varying in amplitude. The 12-lead ECG shown here demonstrates atrial fibrillation with moderate ventricular response rate. [Leung J. Electrocardiographic monitoring. In: Lichtor JL, editor. Preoperative preparation and intraoperative monitoring. Philadelphia: Current Medicine; 1997. Chapter 7. (Miller RD, editor. Atlas of anesthesia; vol. 3).] *Caption from original*



Atrial fibrillation (AF) 12-lead surface electrocardiogram. AF is the most common sustained arrhythmia and is particularly prevalent in the elderly. Characteristic of AF is an irregular ventricular response and rapid irregular oscillations or fibrillatory waves that vary in shape, amplitude, and timing. [Epstein L, Stevenson W, Steven D, Seiler J, Roberts-Thomson K, See V. Arrhythmias. In: Libby P, editor. Essential atlas of cardiovascular disease. 4th ed. Philadelphia: Current Medicine; 2009. Chapter 7.] *Caption from original*

Imaging

- Transthoracic echocardiography may be performed to evaluate the size of the right and left atria and size and function of the right and left ventricles; this also can detect valvular heart disease.
- Transesophageal echocardiography is used to identify thrombi in the left atrium or left atrial appendage.

Special Populations

Age

- Incidence of AF increases with advancing age.
- "Lone AF" more common below age 50.

Co-morbidities

- As under "Pathophysiology and Etiology," a host of other cardiac and metabolic disorders are frequent co-morbidities in patients with AF.
- Binge alcohol consumption predisposes to "holiday heart."

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Complications such as blood clot formation, strokes, and heart failure may arise, but rhythm conversion reduces the chances that such complications will develop.

Mimics

- Atrial flutter
- Multifocal atrial tachycardia
- Supraventricular tachycardia

Time-Dependent Interventions

- Patients may have potentially life-threatening symptoms that need immediate intervention with electrical cardioversion, including decompensated congestive heart failure, hypotension, angina, or cardiac ischemia.

Overall Principles of Treatment

- The initial focus of AF management is rate control to minimize any perfusion stress on the ventricles.
  - The usual approach is with titrated doses of calcium channel blockers or beta-blockers.
- Once rate is controlled (or if patient presents with a controlled ventricular rate), consideration is given to converting the rhythm out of AF back into a sinus rhythm.
  - This may be approached pharmacologically with a variety of potential drugs, such as ibutilide or procainamide, or electrically via synchronized cardioversion.
- If the patient has been in AF for 24 to 48 hours or longer, anticoagulation therapy should be provided before attempting cardioversion, as clots that may have formed in the fibrillating atria or atrial appendage may dislodge and embolize when normal atrial electrical activity is restored. Therapy may be provided acutely with parenteral agents such as unfractionated or low-molecular weight heparin or with fast-acting non-warfarin oral anticoagulants (dabigatran, rivaroxaban, apixaban, edoxaban)
  - Alternatively, cardioversion may be attempted after transesophageal echocardiography that excludes atrial clots
  - Likelihood of stroke or systemic embolization may be assessed with CHA2DS2-VASc score

Risk factor	Points
Age over 75 years	1
Previous stroke/TIA	2
Hypertension	1
Symptoms or signs of LV dysfunction	1
Diabetes mellitus	1

$CHADS_2VASC$ score points for prediction of stroke in atrial fibrillation. (Data from Gage BF, Waterman AD, Shannon W, Boechler M, Rich MW, Radford MJ. Validation of Clinical Classification Schemes for Predicting Stroke: Results From the National Registry of Atrial Fibrillation. JAMA.2001;285(22):2864-2870. https://doi.org/10.1001/jama.285.22.2864.) [Table from Verheugt FWA. The new oral anticoagulants. Netherlands Heart Journal. 2010 Jun;18(6):314–8.] *Caption adapted from original*

- Patients whose AF is resistant to cardioversion or recurs after initially successful cardioversion may be referred to electrophysiology, where the possibility of catheter ablation of the electrical source of the AF can be addressed definitively and specifically.
  - Success rates usually exceed 65–75 %

Disease Course

- The most feared complication of AF is thromboembolism to a critical vascular bed—especially stroke.
- The palpitations of AF may have a very adverse effect on quality of life. They may be symptomatic even in patients with controlled ventricular response.
- Patients with diminished pump function are particularly sensitive to the absence of consistent ventricular filling (the missing "atrial kick") and may experience persistent easy fatigability and even angina.
- Longstanding AF increases mortality.

Chapter 13
Bradyarrhythmias

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Bradyarrhythmias

- Bradycardia

Incidence/Epidemiology

- The bradyarrhythmias encompass a broad range of disorders; therefore, their incidence varies widely.
- Sinus bradycardia may be normal in up to 35 % of people younger than 25 years. It also may be normal in well-conditioned athletes at most ages.
- Sick sinus syndrome becomes more common as people age, with more than 50 % of cases occurring in people over 50, but it may occur at any age.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_13

Differential Diagnosis

- Clinically significant bradycardias may cause a wide range of symptoms, the most common of which are syncope, presyncope, chest pain, general fatigue, dyspnea on exertion, and dyspnea at rest. As such, the differential is broad and far ranging.
- Bradycardias also have a broad range of causes; therefore, the differential diagnosis of the bradycardia itself also is extensive.

Pathophysiology and Etiology

- Bradycardia is defined as a heart rate below 60 bpm.
- Bradycardia generally is caused by two different mechanisms:
  - Slowing, blocking, or failure of impulse generation in the sinus node
  - Block in the conduction system from the atrioventricular (AV) node down through the His–Purkinje system.
- Many different processes may lead to these mechanisms, including intrinsic conduction system disease, other heart diseases, other systemic diseases, and drugs, to name a few.
- When these blocks occur, alternative pacemakers within the heart take over the pacemaker function. Other conduction tissue, or even myocytes, may act as alternative pacemakers. In general, the higher within the conduction system the impulse originates, the faster the rate; if the impulse is generated within or above the bundle of His, the rate generally is enough to maintain adequate cardiac output. This association also may be used as a clue to the location of the block based on the escape rate.
- Although slow heart rates can occur with junctional or ventricular pacemakers, the bradyarrhythmias usually are classified according to the location of the block: either sinoatrial (SA) node dysfunction or AV node dysfunction.
- Sinus node dysfunction:
  - Sinus bradycardia: defined as a sinus node rate less than 60 impulses per minute.
    - An ECG will show normal sinus P waves and a fixed P-P interval that is equal to the R-R interval, with 1:1 AV conduction.
    - It may be physiologic and normal in well-conditioned athletes, in young people, and during sleep.
    - It may be secondary to excess vagal stimulation, which may even occur as a result of a necktie that is too tight.
    - Medications are a common cause, especially beta-blockers, calcium channel blockers, digoxin, and opioids.
    - It also (although less commonly) may be pathologic. Sinus bradycardia may be seen in the setting of acute inferior myocardial infarction (MI), increased intracranial pressure, carotid sinus hypersensitivity, and profound hypothyroidism.

Sinus bradycardia. No other abnormalities noted here except for sinus bradycardia at 50 bpm. [Almasry IO. Evidenced-based approach to bradyarrhythmias. In: Stergiopoulos K, Brown DL, editors. Evidence-based cardiology consult [Internet]. London: Springer; 2014 [cited 2015 May 22]. p. 105–18. Available from: http://link.springer.com/10.1007/978-1-4471-4441-0_9] *Caption adapted from original*

- Sinus arrhythmia (sinus dysrhythmia): similar to sinus bradycardia except for the presence of a variable P-P interval, leading to a slightly irregular rhythm. This is a normal variant and not pathologic. It is common in children and young adults. In the most common situation, the sinus node rate increases with inspiration and decreases during expiration because of the changes in vagal tone with breathing.

Sinus arrhythmia. Rhythmic variation in the sinus rate is noted across the rhythm strip. P-wave morphology and PR intervals remain essentially unchanged. [Foreman B. Common atrial and ventricular arrhythmias. In: Toth PP, Cannon CP, editors. Comprehensive cardiovascular medicine in the primary care setting [Internet]. Totowa, NJ: Humana Press; 2011 [cited 2015 May 22]. p. 459–96. Available from: http://link.springer.com/10.1007/978-1-60327-963-5_24] *Caption from original*

- Sinus arrest (sinus pause). In sinus arrest, the SA node fails to generate an impulse. It is recognized as a pause in the sinus rhythm. During the pause/arrest, no P waves are seen on the ECG. The P-P interval of the two complexes surrounding the pause will not be a multiple of the usual P-P interval, as would be the case if the pause were from an SA exit block. If the pause lasts long enough, there may be an escape beat from somewhere else along the conduction system or the ventricles. This may be a normal variant, but it also occurs in acute MI, intrinsic SA node disease, digitalis toxicity, stroke, and excessive vagal stimulation. Notably, frequent and prolonged sinus pauses may be seen in up to 30 % of patients with obstructive sleep apnea.

Sinus arrest. Note sudden cessation of sinus impulse for 3 s prior to resumption of normal sinus rhythm. [Almasry IO. Evidenced-based approach to bradyarrhythmias. In: Stergiopoulos K, Brown DL, editors. Evidence-based cardiology consult [Internet].

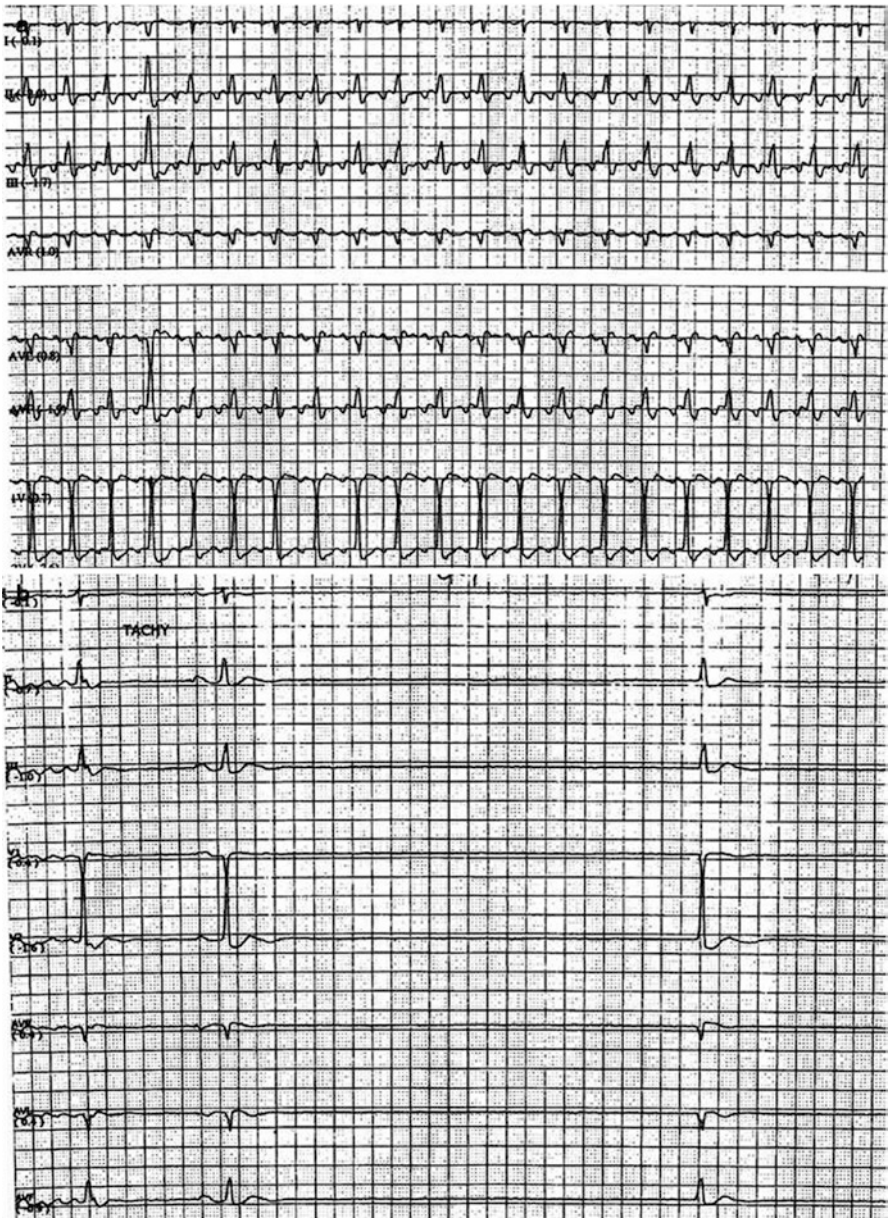
London: Springer; 2014 [cited 2015 May 22]. p. 105–18. Available from: http://link.springer.com/10.1007/978-1-4471-4441-0_9] *Caption adapted from original*

- SA exit block: recognized as a pause in the usual rhythm resulting from the absence of a normally expected P wave, usually because of blocked or slowed impulse generation within the SA node. The P-P interval of the two complexes surrounding the pause will have a P-P interval that is a multiple of the usual P-P interval. SA exit block may be subclassified as first degree; second degree, types I and II; and third degree. These usually are difficult, if not impossible, to see on a surface ECG and require electrophysiologic mapping of the sinus node discharge. These blocks may be seen following acute MI, acute rheumatic fever, and myocarditis, and secondary to drugs such as beta-blockers, calcium channel blockers, digoxin, quinidine, and salicylates. They also may be seen in well-conditioned athletes or secondary to excessive vagal stimulation. They usually are transient and not clinically significant.

Top panel: Type I second-degree sinoatrial exit block. Note the pause that is less than two times the PP interval. Also note the group beating consistent with Wenckebach periodicity. Bottom panel: Type II second-degree sinoatrial exit block. The pause here is two times the PP interval, with the occurrence of a junctional beat prior to the return of a sinus P wave which is followed by unperturbed sinus mechanism before there is another recurrence. [Almasry IO. Evidenced-based approach to bradyarrhythmias. In: Stergiopoulos K, Brown DL, editors. Evidence-based cardiology consult [Internet]. London: Springer; 2014 [cited 2015 May 22]. p. 105–18. Available from: http://link.springer.com/10.1007/978-1-4471-4441-0_9] *Caption from original*

- Sick sinus syndrome (tachycardia–bradycardia syndrome/tachy–brady syndrome): a mixed group of disorders marked by abnormalities of supraventricular impulse formation and conduction that are associated with both tachy- and bradyarrhythmias. It usually is the result of intrinsic disease of the sinus node or the surrounding tissue, sometimes with associated AV nodal disease. The tachyarrhythmias usually are either atrial fibrillation or atrial flutter, and the bradyarrhythmias usually are marked sinus bradycardia, prolonged sinus arrest, and SA block associated with abnormal AV conduction leading to inadequate escape rhythms. On prolonged rhythm monitoring, it is typical to see long periods of tachycardia followed by profound bradycardia upon the spontaneous termination of the tachycardia. It is most

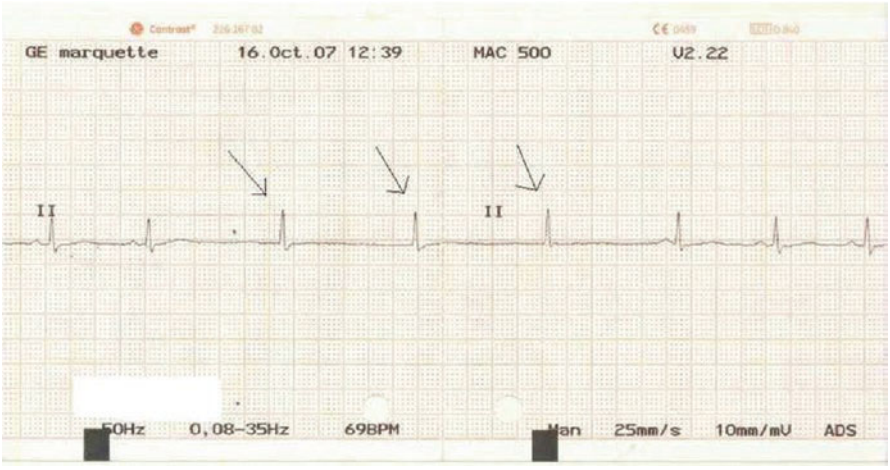
common in the elderly as a result of fibrotic degeneration of conduction tissue. It also may be seen in cardiomyopathies, in connective tissue diseases, and with the use of some medications. It usually is suspected in elderly patients who present with syncope and is an indication for a permanent pacemaker.



(a) Twelve-lead electrocardiogram of an 84-year-old female who presented with altered mental status. Atrial flutter with 2:1 A:V conduction is seen. (b) 12-lead

electrocardiogram showing flutter termination. A 4.9-s period of asystole is noted before ventricular activity resumes. The patient had multiple sinus pauses during sinus rhythm. These rhythms are typical of Tachy–Brady syndrome and are characteristic of sick sinus syndrome [El Hage L, Badhwar N, Goldschlager N. Top ten electrocardiographic (ECG) abnormalities not to miss. In: Stergiopoulos K, Brown DL, editors. Evidence-based cardiology consult [Internet]. London: Springer; 2014 [cited 2015 May 22]. p. 133–48. Available from: http://link.springer.com/10.1007/978-1-4471-4441-0_11] *Caption from original*

- Chronotropic incompetence: failure of the heart rate to increase appropriately with exercise
- Junctional rhythms. Under typical conditions, the sinus node impulses suppress (by nature of being faster) impulse generation distally along the conduction tree. If the sinus impulse is suppressed or blocked, the AV node may take over the pacemaker function. This is termed a junctional or junctional escape rhythm. The AV node naturally discharges at a rate of 40–60 bpm, which usually is enough to maintain cardiac output and blood pressure. As the impulse is generated in the AV node, the QRS complex will be narrow, but because the sinus impulses are blocked, there will be no P waves. Junctional rhythms may be seen after acute inferior MI and in congestive heart failure, myocarditis, hypokalemia, and digoxin toxicity.



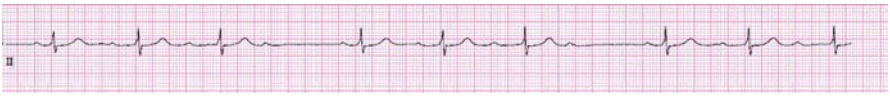
ECG shows transient sinus arrest with escape junctional rhythm. *Arrow* indicates escape junctional rhythm [Bhaskar EM, Moorthy S, Ganeshwala G, Abraham G. Cardiac conduction disturbance due to prallethrin (pyrethroid) poisoning. J Med Toxicol. 2010 Mar;6(1):27–30.] *Caption from original*

- AV node dysfunction
  - AV block is caused by either delayed or blocked conduction of impulses between the atria and the ventricles.

- AV block is classified into first-degree, second-degree (of which there are two types), and third-degree AV block (also referred to as complete heart block).
- First-degree AV block is defined as a P-R interval greater than 0.20 sec on an ECG. This indicates delayed conduction through the AV node, but all impulses are conducted to the ventricles. It may be a normal variant and generally portends no increased risk of further conduction disease or heart disease. It may be associated with increased vagal tone, digoxin toxicity, acute inferior MI, or myocarditis. When there is an underlying cause, the block usually is transient.

First-degree AV block [Mendoza A, Belda S, Salguero R, Granados MA. Congenital complete atrioventricular block associated with QT prolongation: description of a patient with an unusual outcome. Pediatr Cardiol. 2010 Aug;31(6):887–90.] *Caption from original*

- Second-degree AV block is marked by the failure of some sinus impulses to reach the ventricles. On an ECG, some P waves are seen without an associated QRS complex. There are two types: type I (also called Mobitz I or Wenckebach) and type II (Mobitz II).
  - Type I second-degree, Mobitz I AV (Wenckebach) block: There is progressive prolongation of AV conduction (noted as progressive lengthening of the P-R interval) until the atrial impulse is completely blocked and a QRS complex is dropped. The conduction ratio is the ratio of atrial impulses to those that are conducted into the ventricles, i.e., a 4:3 conduction ratio means that three of every four atrial impulses are conducted into the ventricles. In other words, there is a dropped QRS complex after every three sinus beats, so for four P waves, there are only three QRS complexes. This ratio usually is stable for any given patient, but some patients can manifest changing (variable) ratios of block. This block occurs at the level of the AV node. This type of block does not carry an increased risk of progression to third-degree heart block. It usually is transient, reversible, and asymptomatic. It may be seen during acute inferior MI, with myocarditis, with digoxin toxicity, and after cardiothoracic surgery.



Mobitz type I (Wenckebach) Second-Degree AV block. Notice the classic form of Wenckebach in a 4:3 pattern. The PP intervals are fixed, with lengthening of each successive PR interval with progressively decreasing increments and shorter RR intervals prior to the dropped beat. The pause is less than a multiple of the shortest RR interval, the return-cycle PR interval is shorter than the PR interval prior to the dropped beat, and there is obvious group beating periodicity. [Almasry IO. Evidenced-based approach to bradyarrhythmias. In: Stergiopoulos K, Brown DL, editors. Evidence-based cardiology consult [Internet]. London: Springer; 2014 [cited 2015 May 22]. p. 105–18. Available from: http://link.springer.com/10.1007/978-1-4471-4441-0_9] *Caption from original*

- Second-degree, Mobitz II AV block: The P-R interval is constant, and there are nonconducted impulses. As with Mobitz I block, there usually is a constant conduction ratio, but it may be variable. When the conduction ratio is 2:1, it is impossible to tell the difference between Mobitz I and Mobitz II heart block, as progressive P-R prolongation cannot be appreciated. This level of block usually occurs below the AV node (infranodal). If the escape pacemaker is high enough in the conduction system, the QRS complexes may still be narrow, but if the pacemaker is lower, the QRS complexes may be wide. This type of heart block almost always indicates some structural damage to the conduction system and usually is permanent. It carries a high risk of progression to third-degree heart block, especially if it occurs in the setting of an acute anterior MI.

Mobitz type II second-degree AV block. Note that there is ongoing sinus rhythm with a fixed PP interval before there is a sudden failure of conduction to the ventricles demonstrated by a dropped QRS. Note that there is no change in the PR interval preceding and following the dropped QRS, and this recurs later in the strip. The resultant pause is exactly twice the PP interval. Note the narrow QRS in this example that may suggest a nodal site of conduction block. [Almasry IO. Evidenced-based approach to bradyarrhythmias. In: Stergiopoulos K, Brown DL, editors. Evidence-based cardiology consult [Internet]. London: Springer; 2014 [cited 2015 May 22]. p. 105–18. Available from: http://link.springer.com/10.1007/978-1-4471-4441-0_9] *Caption adapted from original*

- Third-degree heart block (complete heart block): All conduction between the atria and ventricles is blocked. This block is seen on an ECG as the absence of a relationship between the P waves and the QRS complexes; therefore, it also is called *AV dissociation*. The atrial rate must be greater than the escape pacemaker rate for this lack of a relationship to be appreciated. If the rates are similar, it may be difficult to determine that there is no relationship between the P waves and QRS complexes (isorhythmic dissociation). A ventricular rate greater than the atrial rate precludes the diagnosis of third-degree heart block. AV dissociation with a ventricular rate greater than the atrial rate may be seen in some accelerated junctional rhythms, as well as in ventricular tachycardia. If the escape pacemaker is within the AV node (nodal), the escape rate is usually 40 to 60 bpm, with narrow QRS complexes. If the escape pacemaker is infranodal, the escape rate may be less than 40 bpm, in which case the QRS complex usually is widened. Nodal complete heart block may be transient, especially in the setting of an acute inferior MI. Infranodal complete heart block usually is permanent and the result of intrinsic conduction system disease, acute ischemia, drugs, or, rarely, Lyme disease.

Third-degree AV block (Complete heart block). Top panel: Ongoing sinus rhythm at a rate of 75 bpm with complete heart block and a narrow junctional escape at just over 40 bpm. Bottom panel: Sinus tachycardia at a rate of 125 bpm with a wide ventricular escape focus at 24 bpm. The sinus tachycardia indicates that this patient may be in distress and is far more likely to be symptomatic upon presentation. [Almasry IO. Evidenced-based approach to bradyarrhythmias. In: Stergiopoulos K, Brown DL, editors. Evidence-based cardiology consult [Internet]. London: Springer; 2014 [cited 2015 May 22]. p. 105–18. Available from: http://link.springer.com/10.1007/978-1-4471-4441-0_9] *Caption adapted from original*

Presentation

Typical/"Classic"

- Bradyarrhythmias often are asymptomatic and sometimes are found on routine evaluation or for evaluation of other complaints. This is especially true for sinus bradycardia, sinus arrhythmia, sinus block, first-degree AV block,

and type I second-degree AV (Wenckebach) block. Sinus bradycardia, sinus arrhythmia, and first-degree AV block may be normal variants. It is a common situation to find one of these abnormalities on an ECG performed for other reasons, such as preoperative clearance in an otherwise healthy person.

- These dysrhythmias also may be associated with other, more serious concerns (e.g., an acute MI or drug overdose or intoxication), and the symptoms of these disorders may predominate in the clinical presentation. In these situations, it often is difficult to discern whether the symptoms are being caused by the primary event or the dysrhythmia. However, these dysrhythmias often are transient and resolve spontaneously or with appropriate treatment of the primary event.
- Patients who have symptoms from their bradyarrhythmias often have vague and nonspecific complaints, such as fatigue, exercise intolerance, shortness of breath (especially on exertion), and feeling generally unwell.
- Most significantly, these dysrhythmias may present acutely with syncope, near-syncope, chest pain, acute dyspnea, and other signs of systemic hypoperfusion (change in mental status, hypotension, cyanosis, i.e., shock state). These presentations are much more likely with heart rates of 40 bpm or less, as well as with greater levels of block.
- Sick sinus syndrome often presents as syncope or near-syncope in elderly patients. Sometimes, however, symptoms from the tachycardia predominate, and the patient will present with palpitations and chest heaviness/pain, followed by syncope, presyncope, or generalized fatigue.

Atypical

- Because there is no "typical" presentation for bradyarrhythmias, almost all presentations are atypical.

Primary Differential Considerations

- Bradycardia is a self-evident diagnosis based on a heart rate less than 50 bpm. The differential diagnosis of *causes* of bradyarrhythmias is broad and includes:
  - Heart blocks or slow atrial fibrillation
  - Primary cardiac causes such as MI with cardiogenic shock
  - Metabolic causes such as hyperkalemia
  - Neurologic causes such as increased intracranial pressure or spinal cord injury
  - Drug toxicity (calcium channel blockers, beta-blockers, digitalis, clonidine)
  - Infections such as myocarditis, rheumatic fever, or Lyme disease
  - Malfunctioning pacemaker

History and Physical Exam

Findings That Confirm Diagnosis

- The diagnosis is considered by finding a slow pulse rate on physical exam, then confirmed by finding a bradyarrhythmia on a 12-lead ECG and/or continuous cardiac monitoring.

Factors That Suggest Diagnosis

- The diagnosis may be suggested in patients presenting with the symptoms reviewed above (syncope, near-syncope, fatigue, exercise intolerance, chest pain or heaviness, palpitations).
- Patients with any of the aforementioned symptoms should undergo 12-lead ECG and may need further, more prolonged cardiac monitoring if the ECG does not secure the diagnosis.

Factors That Exclude Diagnosis

- Because many of these arrhythmias may be both transient and intermittent, they are all difficult to exclude, and the patient may require reassessments over time for complete exclusion. Patients also may require extended cardiac monitoring and/or electrophysiologic study for any of these abnormalities to be completely excluded.

Ancillary Studies

Laboratory

- In general, there are no specific laboratory tests that are diagnostic for any of these arrhythmias.
- All patients should have their electrolyte levels checked, as hypo- and hyperkalemia may lead to or exacerbate some of these disturbances.
- Thyroid-stimulating hormone levels also should be checked, as hypothyroidism also may cause bradycardia (most commonly sinus bradycardia).
- Patients on digoxin should have their serum levels checked, as digoxin toxicity may cause many of these arrhythmias.

- Patients who present with more acute symptoms, such as chest pain/heaviness or dyspnea, should have their cardiac biomarkers checked, as many of these rhythms may occur in the setting of an acute MI, especially an inferior MI.
- Many times, the laboratory evaluation of these patients is guided by the acuity of the presentation, not the bradyarrhythmia.
- Lyme disease may cause conduction disturbances; therefore, in the correct clinical setting, a Lyme titer may need to be analyzed. Chagas disease also may cause conduction disturbances so in the correct clinical setting, also may need to be evaluated.

Imaging

- Most patients being evaluated for cardiovascular-related complaints will have a chest x-ray, which may indicate contributing issues or show evidence of other heart disease (e.g., heart failure and/or cardiomegaly).
- Echocardiogram (either transthoracic or transesophageal) usually is performed in the workup of patients with symptomatic bradycardias. These studies may help reveal any structural heart disease that may be causative or contributory (e.g., cardiomyopathy, cardiac amyloidosis).

Special Populations

Age

- Most of these arrhythmias increase in incidence as age increases, as they often are associated with underlying heart disease or medication use.
- Exceptions include sinus bradycardia, sinus arrhythmia, and low-level heart blocks, which may be normal variants in the young.
- The most common cause of bradycardia in infancy is hypoxia.
- In adolescents and young adults, the pulse rate may drop normally to 35 to 40 bpm during sleep. This also may be associated with sinus pauses of up to 2 seconds. These findings are normal in this age group and usually do not require further evaluation.
- Complete heart block may be seen in infants and children and is almost always associated with congenital heart disease.
- Children presenting with high-grade heart block and no significant medical history should be evaluated for drug ingestion (digoxin, beta-blockers, calcium channel blockers, other antiarrhythmics, and opiates). It also may be necessary to consider conduction abnormalities from cardiac Lyme disease and, if appropriate (prolonged travel or immigration from endemic areas), Chagas disease.

Co-morbidities

- There are multiple co-morbidities of interest in patients presenting with bradyarrhythmias.
- Many of these disturbances are seen in patients with underlying structural heart disease and in those with coexistent coronary artery disease. Many of these conduction disturbances may be seen with or caused by cardiac medications.
- Increased vagal tone may precipitate many of these abnormalities, so anything that increases vagal tone should be considered (e.g., carotid sinus hypersensitivity, intra-abdominal catastrophe, increased intracranial pressure, drugs).
- As noted, conduction disturbances also may be found in association with many other diseases:
  - Inflammatory: rheumatic heart disease, myocarditis, pericarditis, and collagen vascular diseases such as rheumatoid arthritis and systemic sclerosis
  - Infectious: Lyme disease and Chagas disease
  - Systemic/cardiac amyloidosis
  - Post open heart surgery
  - Post mediastinal radiation therapy
  - Chest trauma
  - Rare genetic and familial diseases, such as myotonic dystrophy

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is critical to consider the entire clinical picture when confronted with a patient who is bradycardic.
- It must be determined whether the patient is symptomatic and, if so, whether the symptoms arise from the bradycardia itself or an underlying/causative disorder.
- It is critical to look for these underlying disorders and not to stop at the diagnosis of bradycardia.
- All patients who are bradycardic should have a 12-lead ECG and, if in an appropriate clinical setting, continuous cardiac and vital sign monitoring.

Mimics

- Because bradycardia usually is defined by an absolute rate, there are no mimics; however, multiple potential etiologies must be considered in patients with bradycardia.

Time-Dependent Interventions

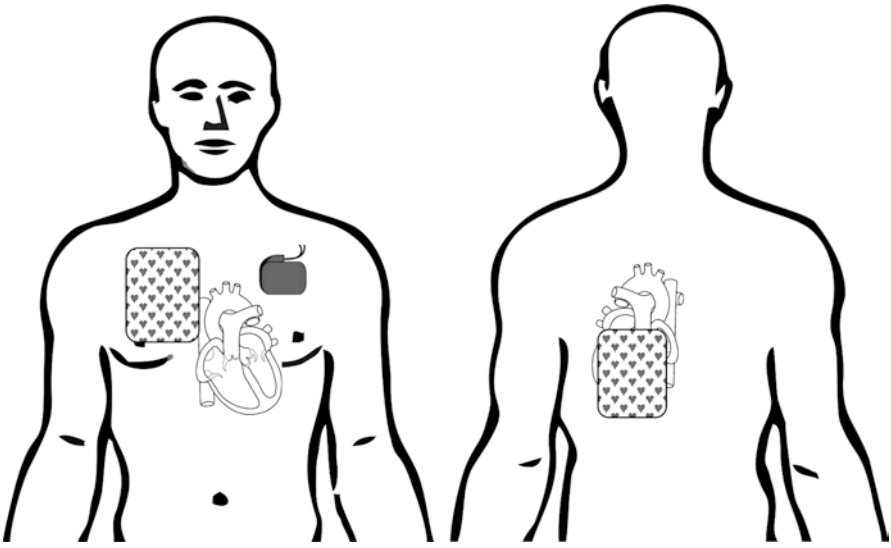
- Time-dependent interventions in bradycardias are necessary only in patients who have symptoms and show signs of reduced cardiac output, such as hypotension, a change in mental status, cyanosis, and syncope.
- In these situations, treatment must begin before obtaining a complete database.
- When a patient demonstrates any of these signs or symptoms, it is critical to act quickly to attempt to return cardiac output to more normal levels.
- Support of airway, breathing, and circulation is of paramount importance. All patients should have supplemental oxygen and adequate intravenous access for administration of medications and fluid. All unstable, or potentially unstable, patients with an arrhythmia should have defibrillator pads placed and attached to the defibrillator/monitor.

Overall Principles of Treatment

- As mentioned earlier, support of airway, breathing, and circulation is the most important management principle.
- All unstable, or potentially unstable, patients should have supplemental oxygen, adequate intravenous access for administration of medications and fluid, and defibrillator pads placed and attached to the defibrillator/monitor.
- In general, emergent treatment of bradycardias is not necessary unless the heart rate is less than 50 bpm and associated with signs of hypoperfusion, or if there is a risk of progression to complete heart block.
- Several urgent/emergent treatments are common and relevant to all the bradycardias:
    - Atropine. Atropine is a class II medication in the treatment of symptomatic bradycardias. It is a naturally occurring antimuscarinic drug that competitively antagonizes the effects of acetylcholine and other antimuscarinic agents. It increases the rate of sinus node firing (automaticity) and enhances AV nodal conduction. Because it blocks vagal activity, it sometimes is described as parasympatholytic or vagolytic. It is administered intravenously as 0.5-mg boluses (in situations other than bradycardia, it may be given as 1-mg boluses). It may be given every 5 minutes until the desired effect is achieved, or until a total of 3 mg (0.04 mg/kg) has been administered (this is the fully vagolytic dosage). If the conduction abnormality is an SA or AV nodal problem, it likely will respond to atropine. If the problem is infranodal or lower, the response rate decreases. Atropine's onset of action is about 2 to 4 minutes, and the effects may last for 5 to 6 hours. However, it is important to remember that the effect is temporary. Atropine must be administered with caution in settings of concurrent myocardial ischemia, as it increases the heart rate, which increases myocardial oxygen

demand, and may worsen ischemia. Atropine is not indicated in asymptomatic bradycardia. Atropine likely will have no effect on a transplanted heart, as heart transplants are denervated. Doses below 0.4 mg may cause a paradoxic bradycardia.

- Transcutaneous pacemaker. Transcutaneous pacing is a class I intervention for unstable patients with symptomatic bradycardia. All unstable patients should undergo transcutaneous pacing. Although atropine may be given as a temporizing measure, it should not replace transcutaneous pacing in unstable patients with high-grade (type II second-degree and complete) heart block. Self-adhesive pads are placed with the left pad over the left anterolateral precordial area and the right pad in the right subscapular region. Most patients have capture (i.e., when the pacing impulse results in a heartbeat) with 100 mA of output. Sometimes, however, it may require up to 200 mA of output for capture to occur. Outputs above 200 mA should not be attempted. Transcutaneous pacing may be uncomfortable and painful; therefore, all patients should receive either pain control or sedation with anxiolytics. If it is impossible to induce capture, it may be necessary to move to transvenous pacing.



Placement of transcutaneous pacemaker pads. [Healey JS, Merchant R, Simpson C, Tang T, Beardsall M, Tung S, Fraser JA, Long L, van Vlymen JM, Manninen P, Ralley F, Venkatraghavan L, Yee R, Prasloski B, Sanatani S, Philippon F. Society position statement: Canadian Cardiovascular Society/Canadian Anesthesiologists' Society/Canadian Heart Rhythm Society joint position statement on the perioperative management of patients with implanted pacemakers, defibrillators, and neurostimulating devices. Can J Anaesth. 2012 Apr;59(4):394–407.] *Caption adapted from original*

The right pad is placed in the alternative, right upper anterior chest and apex positions. [Woodcock B. Hemodynamic emergencies. In: Tremper KK, editor. Principles of anesthetic techniques and anesthetic emergencies. Philadelphia: Current Medicine; 1998. 195 p. (Miller RD, editor. Atlas of anesthesia; vol. 4).]

https://www.youtube.com/watch?v=qkSGaJkNqvg
Video demonstrating transcutaneous pacing.

- Transvenous pacing. Transvenous pacing has the same indication as transcutaneous pacing. It requires central venous access because the leads are passed through the central catheter into the heart. This is an invasive procedure, and although it may be attempted emergently at the bedside, it is best performed in conjunction with expert consultation and guidance. Currently, this technique is performed most often under fluoroscopic guidance in a cardiac catheterization laboratory as a bridge to a permanent pacemaker.
- Epinephrine and dopamine. Epinephrine and dopamine may be considered for blood pressure support if atropine and emergent pacing have been unsuccessful. Administration of these agents is only temporizing measure until the patient can be prepared for definitive therapy.
- Specific drug ingestions that lead to symptomatic and/or unstable bradycardias should be treated with specific antidotes if available, but also may be treated with atropine and pacing as required.

Following is a list of recommendations based on the specific bradycardia:

- Sinus bradycardia: generally requires no treatment unless the rate is less than 50 bpm and associated with symptoms, which may occur with profound vagal stimulation. If necessary, treatment may start with atropine and, if necessary, transcutaneous pacing.
- Sinus arrhythmia: requires no treatment.
- Sinus pauses/sinus arrest: treatment should be aimed at the underlying causes.

- Sick sinus syndrome: this is an indication for a permanent pacemaker.
- Junctional bradycardia: usually does not require treatment and is transient. If the patient is symptomatic or unstable, atropine and/or pacing may be used; however, it also is important to search for the underlying cause.
- SA block: often requires no treatment; however, the underlying cause should be evaluated.
- First-degree AV block: usually requires no treatment.
- Second-degree AV block, Mobitz type I (Wenckebach): usually does not require treatment unless the patient has symptoms. It usually is transient, and when the underlying cause is identified and treated, the block usually resolves. If treatment is necessary, most patients will respond to atropine.
- Second-degree AV block, Mobitz type II: these patients are unstable, with a high risk of progression to complete heart block. They should have pacemaker pads placed and attached for use if necessary. Atropine may be used as a temporizing measure (about 60 % of patients respond), but in most circumstances, pacing will be necessary. Because this type of block usually is associated with permanent damage to the conduction system, most patients will require a permanent pacemaker at some point in their care.
- Third-degree heart block (complete heart block): this is an inherently unstable block and usually is symptomatic and hemodynamically significant. It usually indicates permanent damage to the conduction system and requires either transcutaneous or transvenous pacing as a bridge to a permanent pacemaker. Some patients may respond to atropine if the block is higher within the His–Purkinje system.

Disease Course

- As detailed earlier, many of these rhythms/conduction problems are either normal variants or transient and can be resolved with identification and treatment of the underlying disorders.
- Higher-grade AV blocks almost always indicate some permanent damage to the conducting system and require placement of a permanent pacemaker.

Chapter 14
Bronchiectasis

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Bronchiectasis

Incidence/Epidemiology

- It is estimated that between 100,000 and 125,000 people in the United States have bronchiectasis.
- The prevalence increases with age.
- It is more common in women than in men.
- The incidence of bronchiectasis has been decreasing in developed nations.
- The incidence of bronchiectasis may be up to three times higher in developing nations. This is likely due to a combination of environmental and genetic factors that lead to a higher incidence of recurrent pulmonary infections, especially among children and young adults.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_14

Differential Diagnosis

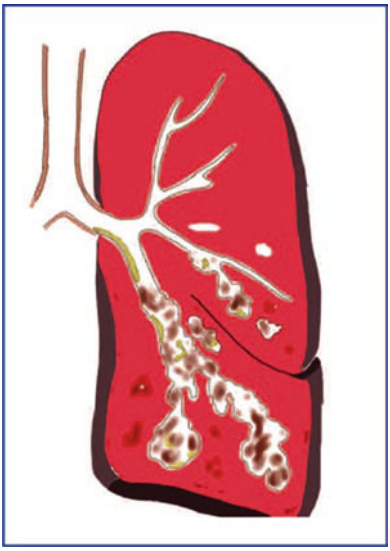
- The differential diagnosis includes all the causes of chronic cough, sputum production, and dyspnea.
- This includes chronic bronchitis, asthma, chronic obstructive pulmonary disease, chronic sinusitis, and idiopathic pulmonary fibrosis, among others.

Pathophysiology and Etiology

- Bronchiectasis refers to lung disease dominated clinically by chronic cough with sputum production. Symptoms are often present for months to years prior to diagnosis.
- The major pathophysiologic change is irreversible airway dilatation with wall thickening and scarring.

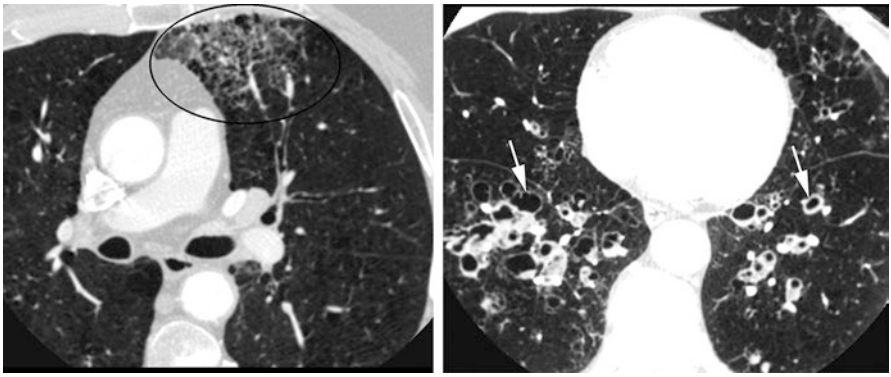
https://www.youtube.com/watch?v=uNeprw1rsgE
Video animation of the pathophysiology of bronchiectasis.

Close inspection of the cut surface of this lung in a case of mild bronchiectasis shows somewhat fibrotic-walled airways, which are dilated and congested. In addition, there is local, patchy emphysema and some cystic change and interstitial scarring. Many cases of lung disease do not show a single, pure format [Suvarna SK. Thorax: Heart, Lungs, Mediastinum, and Pleura. In: Suvarna SK, editor. Atlas of Adult Autopsy [Internet]. Cham: Springer International Publishing; 2016 [cited 2016 Nov 7]. p. 65–160. Available from: http://link.springer.com/10.1007/978-3-319-27022-7_4] *Caption from original*



Bronchiectasis. There is dilatation of the airways with inflammation and increased mucous production [Ruggeri G, Gobbi D, Libri M, Lima M. Pediatric Bronchiectasis. In: Lima M, editor. Pediatric Thoracic Surgery [Internet]. Springer Milan; 2013 [cited 2015 May 11]. p. 351–62. Available from: http://link.springer.com/chapter/10.1007/978-88-470-5202-4_30]

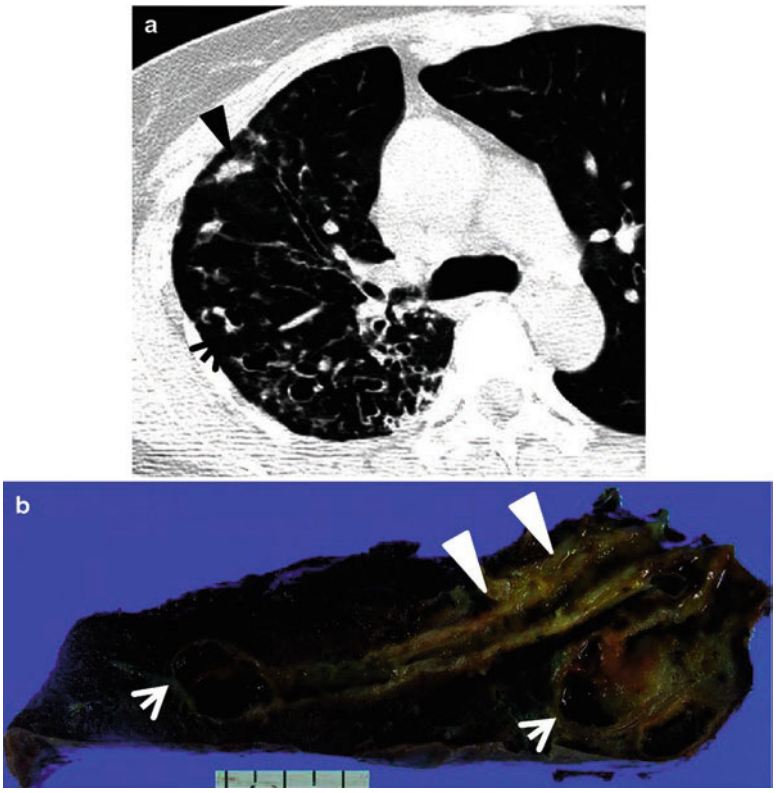
- The lung changes can be focal or diffuse.



Focal bronchiectasis (circled area of upper panel) may be seen in patients with recurrent aspiration or pneumonias. Bilateral and diffuse bronchiectasis (arrows in lower panel) is typically the result of diffuse necrotizing infections in childhood, cystic fibrosis, immotile cilia syndromes, or immunoglobulinopathies, among

others. [Callister T, Budoff M, Braunwald E. Atlas of Cardiovascular Computed Tomography, Volume 01, Chapter 18. In: Budoff M, Narula J, Achenbach SS, editors. Atlas of Cardiovascular Computed Tomography. Philadelphia: Current Medicine; 2007 [cited 2015 May 11]. Book DOI 978-1-57340-267-5] *Caption adapted from original.*

- These changes lead to airways that easily collapse and obstruct airflow.
- The initiation of bronchiectasis requires many factors. It is felt that there needs to be an inciting infectious insult, often in the setting of some impaired host defenses, that leads to airway obstruction that impairs drainage of inflammatory and purulent material and sets up a chronic airway inflammatory response. This leads to chronic inflammation, with permanent scarring, dilatation, and destruction of the airways (both large and small).
- The chronic inflammation leads to recurrent infections, which then lead to continued inflammation, setting up a vicious cycle.
- Many diseases and environmental issues can incite and/or worsen bronchiectasis.
- The pattern of involvement in the lungs may be a helpful clue as to etiology. Focal bronchiectasis points to foreign body aspiration or intrinsic or extrinsic airway compression as the cause.
- Causes/etiologies of bronchiectasis include:
    - Obstruction. Bronchiectasis can result from an aspirated foreign body, intrinsic compression/blockage from an endobronchial lesion or mass, or extrinsic compression from a mass.
- Infection. Can be bacterial pneumonia, atypical pneumonia such as viral or *Mycoplasma*, tuberculous, and non-tuberculous mycobacteria. *Mycobacterium avium*-intracellulare complex (MAC) is the most common non-tuberculous mycobacteria causing bronchiectasis, classically occurring in nonsmoking women over age 50.
- Immunodeficiency. Hypogammaglobulinemias, such as severe, combined immunodeficiency. These patients often have recurrent infections starting in childhood. Immunodeficiency also includes HIV infection and bronchiolitis obliterans after lung transplantation.
- Autoimmune/rheumatologic disorders. Rheumatoid arthritis, Sjogren's syndrome, inflammatory bowel disease.
- Immune-mediated diseases such as allergic bronchopulmonary aspergillosis.
- Genetic causes such as cystic fibrosis, ciliary dyskinesia (by decreasing secretion clearance), alpha-one anti-trypsin deficiency (usually causes early-onset emphysema, but bronchiectatic changes are also common).
- Recurrent aspiration.
- Idiopathic. Often represents from 25 – 50% of cases.
- Cigarette smoking.



Bronchiectasis showing signet ring sign in a 44-year-old man. (a) Lung window image of CT scan (2.5-mm section thickness) obtained at level of the right upper lobar bronchus shows dilated bronchi showing signet ring sign (arrows) in right upper lobe. Also note mucus plugging (arrowhead) in dilated bronchi. (b) Gross pathologic specimen obtained with right upper lobectomy discloses cylindrical bronchiectasis and distal cystic changes (arrows, cystic bronchiectasis). Also note thickened bronchial wall (arrowheads) with active inflammation [Lee KS, Han J, Chung MP, Jeong YJ. Signet Ring Sign. Radiology Illustrated: Chest Radiology [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2015 Nov 19]. p. 139–42. Available from: http://link.springer.com/10.1007/978-3-642-37096-0_15] *Caption from original.*

Presentation

Typical/"Classic"

- The typical presentation of bronchiectasis is one of prolonged (months) cough that produces thick sputum. Usually there is an absence of acute infectious symptoms such as fever. Patients may also complain of dyspnea, especially on exertion. They may also exhibit wheezing.

Atypical

- Patients may present with symptoms more consistent with chronic obstructive pulmonary disease or asthma, with wheezing and shortness of breath being more prominent.
- Patients may also present with a more acutely infectious appearance with fever, associated with productive cough. This is especially common if they have been undiagnosed and are suffering from an acute infectious exacerbation from their undiagnosed bronchiectasis.

Primary Differential Considerations

- Asthma
- Acute and chronic bronchitis
- Cystic fibrosis
- GERD
- Pneumonia
- Alpha-1-antitrypsin deficiency

History and Physical Exam

Findings That Confirm Diagnosis

- A typical presentation with prolonged cough productive of thick sputum will strongly suggest the diagnosis, but the diagnosis is usually only confirmed by typical findings on CT scan of the chest.

Factors That Suggest Diagnosis

- Again, the typical symptoms should strongly suggest the diagnosis.
- This is especially true if the patient has any of the known predisposing conditions.

Factors That Exclude Diagnosis

- There are no historical or physical examination findings that can reliably exclude the diagnosis.
- Bronchiectasis may coexist with many other diseases, especially COPD.

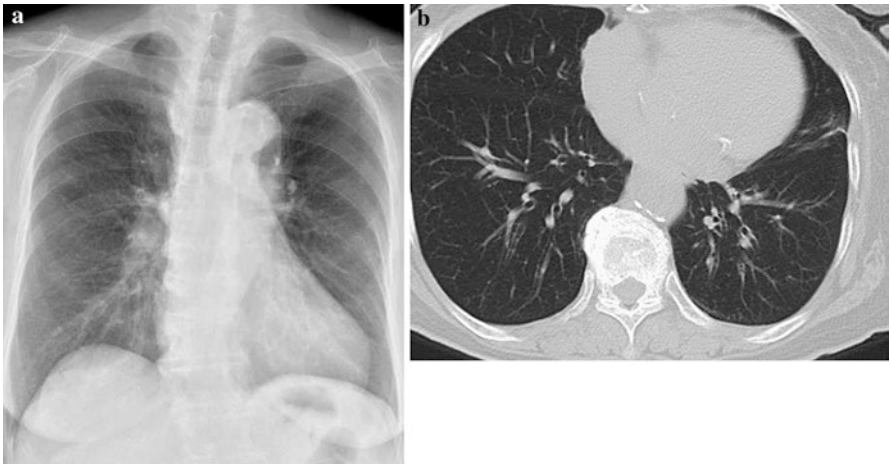
Ancillary Studies

Laboratory

- Although there are no laboratory tests specifically needed for the diagnosis, patients will usually require a CBC with differential and basic chemistries in the evaluation. They may also require tests specific for the disorder if they need to be evaluated for any of the etiologies of bronchiectasis, such as tests for RA, SS, and alpha-one antitrypsin.
- Sputum culture may be necessary when trying to evaluate for MAC or other mycobacterial causes of bronchiectasis. Sputum culture may also be helpful for management of acute infectious exacerbations of bronchiectasis.

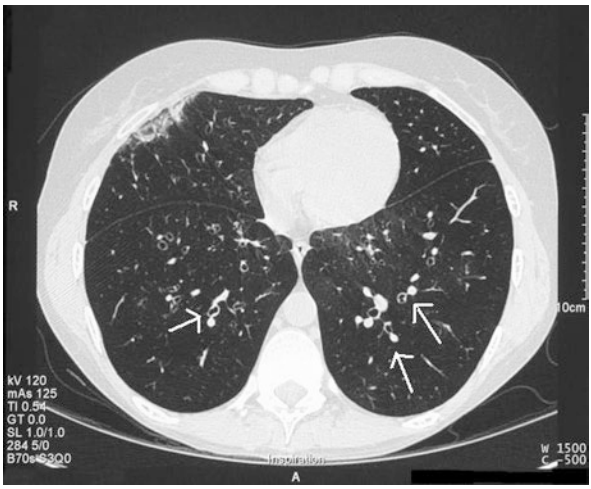
Imaging

- Chest CT is the diagnostic imaging study of choice for confirming the diagnosis of bronchiectasis.
- Plain chest x-ray may show findings consistent with bronchiectasis (such as dilated bronchioles), but CT is necessary to confirm the diagnosis.

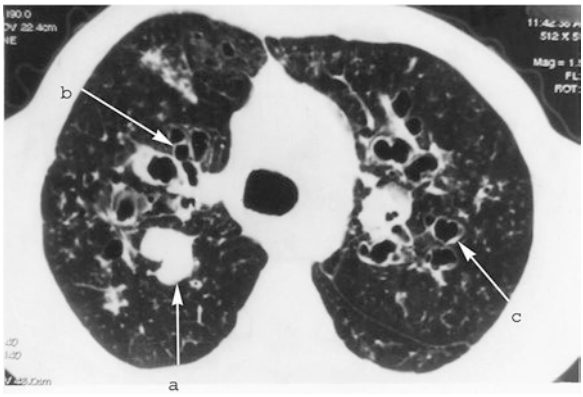


A Chest X-ray revealed clear lung fields. b High-resolution CT image through the lungs at the level of bronchus shows right lower lobe and lingular bronchiectasis. [Toyoda M, Yokomori H, Kaneko F, Yoshida H, Takahashi A, Hoshi K, Takeuchi H, Tahara K, Kondo H, Motoori T. Hepatic granulomas as primary presentation of Mycobacterium avium infection in an HIV-negative, nonimmunosuppressed patient. Clinical Journal of Gastroenterology. 2009 Dec;2(6):431–7.] *Caption adapted from original.*

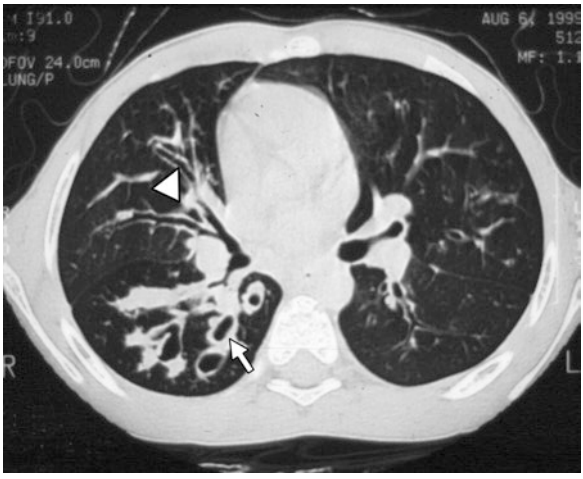
- CT findings in bronchiectasis include airway dilatation, lack of bronchial tapering (usually noticed as tubular structures within 1 cm of the pleural surface), bronchial wall thickening in dilated airways, and a large amount of dried secretions (tree-in-bud pattern).
- The signet-ring sign on CT is when there is a cross-sectional airway with a diameter that is at least 1.5 times larger than an adjacent vessel.



(CT Thorax): Resolution of areas of consolidation and "signet ring sign". The signet ring sign is a finding seen on CT scans of the thorax. It consists of a small circle of soft tissue attenuation that abuts a ring of soft tissue attenuation surrounding a larger low attenuating circle of air and is indicative of bronchiectasis. [From article: Invasive pulmonary aspergillosis 10 years post bone marrow transplantation: a case report. Journal of Medical Case Reports. 2009;3(1):26. https://doi.org/10.1186/1752-1947-3-26, at http://link.springer.com/article/10.1186%2F1752-1947-3-26/fulltext.html; by Rifat Rashid, David W Denning, © Rashid and Denning; licensee BioMed Central Ltd. 2009; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption adapted from original.*



High resolution chest computed tomography scan (lung window) showing (a) mucus-filled dilated bronchi (arrow) and extensive bilateral central bronchiectasis characterised by (b) "string of pearls" and (c) "signet ring" appearances [Shah A. How to Diagnose Allergic Bronchopulmonary Aspergillosis. In: Comarú Pasqualotto A, editor. Aspergillosis: From Diagnosis to Prevention [Internet]. Dordrecht: Springer Netherlands; 2009 [cited 2015 Nov 19]. p. 725–45. Available from: http://www.springerlink.com/index/10.1007/978-90-481-2408-4_43] *Caption from original.*



Computed tomographic image of bronchiectasis. Chest CT showing diffuse dilated bronchi (bronchiectasis), especially in the right lower lobe. Thick-walled bronchi are seen. Also present is the "signet-ring" sign (arrow), in which the diameter of the airway (lumen) is greater than that of the adjacent vessel. Apparent in the right middle lobe is "tram-tracking" (arrowhead), with absence of tapering of the peripheral bronchi. [MacLusky I, Solomon M, Laxer R, Ford-Jones EL, Friedman J, Gerstle T. Atlas of Pediatrics, Volume IA, Chapter 14. In: Laxer RM, editor. The Hospital for Sick Children: Atlas of Pediatrics. Philadelphia, PA: Current Medicine Group; 2005. 519 p. ISBN 1-57340-188-9] *Caption from original.*

- Most patients with bronchiectasis will undergo bronchoscopy during evaluation. This is most important in patients with focal bronchiectasis to exclude airway obstruction from a mass or foreign body.
- Pulmonary function testing can help in gauging the functional impairment of the patient.

Special Populations

Age

- The incidence of bronchiectasis increases with age.
- Patients with cystic fibrosis can develop clinically significant bronchiectasis in adolescence or young adulthood.

Co-morbidities

- Co-morbidities of interest include all the etiologies listed above.
- Bronchiectasis may coexist with COPD and other chronic lung diseases.
- Bronchiectasis may also coexist with causes of chronic dyspnea and cough, such as congestive heart failure.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step.
- It is important to perform appropriate imaging in patients in whom the diagnosis is being considered.
- A search for the possible etiology should be performed for all patients being evaluated for bronchiectasis.

Mimics

- Typical mimics of bronchiectasis include COPD/emphysema, asthma, and pulmonary fibrosis.

Time-Dependent Interventions

- Time-dependent interventions in bronchiectasis are rarely necessary. This is a chronic, slowly progressive disease.
- Acute exacerbations often benefit from the timely use of antibiotics, as well as from bronchial hygiene measures (help to enhance secretion clearance) such as chest physiotherapy, mucolytics, hydration, and sometimes bronchodilator therapy.

Overall Principles of Treatment

- The general treatment of bronchiectasis involves:
  - control of any active infection.
  - attempts to improve bronchial hygiene to help minimize the risk of repeated infections.
- Antibiotics are usually administered for acute exacerbations. These are suspected clinically in the presence of a worsened cough, qualitative (and often quantitative) change in the sputum, and sometimes fever. The most commonly isolated causative organisms of acute infectious exacerbations are *Haemophilus influenza*, and *Pseudomonas aeruginosa*. The typical antibiotics used are fluoroquinolones, such as ciprofloxacin and levofloxacin.
- The decision to treat *Mycobacterium avium*-intracellulare complex (MAC) is difficult. This organism can exist as a colonizer as well as a pathogen, and the treatment regimens are prolonged and often poorly tolerated. MAC, however, is the most common non-tuberculous mycobacterial cause of bronchiectasis. The diagnosis of this infection, and the decision to treat, is often guided by expert opinion.
- Multiple approaches are usually taken to try and enhance secretion clearance (bronchial hygiene) in these patients.
  - Maintaining adequate hydration and the use of mucolytics to keep secretions thin.
- Use of bronchodilators.
  - Chest physiotherapy, including chest percussion and newer mechanical devices.
- The use of systemic glucocorticoids is controversial. There has been no compelling evidence demonstrating improvements in pulmonary function or of lower exacerbation rates from their use.
  - Oral or systemic glucocorticoids may be necessary for some patients depending upon the etiology of their bronchiectasis. Patients with allergic bronchopulmonary aspergillosis, Rheumatoid arthritis, and Sjogren's

syndrome may benefit from glucocorticoids for both their bronchiectasis and their underlying disease.

- In severe or refractory cases, surgery (such as resection of involved lung tissue) may be considered. This is especially true of patients with focal bronchiectasis.
- End-stage patients may be considered for lung transplantation.
- All patients with chronic respiratory conditions should be kept up to date on vaccinations, especially influenza and pneumococcal. Appropriate use of these vaccinations can help reduce the rate of recurrent infections.
- Patients who smoke should be counseled about cessation and offered help with quitting.

Disease Course

- Bronchiectasis is a chronic, recurrent, progressive disease.
- Outcomes and course vary widely based upon the underlying etiology.
- The decline in lung function is similar to that seen in patients with COPD.

Chapter 15
Bronchiolitis

Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Formally known as Respiratory Syncytial Viral (RSV) pneumonia, but many other viruses (such as metapneumovirus, adenovirus, parainfluenza virus) may cause the same clinical disease.

Incidence/Epidemiology

- Typically affects infants under 2 years of age.
- Reported peak incidence between 2 and 6 months.
- Seasonal peaks during fall and winter.
- Bronchiolitis is the leading cause of hospitalization in young children.

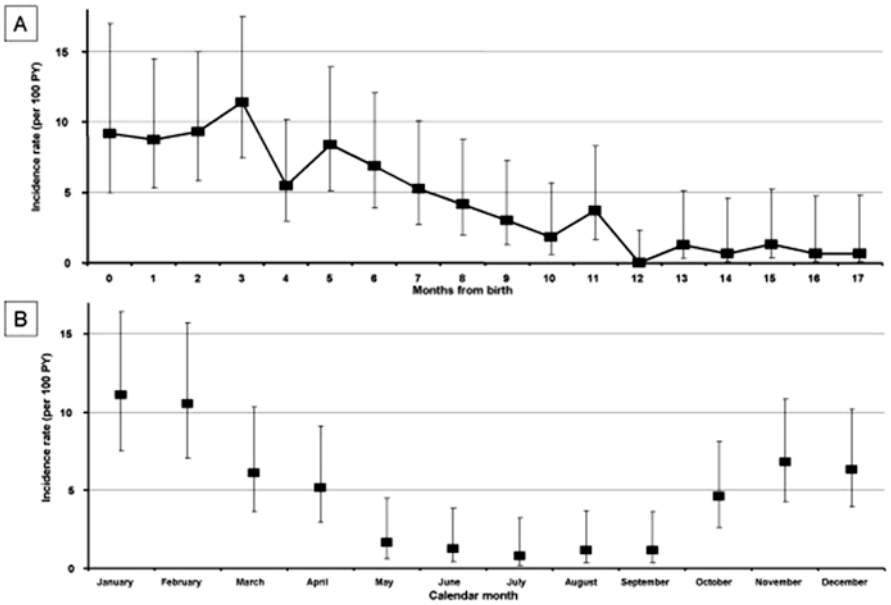
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_15

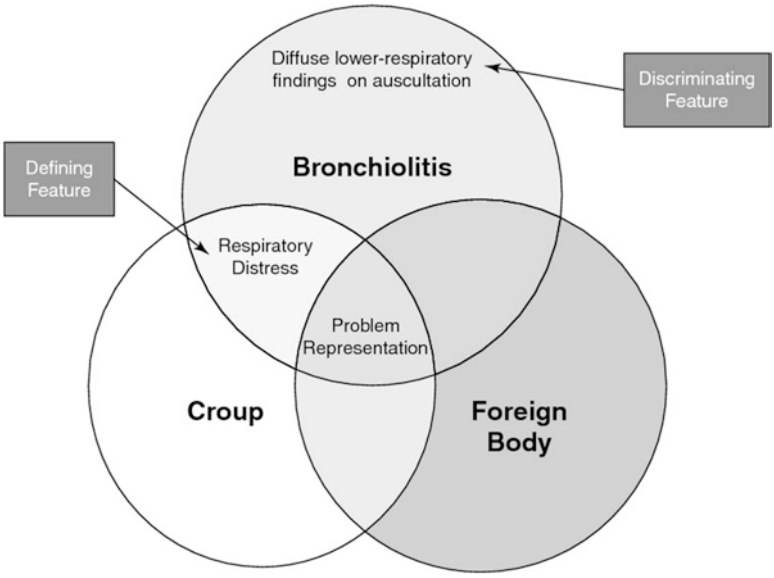


Incidence rates of hospitalizations for bronchiolitis by age (in months) (section A) and by calendar month (section B) in pre-term infants; Rome, Italy 2000-2006. [From article: Incidence and risk factors of hospitalization for bronchiolitis in pre-term children: a retrospective longitudinal study in Italy. BMC Pediatrics. 2009 Sept 10; 9:56; https://doi.org/10.1186/1471-2431-9-56, at http://bmcpediatr.biomedcentral.com/articles/10.1186/1471-2431-9-56; by Patrizio Pezzotti, Jessica Mantovani, Nicoletta Benincori, Eleonora Mucchino, Domenico Di Lallo, © Pezzotti et al; licensee BioMed Central Ltd. 2009; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

Differential Diagnosis

The typical affected infant presents with fever and wheezing, and as such initially prompts these differential considerations:

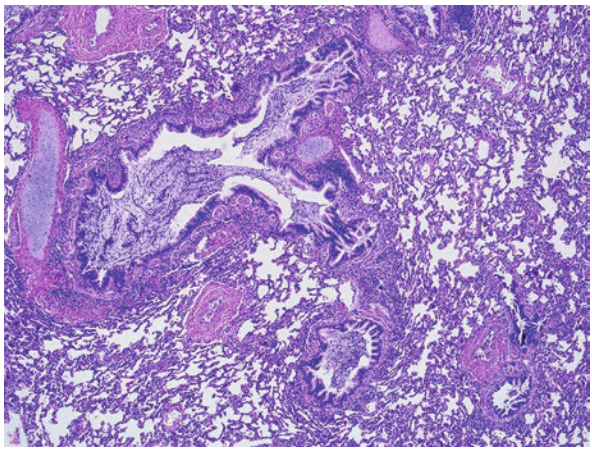
- Bacterial pneumonia
- Chlamydial pneumonia
- Foreign-body aspiration
- Reactive airway disease/asthma
- Aspiration pneumonia
- Congenital heart disease
- Vascular rings



The problem representation allows identification of three illness scripts that fit the defining features of this toddler with respiratory distress case. Diffuse lower respiratory findings on auscultation is the key discriminating feature, which allows a diagnosis of bronchiolitis [Mutnick A, Barone M. Assessing and Remediating Clinical Reasoning. In: Kalet A, Chou CL, editors. Remediation in Medical Education [Internet]. New York, NY: Springer New York; 2014 [cited 2016 Jul 28]. p. 85–101. Available from: http://link.springer.com/10.1007/978-1-4614-9025-8_6] *Caption from original*

Pathophysiology and Etiology

- Viral infiltration of terminal bronchioles results in edema, increased mucous production, and sloughing of respiratory epithelial cells.



Influenza virus infection. Like other forms of respiratory viral infection, influenza may cause a lymphocytic or necrotizing bronchiolitis, in this case associated with mucus stasis in the bronchioles (H&E, 40×). Autopsy examination following fatal influenza viral infection typically shows a necrotizing bronchitis and bronchiolitis with pulmonary edema and diffuse alveolar damage in the background (not shown) [Shah KK, Dishop MK. Infantile Viral Illnesses. In: Fraire AE, Woda BA, Welsh RM, Kradin RL, editors. Viruses and the Lung [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2016 Jul 28]. p. 143–58. Available from: http://link.springer.com/10.1007/978-3-642-40605-8_17] *Caption from original*

- Lymphocytic infiltration causes the typical pattern of peribronchial cuffing seen on plain chest radiographs.
- Known causative viruses include RSV, metapneumovirus, rhinovirus, parainfluenza virus, and adenovirus.

Presentation

Typical/"Classic"

- There is often a 2 to 4-day prodrome consisting of cough and rhinorrhea.
- Infants present after the prodrome with fever, increasing cough, and variable degrees of respiratory distress.
- Patients manifest a wide range of work of breathing, characterized by tachypnea, expiratory prolongation, retractions, and in more severe cases, grunting.

Atypical

- In infants less than 6 weeks of age, apneic episodes may be the first sign of bronchiolitis.

Primary Differential Considerations

- Early diagnostic consideration should also be given to:
  - Asthma
  - Pneumonia
  - Croup

- Congenital heart disease
- Aspiration pneumonitis

History and Physical Exam

- Historically an infant with a mild URI (prodrome, as above) will develop a progressively worsening cough.
- At initial presentation, most infants will have signs of lower respiratory disease.
- Most infants will be febrile, increasing insensible fluid losses.
- Excessive work of breathing may severely impair the ability to feed, resulting in variable degrees of dehydration.
- Cough, retractions, tachypnea, and grunting may be present.
- Auscultation will reveal expiratory prolongation, impairment of air entry, and ronchi/wheezing.

Findings That Confirm Diagnosis

- The typical clinical syndrome, when seasonally encountered (fall and winter) makes the diagnosis obvious.
- Viral testing will further identify the particular etiologic agent.

Factors That Suggest Diagnosis

- As mentioned previously, bronchiolitis is a seasonal epidemic, providing the caregiver with obvious signs.

Factors That Exclude Diagnosis

- The presence of tachycardia with a gallop or cardiomegaly points towards congenital heart disease.
- Toxic appearance, hyperthermia, and lobar infiltrates suggest bacterial pneumonia.

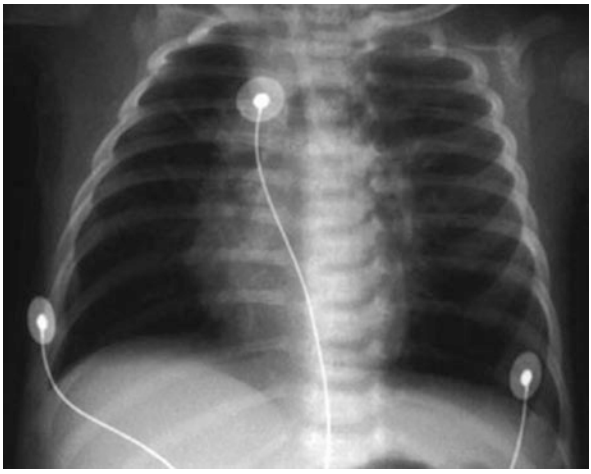
Ancillary Studies

Laboratory Studies

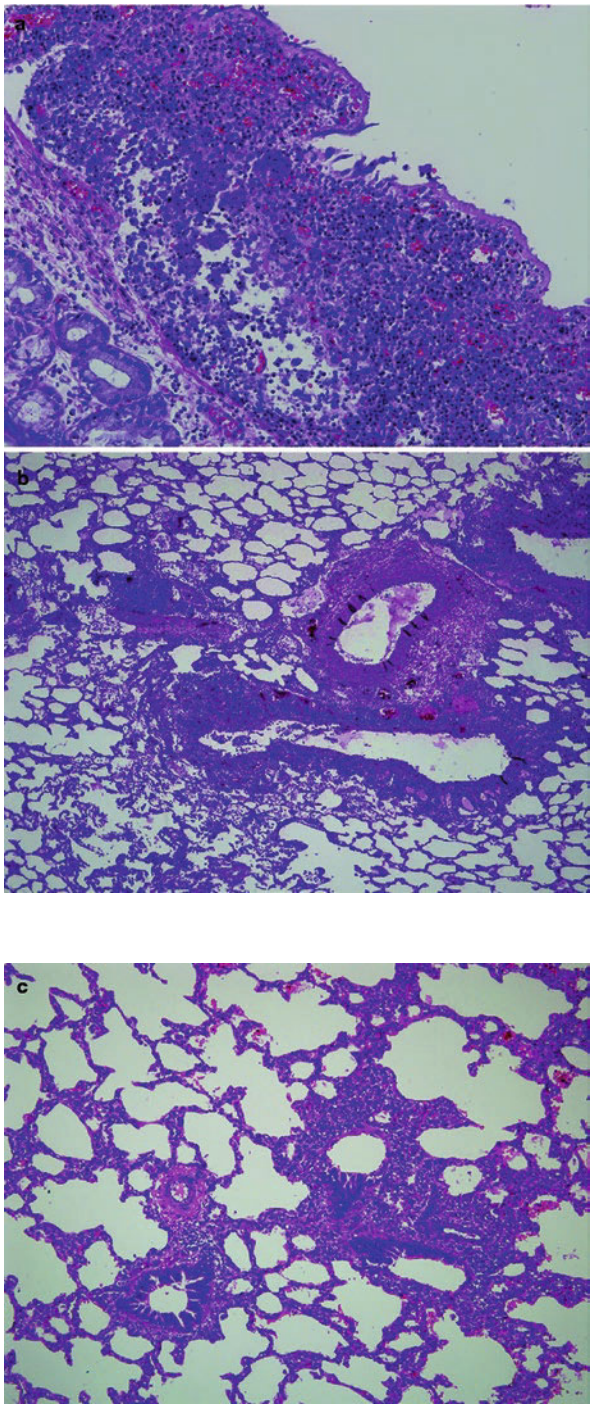
- Viral testing is optional in atypical cases (specifically infants who present only with apnea) and in facilities that have co-bedding of pediatric inpatients.
- Blood work is not indicated.

Imaging

- Chest radiographs will demonstrate hyperinflation, interstitial disease, and peribronchial cuffing; in some instances, variable degrees of atelectasis may be present.



RSV-bronchiolitis. Markedly hyperinflated lungs with flattening of the diaphragm and peribronchial hilar infiltrates are demonstrated on the chest radiograph. [Staatz G. Bronchitis and Bronchiolitis in Childhood. In: Baert AL, editor. Encyclopedia of Diagnostic Imaging [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2008 [cited 2016 Jul 28]. p. 203–5. Available from: http://www.springerlink.com/index/10.1007/978-3-540-35280-8_337] *Caption from original*



a
b
c

Respiratory syncytial virus infection in an infant. The prototypic infantile respiratory virus, RSV, causes a lymphocytic bronchitis and bronchiolitis. (a) This bronchus demonstrates a cuff of lymphocytes in the submucosa (H&E, 200×). (b) Circumferential lymphocyte infiltrates are also noted in the small airways (H&E, 100×). (c) Bronchiolitis may be accompanied by an interstitial pneumonitis, characterized by interstitial widening by lymphocyte infiltrates. Syncytial-type multinucleate cells are absent or rare in lung tissues from otherwise healthy infants but are characteristic of the viral cytopathic effect seen in culture in the diagnostic virology laboratory (H&E, 100×) [Shah KK, Dishop MK. Infantile Viral Illnesses. In: Fraire AE, Woda BA, Welsh RM, Kradin RL, editors. Viruses and the Lung [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2016 Jul 28]. p. 143–58. Available from: http://link.springer.com/10.1007/978-3-642-40605-8_17] *Caption from original*

Bronchiolitis and pneumomediastinum. Frontal chest radiograph in a patient with RSV infection demonstrates a combination of bilateral perihilar atelectasis and hyperexpanded lungs. Note the presence of pneumomediastinum (arrow) with gas tracking up the neck soft tissues [Krol JJ, von Herrmann PF, Challa HR, Dillon JE. Imaging of Pediatric Emergencies. In: Singh A, editor. Emergency Radiology [Internet]. New York, NY: Springer New York; 2013 [cited 2016 Jul 28]. p. 361–73. Available from: http://link.springer.com/10.1007/978-1-4419-9592-6_26] *Caption from original*

Special Populations

Age

- Children older than 3 may contract viral infections that present identically to bronchiolitis, though RSV titers will be negative.

Co-morbidities

- Risk factors for the development of apnea include:
  - History of prematurity (less than 35 weeks)
  - Age less than 2 months
  - Presence of congenital heart disease
  - Presence of marked atelectasis

Pitfalls in Diagnosis

- Most patients present with typical symptomatology.
- Not considering bronchiolitis in infant apneic spells would be unwise.

Critical Steps Not to Miss

- Obtaining a careful birth history is mandatory.
- There is usually an older child in the home with a simple cold.

Mimics

- As previously mentioned, bacterial pneumonia may present with similar findings.
- New onset CHF will often present with respiratory distress and wheezing.

Time-Dependent Interventions

- Supplemental oxygen is often necessary.
- In dehydrated infants, IV fluids are indicated.

- Nasopharyngeal suctioning may dramatically lessen the work required to breathe.
- The use of albuterol has recently been discouraged in the literature; many practitioners, however, still favor a single albuterol treatment in an attempt to identify the rare patient with reversible bronchospasm.
- Steroids are NOT recommended.
- Severe cases may respond to aerosolized racemic epinephrine.

Overall Principles of Treatment

- Simple correction of hypoxemia and fluid deficits are important first steps.
- Unfortunately, most infants will not respond to bronchodilators.
- Hospital admission is often the only option.

Disease Course

- Studies have demonstrated that this is a 14-to-21-day illness with vacillating degrees of respiratory compromise.
- The cough may take 2 weeks to resolve

Chapter 16
Carbon Monoxide Poisoning

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, Victoria G. Riese, and Jaime Friel Blanck

Name and Synonyms

Carbon Monoxide (CO) Poisoning

Incidence/Epidemiology

- CO poisoning is responsible for up to 40,000 emergency department visits and 5000 to 6000 deaths a year.
- CO poisoning is unintentional in about 500 cases annually, whereas the rate of intentional poisoning is 10 times higher.
- The case-fatality rate ranges from 0 % to 31 %.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_16

Differential Diagnosis

- Acute respiratory distress syndrome
- Depression and suicide
- Diabetic ketoacidosis
- Encephalitis
- Gastroenteritis
- Headache, tension
- Hypothyroidism and myxedema coma
- Labyrinthitis
- Lactic acidosis
- Meningitis
- Methemoglobinemia
- Migraine headache
- Pediatrics, hypoglycemia
- Toxicity, alcohols
- Toxicity, narcotics

Pathophysiology and Etiology

- CO is an odorless, tasteless, colorless, nonirritating gas formed by hydrocarbon combustion. It binds to hemoglobin and diminishes the ability to absorb oxygen.
- CO poisoning interferes with oxygen transport to the cells and possibly results in electron transport failure.
- CO combines preferentially with hemoglobin to produce carboxyhemoglobin (COHb), displacing oxygen and reducing systemic arterial oxygen.
- CO poisoning may cause tissue hypoxia and impair tissue perfusion.
- Exogenous sources of CO include the following:
    - Smoke inhalation
    - Poorly functioning heating systems
    - Improperly vented fuel-burning devices
    - Motor vehicles in poorly vented areas
    - Open-air motorboat exhaust
    - Underground electrical cable fires
    - Spray paints and solvents—methylene chloride
    - Wood stoves
    - Tobacco smoke

Presentation

Typical/"Classic"

- Highly variable and nonspecific
- Mild to moderate poisoning: headache, malaise, nausea, dizziness, weakness, vomiting, blurred vision, and shortness of breath
- Severe CO toxicity: seizures, syncope, coma, myocardial ischemia, ventricular arrhythmias, pulmonary edema, and profound lactic acidosis

Atypical

- Unexplained alteration in mental status

Primary Differential Considerations

Consistent with the presentation of CO toxicity, the following differential diagnoses also may apply:

- Sepsis
- Intoxication
- Ketoacidosis
- Hypoglycemia
- Atypical migraine
- Viral syndrome

History and Physical Exam

Findings That Confirm Diagnosis

- There are no physical exam findings that confirm the diagnosis of CO poisoning.

Factors That Suggest Diagnosis

- History and physical exam with headache, nausea, vomiting
- Acute infarction in the globus pallidus bilaterally

- Other forms of pure hypoxia produce similar findings.
- "Cherry red" appearance of lips and skin (a late finding)

The cheeks and neck are red in this patient with carbon monoxide poisoning. [Allen HB. Dermatology terminology [Internet]. London: Springer; 2010. Chapter 8, Miscellaneous disorders; [cited 2015 Sep 9]; p. 171–85. Available from: http://link.springer.com/10.1007/978-1-84882-840-7_8] *Caption from original*

Carboxyhemoglobin saturation (%)	Signs and symptoms
5–10	Visual acuity impairment
11–20	Flushing, headache
21–30	Nausea, impaired dexterity
31–40	Vomiting, dizziness, syncope
41–50	Tachypnea, tachycardia
>50	Coma, death

Signs and symptoms of carbon monoxide poisoning [Knighton J. Nursing management of the burn-injured person. In: Jeschke MG, Kamolz L-P, Shahrokhi S, editors. Burn care and treatment [Internet]. Vienna: Springer; 2013 [cited 2015 Sep 9]. p. 111–47. Available from: http://link.springer.com/10.1007/978-3-7091-1133-8_8] *Caption from original*

COHb concentration	Symptoms
Up to 10 %	No significant symptoms (smoker)
10–15 %	Possible shortness of breath on physical exertion (heavy smoker)
15–25 %	Usually no effects when resting, but shortness of breath on physical exertion
25–35 %	Headache, dizziness, vomiting, impaired judgement, impaired vision
35–45 %	Confusion, signs of paralysis, syncope on mild exertion
45–55 %	Severely impaired consciousness or loss of consciousness, collapse, life-threatening situation after prolonged exposure
55–65 %	Cramps, apnea
From ca. 65 %	Imminent threat of death

Stages of carbon monoxide poisoning [Dettmeyer RB, Verhoff MA, Schütz HF. Forensic medicine [Internet]. Berlin, Heidelberg: Springer; 2014. Chapter 30, Forensic toxicology; [cited 2015 Sep 9]; p. 495–542. Available from: http://link.springer.com/10.1007/978-3-642-38818-7_30] *Caption from original*

Factors That Exclude Diagnosis

The only way to exclude CO toxicity definitively is with an arterial blood gas panel with co-oximetry.

Ancillary Studies

Laboratory

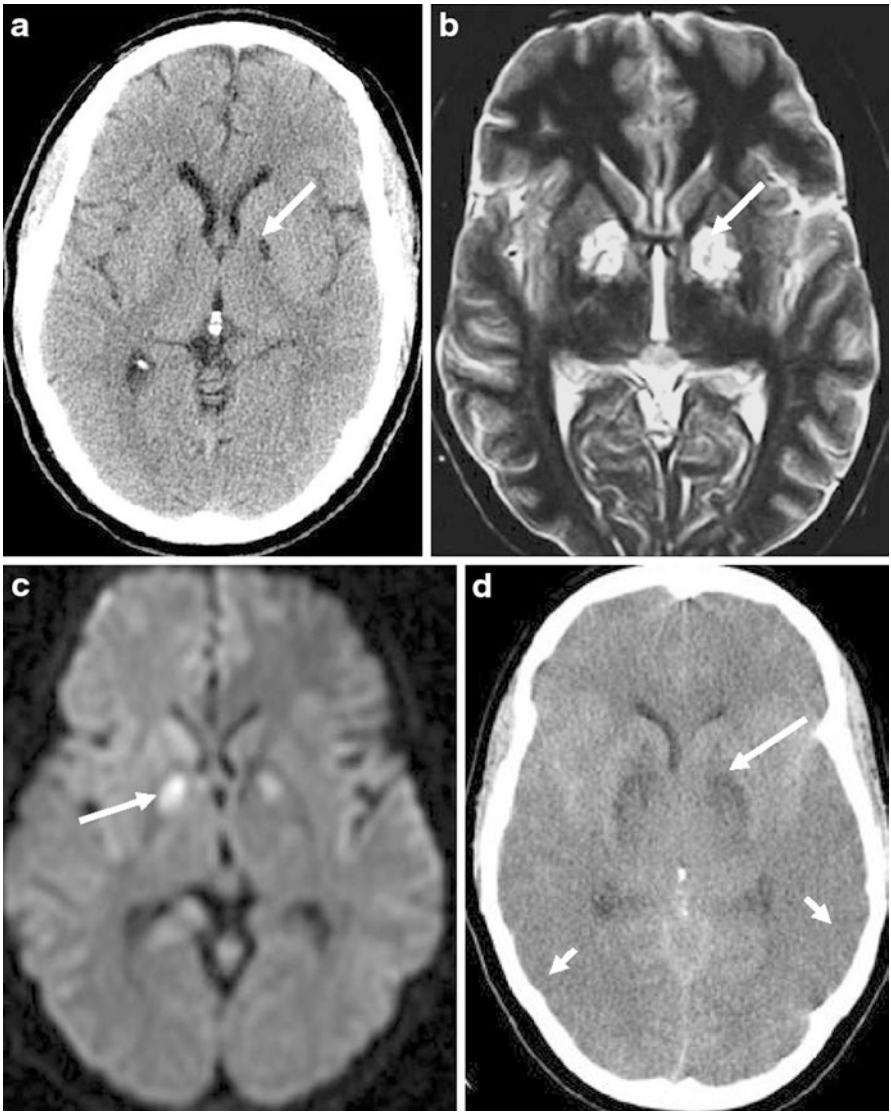
- Elevated COHb level
  - Nonsmokers may have up to 3 %, smokers 10 % to 15 %. Anything above these levels may be considered CO poisoning.
- In CO poisoning as a result of suicide attempt, a drug screen should also be obtained.

Electrocardiography

- Sinus tachycardia/arrhythmias/myocardial injury

Computed Tomography (CT) of the brain

- Hypoattenuation of the globus pallidus and white matter changes



Four different patients with history of carbon monoxide poisoning. a Noncontrast head CT shows focal low density in bilateral globus pallidus (arrows). b Transaxial T2 weighted image shows bilateral symmetric hyperintensity involving globus pallidus (arrows). c DWI shows bilateral pallidal diffusion restriction (arrows). d Noncontrast head CT shows diffuse anoxic injury (short arrows) in addition to the basal ganglia hypodensities (long arrow) [Moore MJ, Vagal AS, Strub WM, Leach JL. Reducing the gray zone: imaging spectrum of hypoperfusion and hypoxic brain injury in adults. Emerg Radiol. 2010 Mar;17(2):123–30.] *Caption from original*

Special Populations

Age

- Older patients with limited cardiopulmonary reserve may develop clinical manifestations at lower CoHb levels.

Co-morbidities

- Pregnancy
  - The fetus is particularly sensitive to hypoxemia, so both mother and child are at significant risk.
- Patients with preexisting lung disease are affected more severely by CO-induced hypoxemia.

Pediatric Considerations

- Signs and symptoms may be subtle and nonspecific.
- Infants and toddlers may have fussiness and difficulty feeding.
- Signs and symptoms in older children are similar to those in adults: headache, nausea, and vomiting.
- Younger children experience problems earlier in exposure because of of higher rates of oxygen utilization and minute ventilation.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Without the patient's history, CO toxicity may be difficult to diagnosis. Standard pulse oximetry cannot screen for CO exposure.

- All individuals at a fire scene and/or with significant thermal injury should be evaluated for CO poisoning.

Mimics

- Most common misdiagnosis is viral syndrome.
- Very high or very low blood glucose levels may present similarly to CO toxicity.

Time-Dependent Interventions

- CO poisoning is associated with high morbidity and mortality. In the absence of exposure history, CO poisoning must be considered in two or more patients who present with similar symptoms simultaneously.
- Oxygen therapy should be started while COHb tests results are pending.
- Hyperbaric oxygen (HBO) therapy, if available, should be considered, especially in cases of severe exposure and in pregnant patients.

Overall Principles of Treatment

- 100 % oxygen therapy is the main treatment for CO poisoning.
- HBO is indicated in anyone who experienced unconsciousness, cardiovascular instability or ischemia, persistent mental and/or neurologic deficits, or a COHb level greater than 25 %.
  - HBO may help the late neurocognitive outcomes.
- HBO should be considered in pregnant patients with elevated COHb levels.

Disease Course

- Outcomes are difficult to predict, even when the CO level is known. Patients with cardiac arrest or coma may recover fully after treatment. The mortality rate in severe CO toxicity is 33 % or higher.

Chapter 17
Chest Neoplasms

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Chest Neoplasms

Incidence/Epidemiology

- The incidence of chest neoplasm varies widely by tumor type.
- Chest neoplasms are of much higher incidence in adults.
- Over large populations, chest neoplasia incidence follows tobacco abuse patterns and therefore is more common in older males.
- In women, lung and breast tumors are most common.
- Metastases of colon cancer to the thorax are not uncommon.

Differential Diagnosis

- Many neoplasms may present as chest masses.
- They may be either benign or malignant lesions.

C. J. Rees
Emergency Department, Pennsylvania Hospital, Philadelphia, PA, USA

C. V. Pollack, Jr. (✉)
Department of Emergency Medicine, Thomas Jefferson University, Philadelphia, PA, USA

V. G. Riese
Librarian Consultant, Eldersburg, MD, USA

© Springer Nature Switzerland AG 2019

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_17

- There are primary chest masses and secondary masses. Secondary masses are metastatic lesions that have primary tumors somewhere other than the chest.
- Primary tumors of the chest include:
  - Breast cancer
  - Lung cancer
  - Esophageal cancer
  - Primary cardiac tumors
  - Primary tumors of the ribs and spine
  - Soft tissue sarcomas
  - Mesothelioma
  - Multiple myeloma
  - Lymphoid tumors
- Many different types of tumors can metastasize to the chest.

Pathophysiology and Etiology

- Pathophysiology varies based on primary vs metastatic etiology, and invasive vs more benign tissue types.
- There are behavioral (e.g., smoking) and genetic (e.g., BRAC1 gene) predispositions to chest tumors.

Presentation

Typical/"Classic"

- Tumors within the chest are often asymptomatic.
- They are most commonly found during diagnostic studies for other reasons.
- Symptoms, if present, are usually the result of direct compression from tumors or direct infiltration into surrounding structures. If the surrounding structures infiltrated are blood vessels, hemoptysis may result.
- Lymphoproliferative tumors often cause constitutional symptoms.
- Bronchogenic carcinoma may present as a postobstructive pneumonia.
- Breast or chest wall tumors may be palpable or painful, prompting presentation.

Atypical

- Fulminant presentations with respiratory insufficiency or massive hemoptysis are unusual.
- Vague constitutional symptoms, such as nagging cough and weight loss, may be presenting symptoms.

Primary Differential Considerations

Prompt consideration also should be given to the possible diagnosis of:

- Pneumonia and other infectious etiologies
- Thymus enlargement
- Pneumoconiosis
- Pulmonary nodule

History and Physical Exam

Findings That Confirm Diagnosis

- The diagnosis is usually confirmed only through pathologic interpretation of biopsy specimens.

Factors That Suggest Diagnosis

- These are often asymptomatic and found incidentally when performing diagnostic imaging studies for other reasons.

Factors That Exclude Diagnosis

- Advanced imaging studies (CT, MRI) can exclude masses of significance.

Ancillary Studies

Laboratory

- Laboratory studies are sometimes helpful in evaluating chest masses. There may be evidence of lymphoproliferative disorders on a complete blood count. Multiple myeloma is often associated with anemia, renal insufficiency, hypercalcemia, and an anion gap less than 5.

Imaging

- Most chest neoplasms are found incidentally during diagnostic imaging of the chest for other reasons.

- They most often are discovered on either plain chest x-ray or CT scan of the chest.
- Primary cardiac lesions may be found on echocardiogram

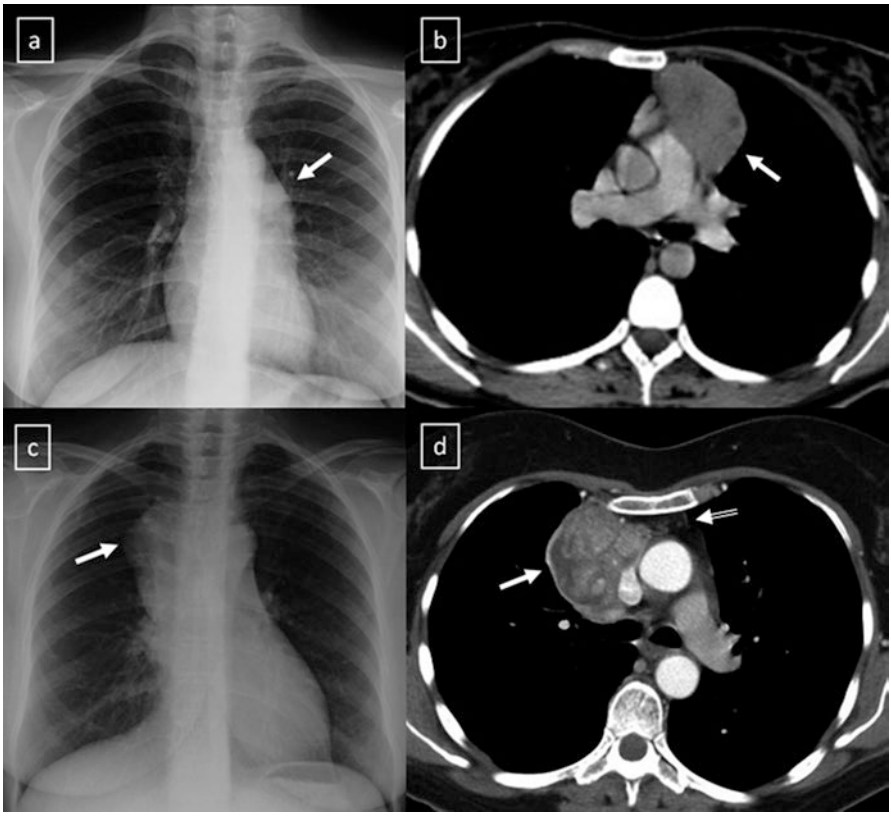
Special Populations

Age

- Chest neoplasms may occur in any age group.

Co-morbidities

- There are many potential co-morbidities to consider depending on the specific type of neoplasm. COPD is often present in patients with bronchogenic carcinoma.
- Thymus mass (thymoma) is associated with myasthenia gravis in about one-half of cases.



a, b Stage II thymoma (WHO type B1) in a 33-year-old woman who presented with myasthenia gravis. Frontal chest radiograph shows a hilum overlay sign (arrow) of a suggestive anterior mediastinal mass. Contrast-enhanced CT scan confirms the presence of a low-heterogeneous anterior mediastinal mass (arrow). Note the indentation of the arterial trunk pulmonary by the mass. c, d Stage III thymoma (WHO type B2) in a 54-year-old woman. Frontal chest radiograph reveals a lobulated mediastinal mass (arrow) on the right side. Contrast-enhanced CT scan demonstrates an enhanced anterior mediastinal mass (arrow) with infiltration of surrounding fat (open arrow) [From article: A diagnostic approach to the mediastinal masses. Insights into Imaging. 2013 Feb;4(1):29–52. https://doi.org/10.1007/s13244-012-0201-0, at http://link.springer.com/article/10.1007%2Fs13244-012-0201-0/fulltext.html; by Sergi Juanpere, Noemí Cañete, Pedro Ortuño, Sandra Martínez, Gloria Sanchez, Lluis Bernado, © The Author(s) 2012; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

Pitfalls in Diagnosis

Critical Steps Not to Miss

- A thorough medical history and chest imaging are essential early in the evaluation of a chest tumor

Mimics

- Infection is the primary mimic of neoplasms in the chest

Time-Dependent Interventions

- Ensuring adequate oxygenation
- Imaging to establish likely etiology

Overall Principles of Treatment

- Treatment depends on the type of neoplasm and whether any symptomatic obstruction or compression exists.

Disease Course

- Disease course depends on the specific diagnosis.

Chapter 18
Chronic Obstructive Pulmonary Disease

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Chronic Obstructive Pulmonary Disease; COPD; Emphysema

Incidence/Epidemiology

- COPD affects about 5 % of the U.S. population.
- COPD is reported as the third- or fourth-leading cause of death in the U.S, depending upon the survey. COPD is directly responsible for about 120,000 deaths per year in the U.S.
- COPD is associated with a very high rate of medical resource utilization. The majority of these costs are for hospitalization of acute exacerbations of COPD.
- In the U.S., nearly 2 % of all hospital admissions are directly attributable to COPD. It is considered a major contributing factor in another 9 % of hospital admissions. In patients older than 65, the percentage of all hospital admission related to COPD approaches 20 %.
- COPD is the only major cause of death that is increasing in the U.S.

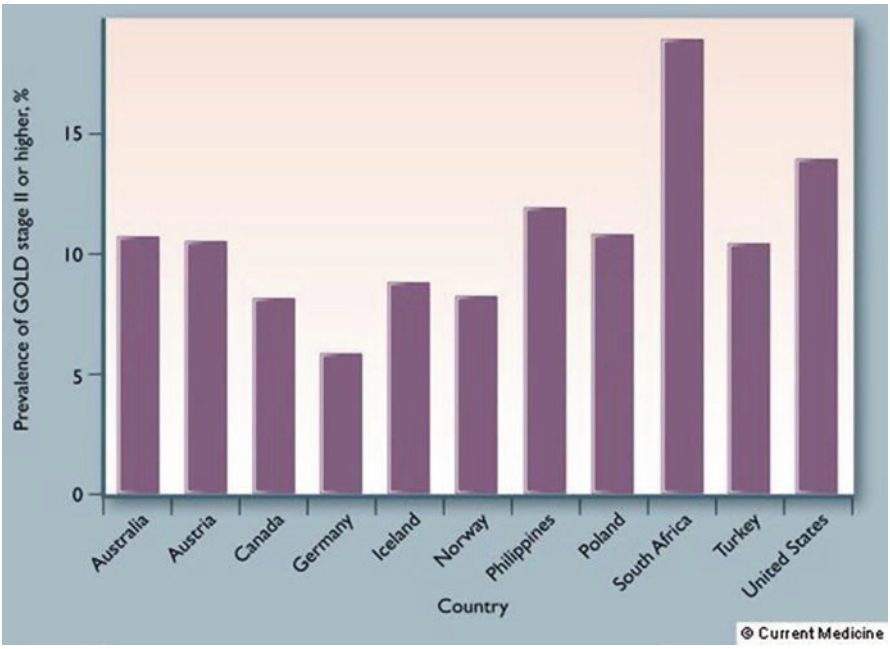
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_18

- The incidence and mortality of COPD in women is increasing worldwide. This is likely related to the increased incidence of smoking among women during the last 50 years.
- Tobacco smoke is the major risk factor for developing COPD, but only 15 % of smokers will develop COPD.
- Alpha-1 antitrypsin deficiency accounts for less than 1 % of COPD cases.



Worldwide prevalence of chronic obstructive pulmonary disease (COPD). The prevalence of COPD (in 2007) in different geographic regions based on the Burden of Obstructive Lung Disease data [Buist AS, McBurnie MA, Vollmer WM, et al. International variation in the prevalence of COPD (the BOLD Study): a population-based prevalence study. Lancet. 2007; 370:741 -750.] is presented based on results for specific cities within the countries listed. The reasons for these regional differences are not entirely clear and may be due to different environmental exposures (smoking, biomass, occupation), as well as possibly genetic factors. [Cho M, Silverman E. Genetics and Racial, Ethnic, and Gender Characteristics of COPD. In: Crapo JD, editor. Atlas of Chronic Obstructive Pulmonary Disease. Philadelphia, PA: Current Medicine Group; 2009. 160 p. ISBN: 978-1-57340-294-1] *Caption from original*

Differential Diagnosis

- The primary symptoms of COPD are dyspnea (usually exertional early in the disease course), cough, and sputum production.

- The differential diagnosis of these symptoms is broad, and includes many diseases and organ symptoms.
- Patients may present with worsening fatigue, exercise or activity intolerance, and often complain of daily cough for many months.
- In patients without a current diagnosis of COPD, the differential includes:
    - Congestive heart failure
    - Interstitial lung disease
    - Thromboembolic Disease (pulmonary embolism)
    - Asthma
    - Bronchiectasis
    - Tuberculosis
    - Bronchiolitis
    - Airway obstruction from bronchogenic or metastatic cancer, lymphadenopathy (sarcoidosis), and tracheal stenosis/scarring.
- It is important to remember that many of these disorders can occur together.
- In patients with an existing diagnosis of COPD, who present with acute dyspnea (exacerbation of COPD), the cause of the exacerbation needs to be investigated. The differential for acute dyspnea in these patients is also broad, and includes:
    - CHF/pulmonary edema
    - Acute coronary syndrome
    - Pneumonia
    - Viral respiratory infection
    - Pulmonary embolism
    - Pleural effusion
    - Pneumothorax
    - Pericardial effusion
    - Mucous plugging of bronchi
    - Rib fracture from severe coughing
    - Electrolyte imbalance (especially hypokalemia and hypocalcemia)

Pathophysiology and Etiology

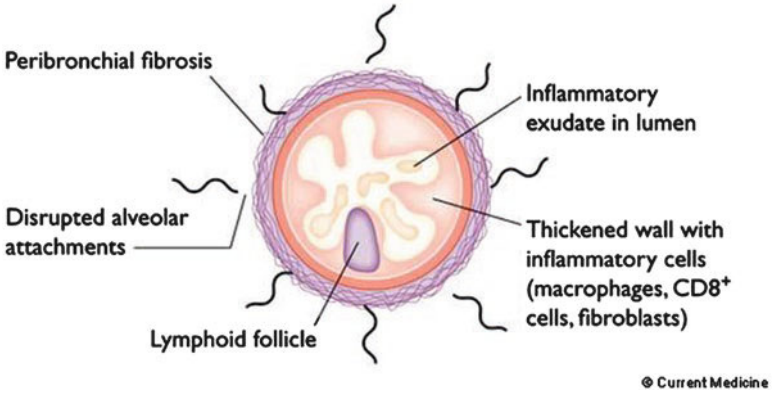
- Chronic obstructive pulmonary disease (COPD) is a disease characterized by chronic, progressive airflow obstruction.
- The Global Initiative for Chronic Obstructive Lung Disease (GOLD), sponsored by the National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO), defines COPD as follows: “Chronic obstructive pulmonary disease (COPD), a common preventable and treatable disease, is characterized by airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles or gases. Exacerbations and comorbidities contribute to the overall severity in individual patients.”

Global Initiative for Chronic Obstructive Lung Disease, GOLD [3]: $FEV_1/FVC < 70\%$		
I:	Mild COPD	$FEV_1 \geq 80\%$ predicted
II:	Moderate COPD	FEV_1 50- < 80% predicted
III:	Severe COPD	FEV_1 30- < 50% predicted
IV:	Very severe COPD	$FEV_1 < 30\%$ predicted
British Thoracic Society, BTS [2]: $FEV_1/VC < 70\%$ and $FEV_1 < 80\%$ predicted		
I:	Mild COPD	FEV_1 60- < 80% predicted
II:	Moderate COPD	FEV_1 40-59% predicted
III:	Severe COPD	$FEV_1 < 40\%$ predicted

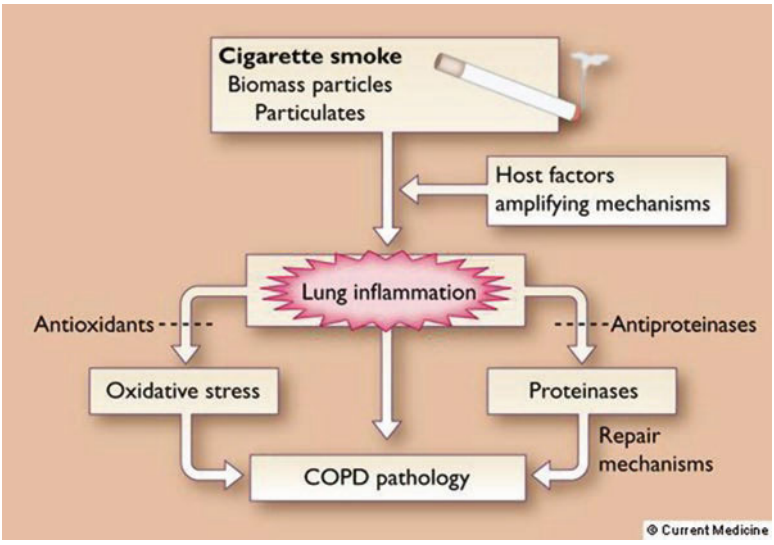
A group labelled BTS stage 0 was created for subjects with $FEV_1 \geq 80\%$ predicted: i.e. identical with mild COPD according to the GOLD criteria.

Severity criteria of COPD. [3] BTS: BTS guidelines for the management of chronic obstructive pulmonary disease. The COPD Guidelines Group of the Standards of Care Committee of the BTS. Thorax 1997, 52:S1-28. [2] Pauwels RA, Buist AS, Calverley PMA, Jenkins CR, Hurd SS: Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease: NHLBI and WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD): executive summary. Respiratory Care 2001, 46:798-825. [From article: Health-related quality of life is related to COPD disease severity. Health and Quality of Life Outcomes. 2005 Sep 9;3(1):56. https://doi.org/10.1186/1477-7525-3-56, at http://link.springer.com/article/10.1186%2F1477-7525-3-56/fulltext.html; by Elisabeth Ståhl, Anne Lindberg, Sven-Arne Jansson, Eva Rönmark, Klas Svensson, Fredrik Andersson, Claes-Göran Löfdahl, Bo Lundbäck, © Ståhl et al; licensee BioMed Central Ltd. 2005; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0]

- The pathophysiology of COPD involves the airways, lung parenchyma, and pulmonary vasculature.
  - Airways: The most significant pathologic change in the airways involves chronic inflammation from exposure to cigarette smoke and other pollutants, which leads to several permanent anatomic changes such as:
    - Mucous gland hyperplasia and increased numbers of goblet cells, resulting in increased mucous secretion. Increased mucous secretion and stasis leads to pathogenic bacterial colonization.
    - Increased mucous-secreting and goblet cells replace surfactant-secreting cells, which augments collapse and destruction of the small airways.
    - Increased induction of inflammatory cells with increased local protease production, accelerating tissue damage and breakdown.
    - Fibrosis with loss of elastic recoil, narrowing, collapse, and subsequent destruction and reduction in the number of small airways.
    - There is also squamous metaplasia within the airways resulting in an increased risk for cancer.

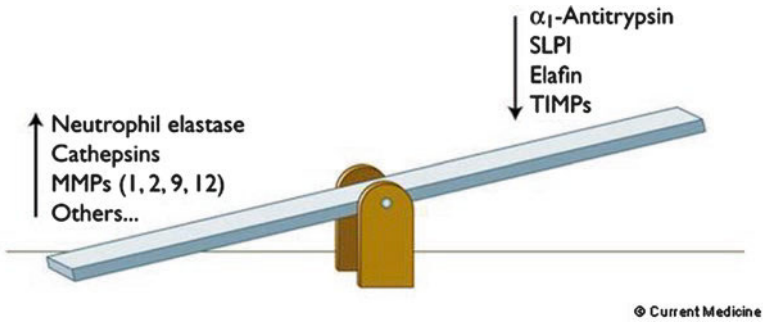


Overview of small airways in COPD: schematic view [Barnes PJ. Pathophysiology of COPD. In: Crapo JD, editor. Atlas of Chronic Obstructive Pulmonary Disease. Philadelphia, PA: Current Medicine Group; 2009. 160 p. ISBN: 978-1-57340-294-1] *Caption adapted from original*

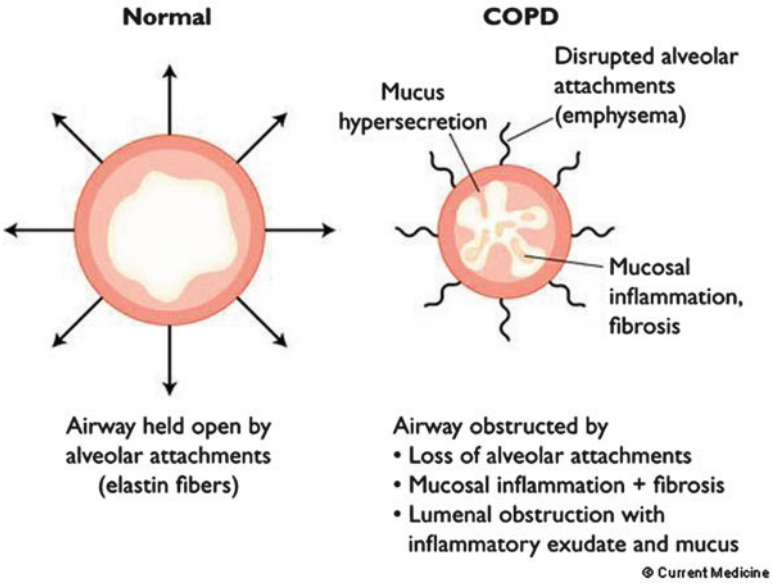


Link between inflammation and airway obstruction in chronic obstructive pulmonary disease (COPD). Chronic exposure to inhaled cigarette smoke and biomass particles (wood smoke) results in chronic inflammation of the lungs. Genetic and other unknown factors are responsible for the increased susceptibility to inhaled irritants. Inflammation generates reactive oxygen species (oxidative stress), which is normally counteracted by endogenous antioxidant mechanisms, but these may be defective in COPD. Inflammation also activates proteinases, which result in connective tissue destruction. This may be countered by antiproteinases and repair mechanisms that may also be defective in COPD.

[Barnes PJ. Pathophysiology of COPD. In: Crapo JD, editor. Atlas of Chronic Obstructive Pulmonary Disease. Philadelphia, PA: Current Medicine Group; 2009. 160 p. ISBN: 978-1-57340-294-1] *Caption from original*



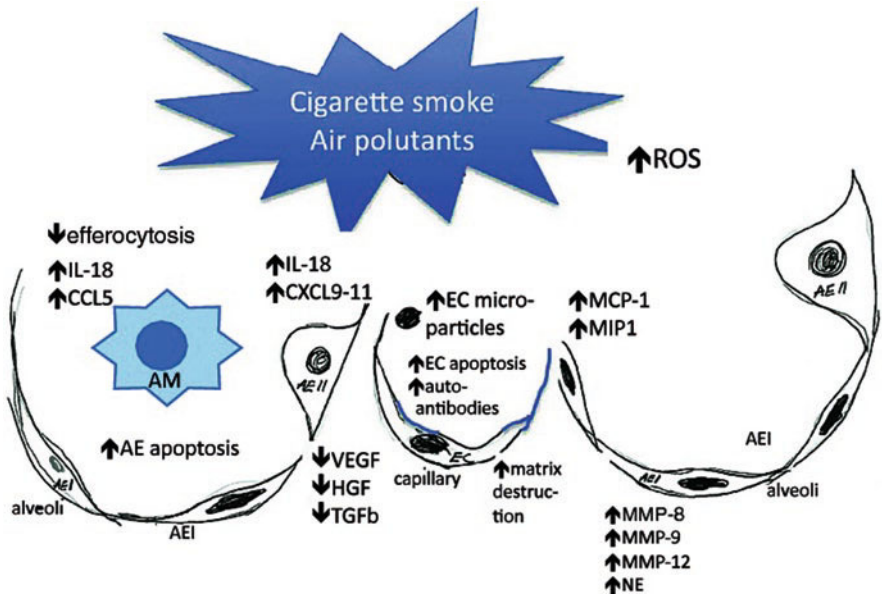
Protease-antiprotease imbalance in COPD: schematic view. Protease–antiprotease imbalance in chronic obstructive pulmonary disease (COPD). In COPD the balance appears to be tipped in favor of increased proteolysis, either because of an increase in proteases, including neutrophil elastase, cathepsins, and matrix metalloproteinases (MMPs), or a deficiency in antiproteases, which may include α_1-antitrypsin, elafin, secretory leukoprotease inhibitor (SLPI), and tissue inhibitors of matrix metalloproteinases (TIMPs). [Barnes PJ. Pathophysiology of COPD. In: Crapo JD, editor. Atlas of Chronic Obstructive Pulmonary Disease. Philadelphia, PA: Current Medicine Group; 2009. 160 p. ISBN: 978-1-57340-294-1] *Caption from original*



Mechanisms of airflow limitation in COPD: schematic view. Mechanisms of airflow limitation in chronic obstructive pulmonary disease (COPD). The airway in normal

subjects is distended by alveolar attachments, which contain elastin fibers during expiration, allowing alveolar emptying and lung deflation. In COPD these attachments are disrupted due to emphysema, thus contributing to airway closure during expiration, trapping gas in the alveoli and resulting in hyperinflation. Peripheral airways are also obstructed and distorted by airway inflammation and peribronchiolar fibrosis (chronic obstructive bronchiolitis), and by occlusion of the airway lumen by inflammatory exudate and mucus secretions that may be trapped in the airways due to poor mucociliary clearance. [Barnes PJ. Pathophysiology of COPD. In: Crapo JD, editor. Atlas of Chronic Obstructive Pulmonary Disease. Philadelphia, PA: Current Medicine Group; 2009. 160 p. ISBN: 978-1-57340-294-1] *Caption from original*

- Lung Parenchyma. The lung parenchymal changes are also called emphysema. The changes mostly affect the acinus, the functional unit distal to the terminal bronchiole that includes the respiratory bronchiole, alveolar ducts, alveolar sacs, and alveoli. There is destruction of this unit leading initially to collapse and then subsequent enlargement as air becomes trapped within the destroyed unit. The loss of elastic recoil prevents the air from escaping. There are three subtypes of emphysema:
  - Centrilobular: This involves the proximal acinus (predominately the respiratory bronchioles.) It is the form most strongly associated with cigarette smoking.
  - Panacinar: This involves all parts of the acinus, and is mostly seen with alpha-1 ant-trypsin deficiency.
  - Distal (paraseptal): Affects predominately the alveolar ducts.
- Pulmonary vasculature. Chronic hypoxia leads to reflex vasoconstriction of the small pulmonary arteries, which results in intimal hyperplasia, smooth muscle hypertrophy and hyperplasia, and ultimately pulmonary hypertension.



Destruction of the lung maintenance program in emphysema. Chronic exposure to cigarette smoke leads to a change in the local milieu: increased release of proinflammatory mediators (IL-8, IL-18, CCL5, IL-8, IFNgama, MIP1) that contribute to paracrine and autocrine signaling, impairment in efferocytosis, decreased levels of growth and survival factors (most notably VEGF and HGF), and extracellular matrix degradation (increased levels of matrix metalloproteases MMP-9 and MMP-12). Increased apoptosis of endothelial and epithelial cells might contribute to autoantibody formation. Reduced levels of TGF might signal delay repair processes and contribute to inflammatory cell activation. AM – alveolar macrophage; AEI – alveoli type I cell; AEII – alveoli type II cell; EC – capillary endothelial cell; ROS – reactive oxygen species [Taraseviciene-Stewart L, Voelkel NF. Immunopathology of COPD. In: Rogers TJ, Criner GJ, Cornwell WD, editors. Smoking and Lung Inflammation [Internet]. Springer New York; 2013 [cited 2016 May 16]. p. 1–27. Available from: http://link.springer.com/chapter/10.1007/978-1-4614-7351-0_1] *Caption from original*

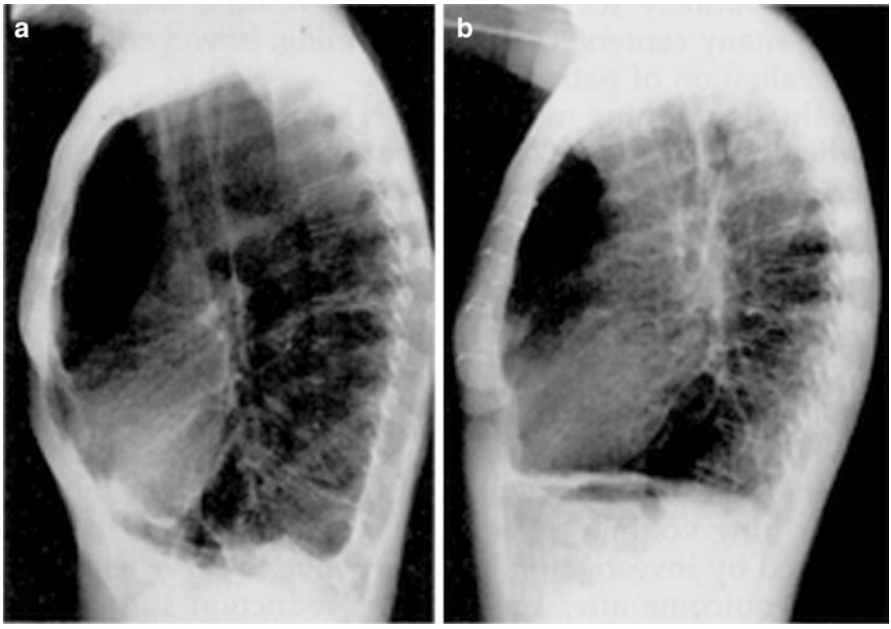
- The single largest risk factor for the development of COPD is cigarette smoking. In the United States, nearly 80 % of patients diagnosed with COPD have history of cigarette smoking. The amount and duration of smoking are the largest predictors of disease severity. The single most reliable predictor for finding airflow obstruction on spirometric testing is a greater than 40 packs-per-year history of cigarette use.
- However, only 15 % of smokers will develop COPD.
- Smoking is the largest risk factor for the development of COPD, but not the only risk factor. Twenty percent of patients with COPD do not have a significant history of cigarette smoking. Other causes of COPD include occupational exposures (such as coal mining, gold mining, and cotton dust). There are also genetic causes, such as alpha-1 anti-trypsin deficiency, although this accounts for less than 1 % of cases of COPD.
- There is currently no strong evidence linking air pollution or second-hand smoke to the development of COPD.

Presentation

Typical/"Classic"

- The most common presenting symptoms of COPD are exertional dyspnea and chronic cough with sputum production.
- COPD is a slowly progressive disease with a prolonged asymptomatic phase. Patients are often unaware of the dyspnea, or just relate it to aging or poor fitness. They will often adjust their activities to limit the symptoms of dyspnea.
- Wheezing is often a later symptom.

- The course is one of slow progression with intermittent exacerbations of dyspnea and cough.
- Early in the course of the disease, the patient may have no physical signs of the disease.
- As the disease progresses, patients may develop the more classic signs of COPD, such as a barrel chest (increased AP diameter from air trapping), prolonged expiration with expiratory wheezing, decreased breath sounds, tachypnea, and pursed lip breathing.



A lateral chest X-ray is shown. (a) Depicts the patient before lung volume reduction surgery (LVRS): the thorax is barrel-shaped with high transparency of the lungs, a large retrosternal air-filled space, and a flattened to concave diaphragm. The chest X-ray of the same subject (b) is shown 3 months after LVRS: the lung fields are less transparent, the air-filled retrosternal space decreased significantly, and the diaphragm exhibits an almost normal, convex shape. [Sullivan EA. Lung Volume Reduction. In: Slinger P, editor. Principles and Practice of Anesthesia for Thoracic Surgery [Internet]. Springer New York; 2011 [cited 2016 May 16]. p. 511–21. Available from: http://link.springer.com/chapter/10.1007/978-1-4419-0184-2_36] *Caption from original*

- Patients will often be noted to need to sit up and lean forward with their hands on their knees (tripod position) as this increases accessory muscle use (sternocleidomastoid, scalene, and intercostal muscles) and diaphragmatic excursion, both of which help to improve lung volumes.

- Patients with advanced disease will often have significant wasting with loss of muscle mass and subcutaneous fat. This is an independent predictor of a very poor prognosis.
- Clubbing of the digits is not a sign of COPD. If a patient with COPD develops clubbing, there is usually another cause, such as the interval development of lung cancer.

Atypical

- COPD less commonly presents initially with wheezing.
- COPD can present with chest tightness as the predominant symptom.

Primary Differential Considerations

- Initial consideration in patients with an acute presentation should be given to these differential diagnoses:
  - Asthma
  - Congestive heart failure
  - Pulmonary hypertension
  - Pulmonary embolism
  - Pneumonia

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical exam findings that can confirm COPD. There is a large overlap with other disease states that cause dyspnea, such as asthma, congestive heart failure, and bronchiectasis.
- The diagnosis can be nearly confirmed when a patient presents with the typical symptoms of dyspnea on exertion with a chronic cough and sputum production associated with findings on spirometry of a forced expiratory volume in one second (FEV_1) less than 80 % of predicted and a ratio of FEV_1 to the forced vital capacity (FVC) of <0.7.

Assess and Monitor Disease: Key Points
Consider a diagnosis of COPD in any patient with a cough, dyspnea, or exposure to risk factors and confirm with spirometry.
Spirometry is the gold standard for the diagnosis and assessment of COPD and a postbronchodilator $FEV_1/FVC < 0.70$ confirms the presence of airflow limitation that is not fully reversible.
Health care workers involved in the diagnosis and management of COPD should have access to spirometry.
Severity of COPD is determined by symptoms, spirometric abnormalities, and complications. Changes in therapy should also be based on these factors.
Blood gas measurements should be made in patients with $FEV_1 < 50\%$ predicted or in those with evidence for right heart failure.
Comorbidities are common in COPD and are often the cause of death. They should be actively identified.

Assessment of COPD. [Dransfield MT. Diagnosis of COPD and the GOLD Guidelines. In: Crapo JD, editor. Atlas of Chronic Obstructive Pulmonary Disease. Philadelphia, PA: Current Medicine Group; 2009. 160 p. ISBN: 978-1-57340-294-1] *Caption adapted from original*

Factors That Suggest Diagnosis

- A patient who presents with the typical symptoms of dyspnea, cough, and sputum production, and has a greater than 40 pack-per-year history of cigarette smoking, has a high likelihood of having COPD.

Factors That Exclude Diagnosis

- Normal spirometric findings can exclude the diagnosis in a patient with the classic symptoms.

Ancillary Studies

Laboratory

- There are no lab tests that are diagnostic for COPD. However, many lab tests are helpful in the evaluation of the dyspneic patient to evaluate for other causes of the dyspnea.
- A complete blood count can help assess for anemia as the cause of dyspnea. Patients with advanced COPD may demonstrate polycythemia induced by chronic hypoxemia.

- A BNP (brain natriuretic peptide) level may help to distinguish between COPD and congestive heart failure as the cause of dyspnea. It is important to remember, however, that these diseases may often be present in the same patient.
- An alpha-1 anti-trypsin level should be measured in any patient with early-onset (before age 45) COPD, a non-smoker with COPD, or a family history of premature development of COPD.

Imaging

- Plain chest x-rays are unreliable in the diagnosis of COPD. Only about one-half of patients with moderate COPD will have any findings of COPD on a chest x-ray.
- The classic CXR findings of COPD include flattened diaphragms, an increased antero-posterior diameter of the chest, and increased radiolucency of the lungs. These are usually only seen in moderate-to-severe COPD, and are due to hyperinflation and air trapping.
- CXR can also be used to evaluate for alternative diagnoses (such as lung cancer, CHF, bronchiectasis), co-morbidities (the list also includes lung cancer, CHF, and bronchiectasis), and complications (such as pneumonia, pneumothorax) of COPD that are apparent on chest x-ray.
- CT is more sensitive at detecting the pathologic changes of COPD, but is not often needed to make the diagnosis. CT can be very helpful in the evaluation for alternative diagnoses, co-morbidities, and complications of COPD.

Chest X-rays of a 75-year-old patient with a clinical diagnosis of COPD. Posteroanterior (a) and lateral views (b) show radiographic signs consistent with pulmonary emphysema. Thickening of the bronchial wall is also evident in the lung bases. Tracheostomy was previously placed due to respiratory failure [Larici AR, Franchi P, Occhipinti M, Devicienti E, Mereu M, del Ciello A, Bonomo L. Airway Disease. In: Guglielmi G, Peh WCG, Guermazi A, editors. Geriatric Imaging [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2013 [cited 2016 May 16]. p. 319–52. Available from: http://link.springer.com/10.1007/978-3-642-35579-0_14] *Caption from original*

Pulmonary Function Tests

- PFT's, especially spirometry, are the most helpful studies in diagnosing COPD. They are also useful in assessing the severity of disease, response to treatment, and for following progression.
- Spirometry (the measuring of breathing) is the most useful pulmonary function test in diagnosing and following COPD. Specifically, the forced expiratory volume in one second (FEV1), and the forced vital capacity and their ratio are the most helpful diagnostic tests for COPD.
- Spirometry performed both before and after inhaled bronchodilator use can determine whether airflow limitation is present, and whether it is at all reversible. Airflow limitation that is reversible is characteristic of asthma; airflow that is only partially reversible or is irreversible is consistent with COPD.
- Generally, COPD is felt to be present in a patient with an FEV1 less than 80 % of predicted, and and FEV1/FVC ratio of less than 0.7.

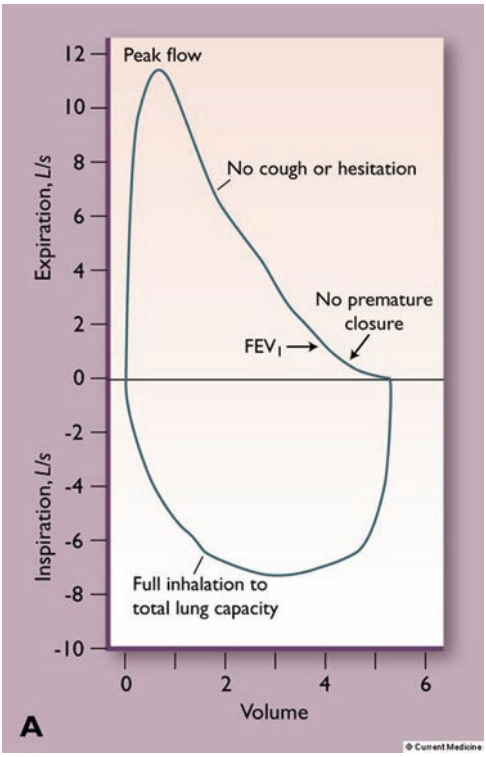
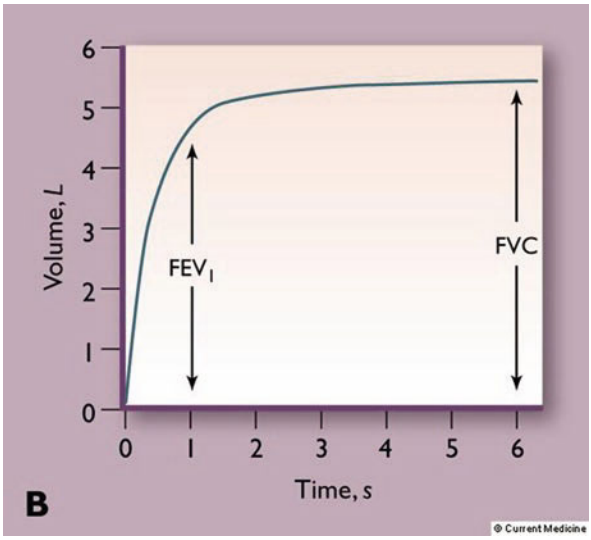
Video demonstrating spirometry procedure, including the patient interview.



Spirometry in diagnosis of COPD [Hegewald M, Crapo R, Jensen R. Clinical Physiology of COPD. In: Crapo JD, editor. Atlas of Chronic Obstructive Pulmonary Disease. Philadelphia, PA: Current Medicine Group; 2009. 160 p. ISBN: 978-1-57340-294-1] *Caption adapted from original*



Spirometry in diagnosis of COPD [Hegewald M, Crapo R, Jensen R. Clinical Physiology of COPD. In: Crapo JD, editor. Atlas of Chronic Obstructive Pulmonary Disease. 2009 edition. Philadelphia, PA: Current Medicine Group; 2009. 160 p. ISBN: 978-1-57340-294-1] *Caption adapted from original*

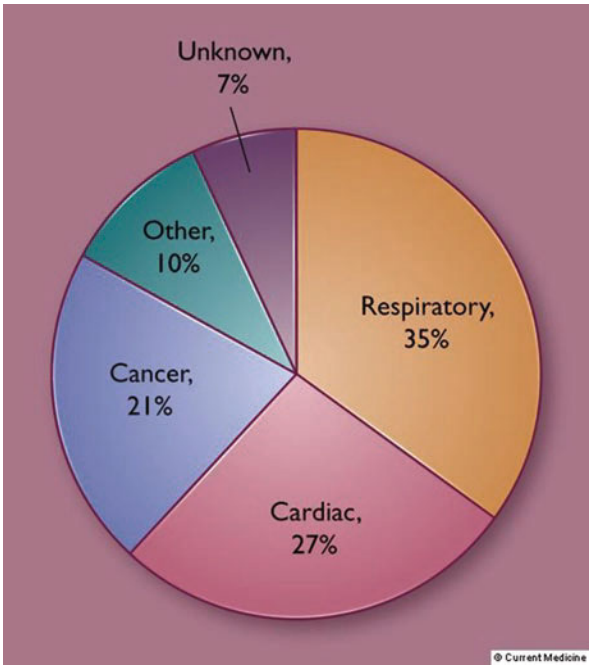
Special Populations

Age

- COPD is a slowly progressive disease that often presents later in life. It is uncommon to diagnose before the sixth decade of life.
- Patients who are diagnosed with COPD before the age of 45 need to be evaluated for alpha-one antitrypsin deficiency.

Co-morbidities

- As a disease of older patients, COPD is often is seen in combination with other diseases, such as coronary artery disease, congestive heart failure, and cancer.



Causes of death in patients with COPD [Make BJ, Crapo JD. The Worldwide Epidemic of COPD: Clinical Phenotypes. In: Crapo JD, editor. Atlas of Chronic Obstructive Pulmonary Disease. Philadelphia, PA: Current Medicine Group; 2009. 160 p. ISBN: 978-1-57340-294-1] *Caption adapted from original*

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is imperative to consider the diagnosis, especially early in the course of the disease when the symptoms may be non-specific and subtle. Interventions such as smoking cessation can help to slow and stop the progression of disease if instituted early in the course.
- It is imperative to consider to alternative diagnoses, such as lung cancer and congestive heart failure.

Mimics

- Any disease that causes dyspnea can mimic COPD.
- Early COPD can sometimes be confused with atypical angina, as COPD, like angina, can cause chest tightness and dyspnea. Smoking is a significant risk factor for both diseases.
- Early in the course it is easily mimicked by asthma (although asthma has reversible airflow obstruction and COPD has irreversible airflow obstruction).
- Later in the course, COPD can mimic CHF, lung cancer with airway obstruction, bronchiectasis, pulmonary fibrosis, and other disorders causing dyspnea and cough.

Time-Dependent Interventions

- COPD cannot be reversed, so it is important to initiate treatment as early as possible to try and prevent progression of symptoms and pathology.
- Smoking cessation is critically important to these patients. It is also very difficult and may require a multi-modal treatment approach that includes pharmacologic and behavioral interventions.

Overall Principles of Treatment

- Therapy for compensated COPD involves numerous modalities including: oxygen therapy when indicated, bronchodilators, corticosteroids, reducing mucous secretion, smoking cessation, and pulmonary rehabilitation.
- Oxygen therapy in chronically hypoxic patients reduces mortality. The goal is to keep the PaO2 $\leq$60 mmHg of oxygen saturation $\geq$90 % at rest. The generally accepted criteria for oxygen therapy are: PaO2 $\leq$55 mmHg, an oxygen saturation of $\leq$88 % on room air, or a PaO2 of 56–59 mmHg in the presence of pulmonary hypertension, cor pulmonale, and polycythemia.
- Bronchodilator therapy does not affect the progression of the disease, but it can provide symptomatic relief and control and reduce exacerbations. Bronchodilator therapy also can improve quality of life. Patients would typically be maintained on long-acting inhaled beta agonists such as salmeterol and formoterol. Short-acting beta agonists such as albuterol are usually reserved for symptom control and for use during acute exacerbations. Inhaled anticholinergics (ipratropium) also cause bronchodilatation. The use of inhaled beta agonists combined with an inhaled anticholinergic improves FEV1 and symptoms better than either of these alone.

- Systemic corticosteroids can be useful in helping to control acute exacerbations, but most authorities don't recommend their long-term use. Only about 20–30 % of patients will note any improvement with the use of oral steroids. Some patients may improve with the use of inhaled steroids, especially those with an FEV1 <50 % of predicted.
- The only measures shown to help with mucous handling are adequate hydration and room humidification. Antitussives, antihistamines, and decongestants are all drying agents, and their use should be limited. Mucolytics and expectorants are of no clear benefit.
- Smoking cessation is the only intervention proven to reduce the rate of disease progression. Smoking cessation also reduces mortality. A multi-modal approach is often necessary and may include both pharmacologic and behavioral therapies.
- Pulmonary rehabilitation can increase exercise tolerance and improve quality of life, and is indicated for moderate-to-severe COPD.
- It is important that patients with COPD receive a pneumococcal vaccine, and also receive yearly influenza vaccination.

Disease Course

- COPD is a chronic, slowly progressive disease. It is marked by periods of relative stability interrupted by acute exacerbations, and a slow, steady decline in lung function.
- The frequency of exacerbations is a surrogate marker for disease progression.

Chapter 19
Cor Pulmonale

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Cor Pulmonale; Right Heart Failure; Pulmonary Heart Disease

Incidence/Epidemiology

- The true incidence and prevalence of cor pulmonale are unknown, as there are no standard diagnostic guidelines, and no definitive diagnostic tests for this condition.
- COPD (Chronic Obstructive Pulmonary Disease) causes about half of all cases of cor pulmonale in North America. Up to one-third of patients with COPD will develop cor pulmonale at some point during the course of their illness.
- Up to 20% of patients with obstructive sleep apnea (OSA) will develop cor pulmonale.
- Pulmonary vascular disorders (primary pulmonary hypertension, chronic thromboembolic disease, and scleroderma lung disease) are rare diseases, but cor pulmonale is a common end-stage complication of these diseases.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_19

- Interstitial lung diseases (ILD), especially idiopathic pulmonary fibrosis (IPF), often lead to cor pulmonale.

Differential Diagnosis

- The differential diagnosis of cor pulmonale is broad, and encompasses all diseases that present with dyspnea, fatigue, and exercise intolerance, such as COPD, asthma, PE, CHF, acute and chronic coronary syndromes, interstitial lung disease, and pulmonary vascular diseases, among many others.
- Also, cor pulmonale does not exist in isolation; it occurs as a complication of other disease processes with the common denominator being the presence of significant pulmonary hypertension.
- It is important in the differential diagnosis of these patients to consider worsening of the underlying disease as a cause of worsening dyspnea.
- It is also important to evaluate these patients for left heart failure from cardiac causes.

Pathophysiology and Etiology

- Cor pulmonale is defined as an alteration in the structure and function of the right ventricle in the presence of underlying chronic lung disease.
- Right-sided heart failure that results from left heart failure is not considered cor pulmonale.
- Cor pulmonale is triggered by the development of pulmonary hypertension.
- There are many diseases that can lead to pulmonary hypertension, and subsequently cor pulmonale. These are reviewed in the section on pulmonary hypertension.
- Pulmonary hypertension (either acutely or chronically) causes changes in right ventricular structure (dilatation with or without hypertrophy) and function (decreased contractility). If present chronically, pulmonary hypertension causes the pulmonary vascular bed to undergo vasoconstriction, remodeling, fibrosis, and ultimately destruction. This leads to further increases in pulmonary artery pressure (the normal PA pressure is about 15 mm Hg), increasing the work of the RV to pump against higher pressures (increased RV afterload), leading to decreases in left ventricular filling and cardiac output, but usually with preservation of left ventricular ejection fraction.
- Chronic cor pulmonale is a chronic, slowly progressive condition that leads to worsening pulmonary hypertension, right ventricular hypertrophy, and dilatation.
- Cor pulmonale can also occur acutely, in the absence of right ventricular hypertrophy. A large pulmonary embolism can cause acute increase in right ventricular

and pulmonary artery pressure, leading to right ventricular dilatation and failure.

Presentation

Typical/"Classic"

- Dyspnea is the most common symptom of cor pulmonale. As many of these patients have significant underlying pulmonary disease, they often note a worsening of chronic dyspnea.
- Other symptoms often attributed to cor pulmonale include:
  - dyspnea on exertion
  - fatigue
  - lethargy
  - exertional syncope
  - exertional angina (even in the absence of coronary artery disease)
- Abdominal pain, ascites, and peripheral edema are also frequently seen in patients with cor pulmonale. These are related more to the left heart changes caused by cor pulmonale.
- Patients often present with worsening dyspnea, often with worsening edema and ascites. They will likely exhibit some degree of hypoxia.

Atypical

- Patients with no history of underlying pulmonary disease may present with acute cor pulmonale.
- These patients usually will have profound dyspnea and be hypoxemic and hypotensive. The most common cause for this will be a large, central pulmonary embolism.

Primary Differential Considerations

- The primary differential diagnoses for cor pulmonale are pulmonary hypertension, pulmonary embolism, constrictive pericarditis, and biventricular heart failure.

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical examination findings that are pathognonomic for cor pulmonale, as many of the symptoms and signs of right heart failure are shared with left heart failure. These symptoms and signs include dyspnea, tachypnea, hypoxia, elevated jugular venous distension, hepatomegaly, and peripheral edema.

Factors That Suggest Diagnosis

- A patient with a history of known, chronic pulmonary disease, and who presents with worsening dyspnea, is a primary candidate for this diagnosis. However, it is important to remember that there are many other causes of worsening dyspnea in these patients (pneumonia, CHF, pulmonary embolism, pneumothorax, profound anemia, and others).
- Physical exam findings that suggest the diagnosis include:
  - A right ventricular third heart sound.
  - Prominent v-waves in the jugular venous pulse. This results from acute tricuspid regurgitation.

https://www.youtube.com/watch?v=ceX3KmZCZhY

An example showing a prominent v-wave in the jugular venous pulse associated with tricuspid regurgitation.

- A right ventricular heave at the left sternal border.
- Carvallo's Sign is an increase in the intensity of the holosystolic murmur of tricuspid regurgitation upon inspiration. This can often be noted with acute cor pulmonale. This finding becomes less apparent as right ventricular failure worsens.
- Central and peripheral cyanosis can be noted, but they are often late signs.
- Patients with end-stage cor pulmonale often have signs of cardiogenic shock such as hypotension, tachycardia, decreased urine output, and peripheral and central cyanosis.

Factors That Exclude Diagnosis

- Cor pulmonale cannot be diagnosed in the presence of left heart failure.

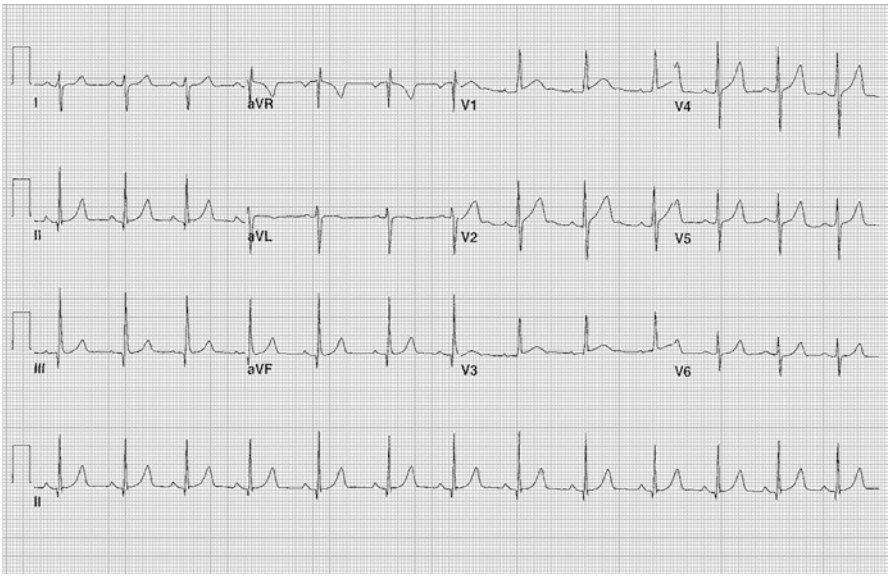
Ancillary Studies

Laboratory

- There are no laboratory studies that are specific for cor pulmonale.
- B-type natriuretic peptide levels should be checked, as they will be elevated. These levels will also be elevated in left heart failure, so they cannot help to distinguish between left heart failure and right heart failure.
- It is helpful to send routine laboratory studies, such as basic chemistries, a complete blood count, thyroid function, and cardiac biomarkers, to evaluate for other causes for the patient's symptoms.

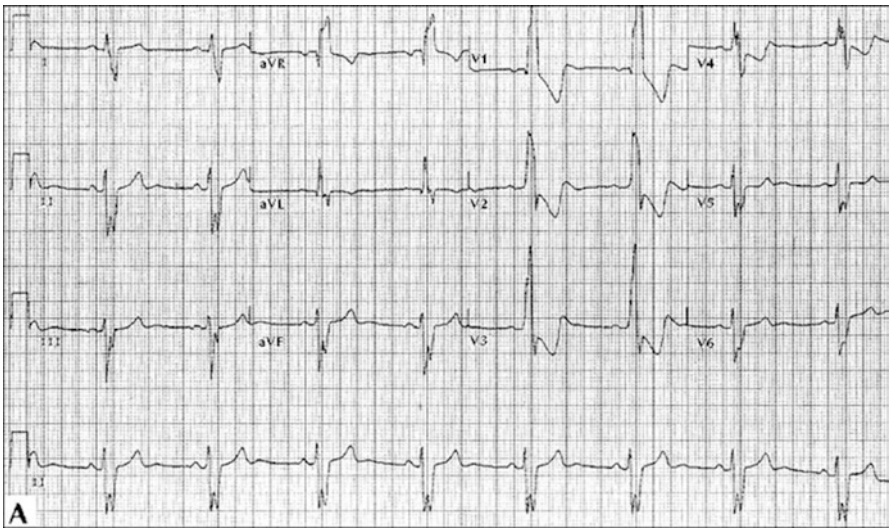
Electrocardiography

- The ECG in cor pulmonale and severe pulmonary hypertension can show a right axis deviation, right ventricular hypertrophy, right atrial enlargement (p pulmonale), and a right bundle branch block. These ECG changes are almost always present in pulmonary hypertension, but can also be present in many other disease states (they are specific but not sensitive).



Electrocardiogram showing the signs of right hypertrophy and right deviation of the cardiac axis in a patient with cor pulmonale [Massimi L, Di Rocco

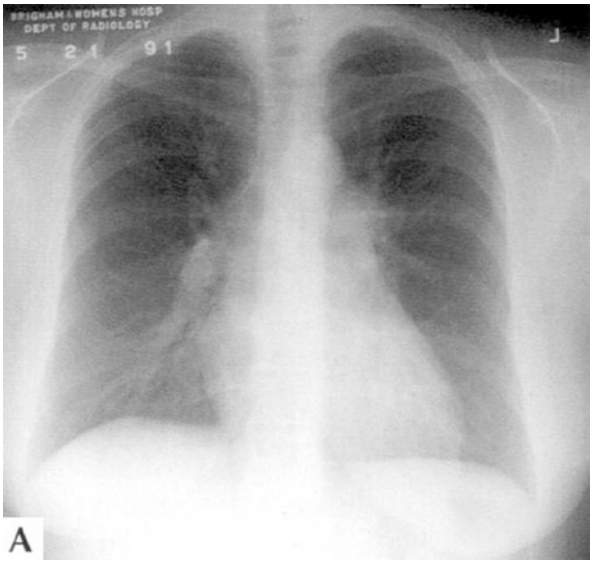
C. Complications Specific to the Type of CSF Shunt: Atrial Shunt. In: Di Rocco C, Turgut M, Jallo G, Martínez-Lage JF, editors. Complications of CSF Shunting in Hydrocephalus [Internet]. Cham: Springer International Publishing; 2015 [cited 2015 Sep 3]. p. 177–85. Available from: http://link.springer.com/10.1007/978-3-319-09961-3_12] *Caption from original*



Electrocardiographic finding with advanced cor pulmonale. Note the complete right bundle branch pattern with an RR′ in lead V1. This tracing demonstrates pressure and volume overload of the right ventricle, consistent with cor pulmonale. [Loh E. Chapter 01. In: Goldhaber S, editor. Cardiopulmonary Diseases and Cardiac Tumors. Philadelphia: Current Medicine; 1995 (Braunwald E, editor. Atlas of heart diseases; vol. 3.)] *Caption adapted from original*

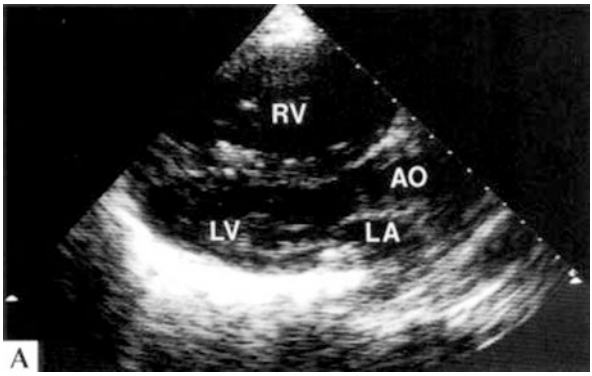
Imaging

- The chest x-ray may be helpful in the evaluation for cor pulmonale. Chronic pulmonary hypertension often leads to enlargement of the main pulmonary artery, hilar vessels, and the descending right pulmonary artery. On the lateral view, there may be loss of the retrosternal air space due to right ventricular enlargement.

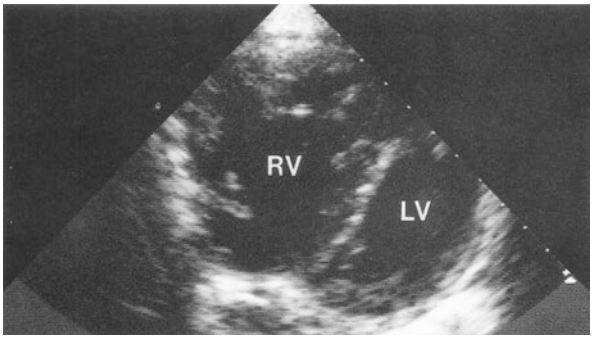


Chest radiograph demonstrating features of advanced cor pulmonale secondary to pulmonary hypertension. Typical radiograph of a patient with primary pulmonary hypertension and cor pulmonale. Note the peripheral oligemia of the pulmonary vessels with mild bilateral enlargement of the main pulmonary arteries.[Loh E. Chapter 01. In: Goldhaber S, editor. Cardiopulmonary Diseases and Cardiac Tumors. Philadelphia: Current Medicine; 1995 (Braunwald E, editor. Atlas of heart diseases; vol. 3.)] *Caption adapted from original*

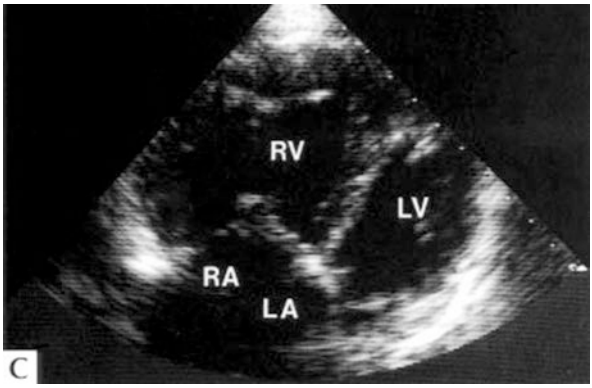
- Transthoracic echocardiography (TTE) can be very helpful in the evaluation for and diagnosis of cor pulmonale and pulmonary hypertension. Pulmonary hypertension alone is associated only with signs of elevated right ventricular pressure. In chronic cor pulmonale there is a thickened (hypertrophied) right ventricular wall and right ventricular dilatation (early in the course of the disease, only hypertrophy may be appreciated). The right ventricular dilatation usually leads to tricuspid regurgitation. Acute cor pulmonale may lead to right ventricular dilatation in the absence of right ventricular hypertrophy. Reduced function of the right ventricle can also often be appreciated on TTE.



Echocardiographic features of the heart in a patient with cor pulmonale. A, Parasternal long-axis view from a patient with advanced primary pulmonary hypertension complicated by cor pulmonale. Note the abnormal flattening of the interventricular septum and its abnormal bulging into the left ventricle (LV), consistent with volume and pressure overload of the right ventricle (RV). [Loh E. Chapter 01. In: Goldhaber S, editor. Cardiopulmonary Diseases and Cardiac Tumors. Philadelphia: Current Medicine; 1995 (Braunwald E, editor. Atlas of heart diseases; vol. 3.)] *Caption from original*



Short-axis view demonstrating a markedly enlarged RV with RV hypertrophy. Abnormal bowing of the interventricular septum into the LV gives a characteristic D configuration of the LV, consistent with volume and pressure overload of the RV. [Loh E. Chapter 01. In: Goldhaber S, editor. Cardiopulmonary Diseases and Cardiac Tumors. Philadelphia: Current Medicine; 1995 (Braunwald E, editor. Atlas of heart diseases; vol. 3.)] *Caption from original*



Apical four-chamber view also demonstrating RV hypertrophy and abnormal septal bowing as described in panels A and B. AO—aorta; LA—left atrium; RA—right atrium. [Loh E. Chapter 01. In: Goldhaber S, editor. Cardiopulmonary Diseases and Cardiac Tumors. Philadelphia: Current Medicine; 1995 (Braunwald E, editor. Atlas of heart diseases; vol. 3.)] *Caption from original*

- Cardiac magnetic resonance imaging (MRI), if available, is superior to transthoracic echocardiography in the evaluation of right ventricular structure and function.
- Right heart catheterization is considered the best diagnostic test for cor pulmonale and pulmonary hypertension. Patients with cor pulmonale will have right ventricular dysfunction as evidenced by an elevated central venous pressure and elevated right ventricular end-diastolic pressure, pulmonary hypertension (PA pressure greater than 25 mmHg), and no evidence of left heart disease, as evidenced by either a normal (less than 15 mmHg) left ventricular end-diastolic pressure. All chamber dimensions and pressures can be directly measured.

Special Populations

Age

- Cor pulmonale is a disease of adults starting in middle-age.
- Most patients with chronic cor pulmonale will have had severe, underlying pulmonary disease for many years prior to the onset of cor pulmonale.
- In the pediatric patient, the vast majority of cases are secondary to cystic fibrosis.
- Neonates with severe bronchopulmonary dysplasia are also susceptible to the development of cor pulmonale.

Co-morbidities

- Many co-morbid conditions can worsen the prognosis, and make the diagnosis of cor pulmonale difficult. These include, but are not limited to, cardiac diseases, other pulmonary diseases, liver disease, and kidney disease.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is imperative that all patients be evaluated for left ventricular dysfunction. The most common cause of right heart failure is left heart failure, and left heart failure precludes a diagnosis of cor pulmonale.
- It is also important to consider all alternative diagnoses that may cause worsening or acute dyspnea in patients with chronic pulmonary and heart disease. This list includes, but is not limited to, pneumonia, CHF, pulmonary embolism, pneumothorax, significant pleural effusion, and acute metabolic issues that can cause dyspnea.

Mimics

- Left heart failure can mimic right heart failure.
- Other diseases that can present in a similar fashion include acute liver failure, acute kidney failure, and others.

Time-Dependent Interventions

- The most important intervention is to decrease the work of breathing by correcting hypoxemia and respiratory acidosis. Correcting these will decrease pulmonary vascular resistance and thereby reduce demands on the right ventricle.

Overall Principles of Treatment

- Optimizing treatment of the underlying lung disease can help improve hemodynamics and lessen the symptoms and progression of cor pulmonale.

- Specific treatment for cor pulmonale consists of managing three physiologic parameters—pulmonary artery pressure; right ventricular pressure; and right ventricular contractility—as follows:
  - Reduce pulmonary artery pressure (reduce right ventricular afterload). This pressure can be reduced by the use of supplemental oxygen to decrease the effect of hypoxia-induced vasoconstriction. This is particularly necessary in hypoxic patients.
  - Reduce right ventricular pressure. Diuretic use has shown some utility in improving hemodynamics in patients with markedly elevated right ventricular pressure. Diuresis must be performed carefully, as over-diuresis can lead to reduced right ventricular filling and a decrease in cardiac output.
  - Improve right ventricular contractility. This therapy is generally reserved for patients with severe cor pulmonale who have resistant hypotension and are in shock. The most common inotropic agents used are dobutamine and milrinone.
- Patients should be evaluated for any underlying or acute issues that, if treated, can help improve the symptoms of cor pulmonale. These include such issues as pulmonary embolism, pneumonia, pneumothorax, and pleural effusions.

Disease Course

- Cor pulmonale is a chronic, progressive disease that occurs only when other underlying pulmonary diseases have progressed and are severe.
- As noted above, acute cor pulmonale is less common but can occur.
- The overall long-term prognosis once cor pulmonale has been diagnosed is poor. Mortality in the first year after the diagnosis of cor pulmonale is around 35%.
- Survival is significantly lessened once cor pulmonale complicates pre-existing lung disease.

Chapter 20
Costochondritis

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Costochondritis; Costosternal Syndrome; Tietze's Syndrome; Chest Wall Pain Syndrome

Incidence/Epidemiology

- Chest pain is a common presenting complaint to both Emergency Departments and primary care offices.
- There are an estimated six million emergency department visits a year for chest pain.
- The evaluation of chest pain utilizes a substantial amount of health care resources, primarily with the goal of excluding life-threatening diagnoses.
- Musculoskeletal causes of chest pain account for up to one-third of all causes in the outpatient evaluation of chest pain.
- The true incidence of costochondritis and other musculoskeletal chest pain syndromes is unknown, as many cases don't present for evaluation.

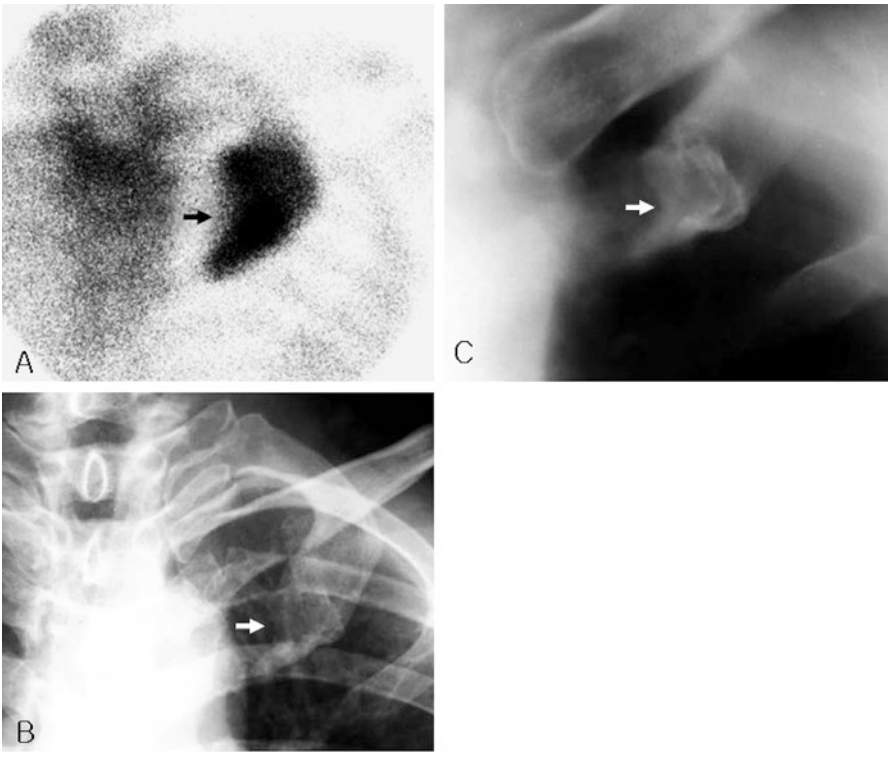
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_20

Differential Diagnosis

- The initial differential diagnosis of chest pain must include all the serious and potentially life-threatening diseases, such as acute coronary syndromes, aortic dissection, pulmonary embolism, and pneumothorax.
- The differential diagnosis of musculoskeletal causes of chest pain is broad. It includes, primarily, inflammatory musculoskeletal pain syndromes such as costochondritis (and others as below), and rheumatic musculoskeletal syndromes such as fibromyalgia, rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis.
- Primary (inflammatory) musculoskeletal chest pain syndromes include:
  - Costochondritis. Costochondritis typically affects those over age 40, and usually involves pain to palpation over the costochondral junctions of the third, fourth, and fifth ribs. Costochondritis is diagnosed more often in women.
  - Tietze's Syndrome. In Tietze's syndrome there is painful swelling of usually one (but sometimes several), costochondral joints. It usually involves either the second or third costochondral junctions. There must be obvious physical signs of inflammation, such as erythema, swelling, and warmth over the affected joint, for the diagnosis to be considered. It is a rare disorder of unknown etiology. Tietze's syndrome is more common in those under 40, and affects both sexes equally.



Inverted C-shape tracer uptake in chronic Tietze's disease. **A** Anterior pinhole scan in a 63-year-old man with tender swelling for 2 months in the left first costochondral junction shows inverted C-shape tracer uptake (*arrow*). **B** Posteroanterior radiograph shows nonspecific calcification (*arrow*). **C** Conventional X-ray tomograph shows inverted C-shape ossification in the costochondral junction (*arrow*) [Bahk Y-W. Infective and Infl ammatory Diseases of Bone. In: Combined Scintigraphic and Radiographic Diagnosis of Bone and Joint Diseases [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2013 [cited 2016 Nov 7]. p. 75–106. Available from: http://link.springer.com/10.1007/978-3-642-25144-3_6] *Caption from original*

- Xiphodynia/xiphalgia. Sharp, pleuritic chest pain that is reproduced by light palpation of the xyphoid process.
- Precordial catch syndrome (sometimes called texidor twinge). Fleeting (lasting seconds to minutes), lancinating episodes of chest pain, often precipitated by deep inspiration.
- Slipped rib syndrome. Pain and often a feeling of fullness usually along the inferior margin of the anterior tenth rib. There is often point tenderness and reproduction of the symptoms with pressure. Thought to be secondary to hypermobility of the distal costal cartilage that occurs after lifting or twisting. More commonly diagnosed in women.
- Sternalis syndrome. Localized tenderness over the sternum thought secondary to inflammation of the overlying sternalis muscle. Rare, more common in women, and often causes bilateral pain, especially with palpation.
- Sternoclavicular subluxation. Another rare diagnosis, marked by spontaneous or traumatic subluxation of a sternoclavicular joint. More commonly noted on the side of the dominant hand, and worsens with pulling and lifting motions. Mostly seen in women 40 – 60 years old, and associated with moderately heavy repetitive tasks.

Pathophysiology and Etiology

- The pathophysiology of costochondritis is felt to primarily involve inflammation of the costochondral junctions. The inflammation may be spontaneous and idiopathic, or may be related to injuries cause by trauma or overuse.

Presentation

Typical/"Classic"

- Chest pain that that is highly localized, and consistently reproducible by light palpation over a small area.
- Usually described as sharp and pleuritic, and often worsens when changing positions, coughing, and sneezing.
- Onset can be sudden, but is more often gradual and insidious.

Atypical

- May present as dull, diffuse pain that is poorly localized.

Primary Differential Considerations

- Initial consideration to patients presenting with these symptoms should be given to the following differential diagnoses:
  - Acute coronary syndrome
  - Pulmonary embolism
  - Pericarditis
  - Pleurisy
  - GERD
  - Herpes zoster (shingles)

History and Physical Exam

Findings That Confirm Diagnosis

- It must be stressed that all the life-threatening causes of chest pain must always be considered in patients presenting with a complaint of chest pain.
- It must also be stressed that reproducibility and chest wall tenderness are not sensitive or specific signs, and they can also occur with acute coronary syndromes.
- The diagnosis can usually be confirmed, after more serious causes of have chest pain have been excluded (either by history and physical or testing), when there is a discrete area of tenderness in which the pain is consistently reproduced by light palpation.

Factors That Suggest Diagnosis

- Chest pain that is sharp, localized, and consistently reproducible by light palpation.

Factors That Exclude Diagnosis

- Chest wall pain syndromes can coexist with many other causes of chest pain, and as such can only be excluded when there is no complaint of chest pain.

Ancillary Studies

Laboratory

- Laboratory studies are inly useful in excluding other diagnoses. There are no laboratory studies that help in the diagnosis of costochondritis or other chest wall pain syndromes.

Imaging

- Imaging studies are only helpful in the exclusion of other diagnoses.

Special Populations

Age

- Costochondritis is more common above the age of 40, but can be diagnosed in any adult age group.
- Costochondritis can affect children as well as adults.
- In some studies of musculoskeletal chest pain in children, costochondritis accounted for nearly 15 percent of final diagnoses.

Co-morbidities

- Costrochondritis can coexist with any other diagnosis. There are no co-morbidities of significance.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is critically important to first consider the life-threatening causes of chest pain.

Mimics

- Costochondritis can present similarly to other, more serious causes of chest pain, such as pulmonary embolism and acute coronary syndrome.

Time-Dependent Interventions

- There are no time-dependent interventions.

Overall Principles of Treatment

- Costochondritis and the other musculoskeletal chest pain syndromes are usually self-limited conditions.
- Treatment is usually conservative, and starts with reassurance that no more serious condition exists.
- Treatment is usually with simple analgesics such as acetaminophen. If acetaminophen is unsuccessful, a trial of NSAIDs may be appropriate.
- In situations where the precipitating event is felt to be trauma or overuse, a short period of rest may be helpful.
- In situations where the pain is well localized, a trial of capsaicin cream, NSAID creams or patches, or lidocaine patches may be helpful.
- In resistant cases, it may be necessary to refer to a pain center for local injections of a glucocorticoid/local anesthetic mixture.

Disease Course

- The course of costochondritis and the other chest wall pain syndromes is generally benign and self-limited and will resolve spontaneously within 2–3 weeks or a month.

Chapter 21
Cyanide Poisoning

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Cyanide Poisoning

Incidence/Epidemiology

- Rare occurrence
- Usually in association with smoke inhalation from a residential or industrial fire
- Occasionally seen as suicidal ingestion

Differential Diagnosis

- Myocardial infarction

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_21

- Meningitis and encephalitis
- Hemlock poisoning
- Pulmonary embolism
- Cardiogenic shock
- Ischemic stroke
- Carbon monoxide toxicity
- Hydrogen sulfide toxicity
- Iron toxicity
- Isoniazid toxicity
- Nonsteroidal anti-inflammatory drug toxicity
- Azide toxicity
- Methanol toxicity
- Strychnine toxicity

Pathophysiology and Etiology

- Mitochondrial toxicity by binding cyanide to ferric ion ($Fe3^{+}$). Oxidative phosphorylation ceases, leading to anaerobic metabolism.
- Rapidly absorbed through gastrointestinal tract and skin
- Rapidly lethal
- Exposure may be
  - From smoke inhalation/fire
    - Formed when structures containing both carbon and nitrogen (such as polyurethane) burn
  - Industrial
    - From metal extraction, electroplating
  - Medical
    - Use of some antineoplastic agents (such as amygdalin) and other infusions (such as nitroprusside) may result in accumulation of toxic levels of cyanide.
  - Diet
    - Fruit pits and bitter almond contain cyanogenic glycosides
  - Tobacco abuse
    - At baseline, chronic smokers have significantly higher blood levels of cyanide than nonsmokers

Presentation

Typical/"Classic"

- Symptoms depend on severity and route of poisoning.
- Central nervous system symptoms, including headache, anxiety, confusion, vertigo, coma, and seizures, are most prominent.
- Also prominent are cardiovascular symptoms, including tachycardia, hypertension then bradycardia and hypotension, atrioventricular block, and ventricular dysrhythmias.
- Skin and lip flushing also may be seen.

Atypical

- Lower-level exposure may delay the onset of the aforementioned signs and symptoms.
- Nausea and vomiting
- Muscular twitching

Primary Differential Considerations

- Because of the wide range of signs and symptoms, the differential is quite large and includes exposure to tricyclic antidepressants, organophosphates, methemoglobin, strychnine, carbon monoxide, or arsine.

History and Physical Exam

Findings That Confirm Diagnosis

- There is no clinical confirmation of cyanide toxicity. This is a laboratory diagnosis in a challenging clinical setting in which early testing of arterial blood gas and lactate levels is important.

Factors That Suggest Diagnosis

- Bright red venous blood
  - Despite hypotension, apnea, or bradycardia, cyanosis usually is not present.
- After hydrogen cyanide inhalation:

  - Bitter almond odor
  - Headache, anxiety, nausea, and metallic taste
- After cyanogen chloride inhalation:
  - Eye and mucous membrane irritation, bronchorrhea, cough, and dyspnea
- After dermal exposure/ingestion:
  - Delayed symptoms: minutes to hours
- After parental exposure:
  - Confusion and combativeness initially may be mistaken as intensive care unit (ICU) syndrome
- After ingestion
  - Nausea and vomiting
  - Large quantities of such foods may result in toxicity

The starchy roots of the cassava plant (*Manihot esculenta*) contain cyanide. The roots are a staple in the diet of people living in the tropics, and inadequate processing of the roots can lead to cyanide poisoning [Lottermoser BG. Mine wastes [Internet]. Berlin, Heidelberg: Springer; 2010. Chapter 5, Cyanidation wastes of gold-silver ores; [cited 2015 Aug 13]; p. 243-262. Available from: http://link.springer.com/10.1007/978-3-642-12419-8_5] *Caption from original*

Factors That Exclude Diagnosis

- There is no clinical exclusion for cyanide poisoning when the presentation is suggestive.

Ancillary Studies

Laboratory

- Basic metabolic panel to assess for anion gap metabolic acidosis
- Serum lactate:
  - Closely correlates with severity of cyanide toxicity
  - A normal level casts doubt on true cyanide poisoning.
  - Levels may be used to monitor treatment progress.
- Central venous blood gas to assess venous arterial PO2 gradient
- Carboxyhemoglobin and methemoglobin levels in concomitant carbon monoxide exposure
- Cyanide levels:
  - May be obtained for diagnostic confirmation, but results will not be available in time to be clinically useful and may be unreliable
  - Levels do not correlate directly with survivability.

Special Populations

Age

- Sodium nitrite–induced 20–30 % level of methemoglobinemia may be lethal in children or anemic patients and should not be given to pregnant patients.
- Pediatric patients are thought to be vulnerable to cyanide exposure because of their higher respiratory rates and immature detoxification systems.

Co-morbidities

- Patients with limited cardiopulmonary reserve who are exposed to cyanide have a poorer prognosis.

Pregnancy

- Fetal demise is possible in cyanide poisoning. Aggressive support and antidotal treatment of the mother are essential.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- The presentation of carbon monoxide poisoning from smoke inhalation is similar to that of cyanide poisoning; thus, clinicians often focus on carboxyhemoglobin levels, neglecting coexistent cyanide toxicity.

Mimics

- Mimics of cyanide poisoning include those listed as differential considerations, especially
  - Carbon monoxide poisoning
  - Phosgene exposure
  - Hydrogen sulfide poisoning
  - Arsine exposure
  - Inert gas exposure

Time-Dependent Interventions

- If clinical history and exam suggest cyanide poisoning, antidotal therapy must be given immediately.

Overall Principles of Treatment

- Decontaminate as soon as possible, removing patient from cyanide source.
  - Rescuers should wear protective suits and respirators until proper decontamination is complete.
- Antidotal treatment involves three strategies: binding of cyanide, use of sulfur donors, and induction of methemoglobinemia.
  - Hydroxocobalamin, a precursor of vitamin B_{12}, contains a cobalt moiety that avidly binds to intracellular cyanide, forming cyanocobalamin.

    - Cyanocobalamin is excreted in urine.
- Sodium thiosulfate
    - Sulfur donor excreted renally
- +/− Sodium nitrite
    - Induces methemoglobinemia, with the goal of a 20–30 % methemoglobin level if tolerated
    - It is CONTRAINDICATED in cases of potential carbon monoxide toxicity.
    - May cause hypotension and tachycardia, vasodilation

Disease Course

- Prognosis depends on level of exposure and extent of symptoms at presentation.
- Even in patients with severe symptoms such as seizures at presentation, prompt administration of antidote improves prognosis.
    - The exception is cardiac arrest, in which even early antidote administration is unlikely to reverse the very poor prognosis.
- Patients who survive cyanide poisoning sometimes have long-term central nervous system complications, such as movement disorders and neuropsychiatric problems.
- Suicide attempts with cyanide often are successful because of the deliberately high toxin load.

Chapter 22
Cyanotic Congenital Heart Disease

Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Cyanotic Congenital Heart Disease

- Refers to a subset of congenital cardiac malformations that favor the development of variable degrees of cyanosis.
- The vast majority of malformations will present in the newborn period and will be diagnosed in the neonatal setting.
- There are, however, variant forms which will "escape" neonatal diagnosis and have their initial cyanotic presentations in the Emergency Department.
- Late presentations are usually encountered in infants with ductus-dependent lesions necessary for pulmonary blood flow (generally left sided outflow obstructions such as hypoplastic left ventricle or coarctation of the aorta).

Incidence/Epidemiology

- Fifteen to 20 percent of all congenital heart disease cases are of the cyanotic variety.
- Cyanotic forms account for nearly 30 percent of fatal cases.

R. M. Cantor

C. V. Pollack, Jr. (✉)
Department of Emergency Medicine, Thomas Jefferson University, Philadelphia, PA, USA

J. F. Blanck
Welch Medical Library, Johns Hopkins University, Baltimore, MD, USA

© Springer Nature Switzerland AG 2019

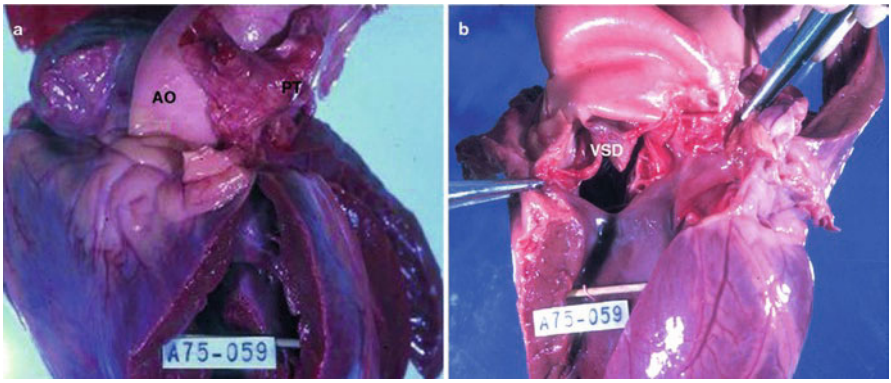
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_22

Differential Diagnosis

- Should be considered in the differential diagnosis of cyanotic congenital heart disease, often represented by the "5 T's":
  - Truncus Arteriosus
  - Transposition of the Great Arteries
  - Tricuspid Atresia
  - Tetralogy of Fallot
  - Total Anomalous Pulmonary Venous Return
- There are other causes of cyanosis in young infants, most traditionally classified into pulmonary insults and hemoglobinopathies (i.e., Methemoglobinemia)

Pathophysiology and Etiology

- The essential common pathway that serves as the basis for all congenital cyanotic cardiac lesions is an inability to deliver oxygen to the general circulation and therefore peripheral target organs.
- The predominant pathophysiology involves variable degrees of right-to-left shunting. Systemic (deoxygenated) blood is unable to access the alveoli, returning to the left side of the heart without being oxygenated. In most cases of cyanotic heart disease, the shunt is intracardiac.



Tetralogy of Fallot. (a, b) Tetralogy of Fallot, the most common cause of cyanotic congenital heart disease, consists of a membranous VSD right ventricular outflow obstruction, rightward displacement of the aorta (AO), and secondary right ventricular hypertrophy. The right ventricular outflow obstruction may take the form of hypoplasia of the pulmonary trunk (PT), pulmonary valvular malformation and stenosis, outflow tract (infundibular) hypoplasia and narrowing, or a combination of all

three components, as seen in this case [Buja LM, Cheong B. Cardiovascular Pathology. In: Krueger GRF, Buja LM, editors. Atlas of Anatomic Pathology with Imaging [Internet]. London: Springer London; 2013 [cited 2016 Jul 29]. p. 43–104. Available from: http://link.springer.com/10.1007/978-1-4471-2846-5_2] *Caption from original*

Presentation

Typical/"Classic"

- Most entities will present within the first few hours of life, with diagnosis made before discharge from the newborn unit.
- Other entities, specifically those with ductal dependency, will only present when the duct closes. The infants will present with varying degrees of shock and/or cyanosis (usually left sided outflow obstructive lesions such as an interrupted aortic arch).

Atypical

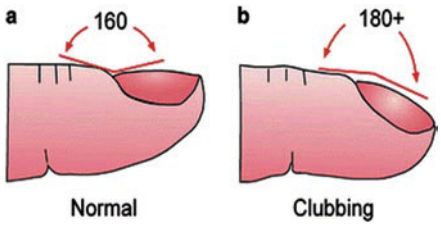
- Infants with Tetrology of Fallot may "escape" diagnosis in the first few days of life, presenting to the ED with what are known as "Tet (hypercyanotic) Spells."
- Management of Hypercyanotic Spells:
  - Provision of supplemental oxygen.
  - Placement in the knee chest position.
    - Sedation with morphine (0.1 mg/kg/dose)
    - Administration of 10-20 cc/kg of normal saline
    - Immediate consultation with a pediatric cardiologist

Primary Differential Considerations

- These specific diagnoses should be considered in patients who present with signs and symptoms of congenital cyanotic heart disease:
  - tricuspid atresia
  - Ebstein's malformation of the tricuspid valve
  - severe pulmonic stenosis with intact ventricular septum
  - complete transposition of the great vessels
  - truncus arteriosus.

History and Physical Exam

- As previously described, the majority of cyanotic congenital lesions will be diagnosed and treated within the first few days of life.
- In some patients, cyanotic presentations may be quite dramatic, unresponsive to any degree of supplemental oxygen (the hyperoxia test).
- Other patients will present with hypoperfusion and frank hypotension. Administration of isotonic volume replacement will often worsen the clinical status, alerting the clinician to the possibility of a cardiogenic etiology as the cause of shock.
- Each particular malformation has a specific set of physical and radiographic findings.
- The presence or absence of a murmur is variable and often not integral in making the diagnosis.



Clubbing. (**a**) The angle at the junction of skin with the nail at the dorsal surface of digits is normally around 160°. (**b**) In children with cyanotic congenital heart diseases this angle becomes wider and may exceed 180°. This is the result of hypoxia in peripheral tissue, which causes the opening of normally collapsed capillaries to better perfuse the hypoxic tissue. Perfusion of these collapsed capillaries will result in expansion of the volume of these peripheral tissues (tips of digits) resulting in clubbing. This phenomenon is seen in other lesions causing hypoxia of peripheral tissue, such as with chronic lung disease and chronic anemia (causing hypoxia through reduction of level of hemoglobin and therefore reduction of oxygen carrying capacity) such as with ulcerative colitis, Crohn's disease, and chronic liver disease [Thompson WR, Mehrotra SM. Cardiac History and Physical Examination. In: Abdulla R, editor. Heart Diseases in Children [Internet]. Boston, MA: Springer US; 2011 [cited 2016 Jul 29]. p. 3–16. Available from: http://link.springer.com/10.1007/978-1-4419-7994-0_1] *Caption from original*

Findings That Confirm Diagnosis

- Echocardiography remains the gold standard.

Factors That Suggest Diagnosis

- The use of the hyperoxia test is traditionally employed to differentiate between pulmonary, cardiac, and hematologic causes of cyanosis in infancy.
- Administer supplemental oxygen.
- If OSAT rises, it is most likely pulmonary disease.
- If OSAT does not rise, consider Cyanotic Heart Disease *or* Methemoglo binemia.
- With the patient on 100% supplemental O_2, and the pO_2 is high and OSAT is low, consider Methemoglobinemia as an etiology,
- With the patient on 100% supplemntalO_2, and the pO_2 is low *and* the OSAT is low, consider cyanotic heart disease as an etiology.

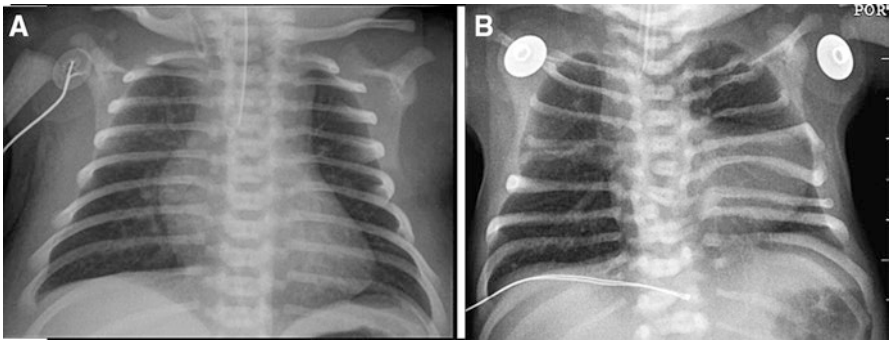
Factors That Exclude Diagnosis

- A normal echocardiogram.

Ancillary Studies

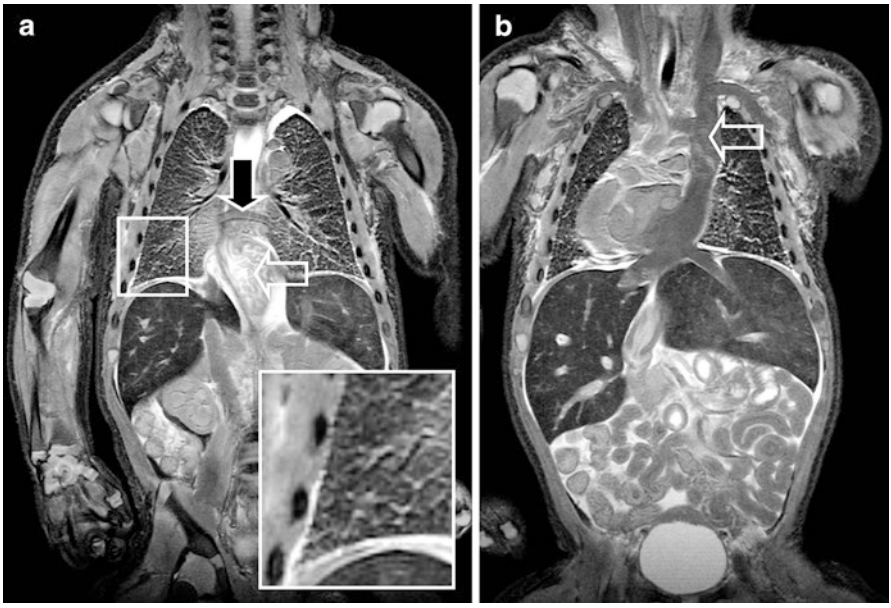
Imaging

- There are certain classic radiographic findings associated with specific forms of cyanotic heart disease in infants:
  - Cardiomegaly is seen with left-sided outflow obstructive lesions.
  - A boot-shaped heart is seen with Tetralogy.
  - An "egg-on-a-string" pattern is seen with Transposition.



Utility of chest radiography in CHD. A: Chest radiograph of a neonate with d-transposition of the great arteries, appearing as an "egg on a string" appearance of the

heart and mediastinum. This pattern-based approach to cardiac morphology is inaccurate and is rarely helpful for clinical management. Cardiac morphology is determined by echocardiography in the neonatal period while the chest radiograph sheds light on physiology. B: Neonate with complex cyanotic congenital heart disease, including mitral atresia, total anomalous pulmonary venous connection to the coronary sinus, double outlet right ventricle, and pulmonary stenosis. The chest radiograph demonstrated decreased pulmonary vascularity, which enabled decision-making regarding initial palliative treatment. The pulmonary blood flow was augmented using a modified Blalock–Taussig shunt. [Krishnamurthy R, Chitkara P. Evidence-Based Approach to Imaging of Congenital Heart Disease. In: Medina LS, Applegate KE, Blackmore CC, editors. Evidence-Based Imaging in Pediatrics [Internet]. New York, NY: Springer New York; 2010 [cited 2016 Jul 29]. p. 339–58. Available from: http://link.springer.com/10.1007/978-1-4419-0922-0_24] *Caption from original*



A neonate with a congenital cyanotic heart disease born at 39 weeks. Maximum support and 100% oxygen did not lead to clinical improvement and the child died. T2-W coronal MRI shows a complete anomalous venous return (arrow) with pulmonary interstitial oedema (insert). A central tendon defect is seen (open arrow) (slice thickness: 2 mm, TR: 5500, TE: 54, FA: 180°). **b** T2-W coronal MRI shows a persistent left superior caval vein (arrow), a dextrocardia and situs intermedius of the liver. Asplenia was also noted [From article: Current techniques in postmortem imaging with specific attention to paediatric applications. Pediatric Radiology. 2010

- Cardiac Enzymes
- Not indicated.

Special Populations

Age

- As discussed, most cases are diagnosed in the first few days of life.

Co-morbidities

- TAPVR is associated with asplenia or polysplenia.

Pitfalls in Diagnosis

- Cyanotic variant
  - Emergency pediatric cardiology consultation is warranted.
- Acyanotic variety
  - Adherence to strict algorhythmic workups of neonatal CHF or respiratory distress will eventually uncover the lesion.

Critical Steps Not to Miss

- Provision of supplemental oxygen
- Early ventilator support
- Immediate PICU or Pediatric Cardiology consultation

Mimics

- Any congenital cardiac lesion causing cyanosis and/or CHF

Time-Dependent Interventions

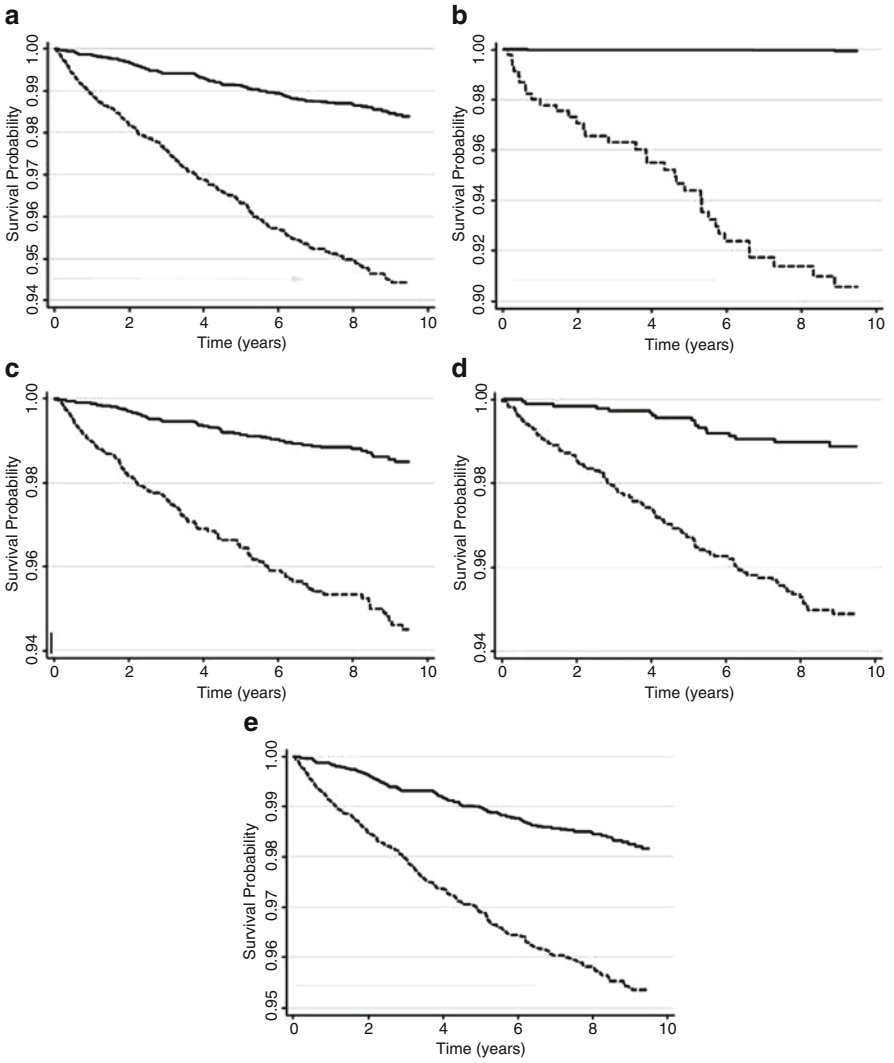
- All interventions are emergent.

Overall Principles of Treatment

- Support oxygenation.
- Urgent echocardiography.
- Arrange specialty consultation to evaluate for surgical management.

Disease Course

- Surgical correction is almost always indicated—the earlier the better.
- Long-term outcomes are dramatically improved after full correction (less than 5%).



Cox survival curves adjusted for age and sex with surgery (solid line) and without surgery (dashed line) of congenital heart diseases patients. Time = 0, time at one and half year of follow-up. (A) Overall congenital heart diseases; (B) Cyanotic congenital heart diseases; (C) Noncyanotic congenital heart diseases; (D) ventricular septal defect; (E)ostium or secundum type atrial septal defect. Chapter 23
Cystic Fibrosis

Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Cystic Fibrosis; CF

- The most common autosomal dominant longevity-reducing disorder among Caucasian groups.

Incidence/Epidemiology

- Cystic fibrosis has a reported incidence of 1 in 2,500 live births.
- Although it is most commonly reported in Caucasian children, due to enhanced diagnostic testing, recognition of cases in non-white populations are on the rise.
- The median predicted survival rate is approximate 37 – 38 years.

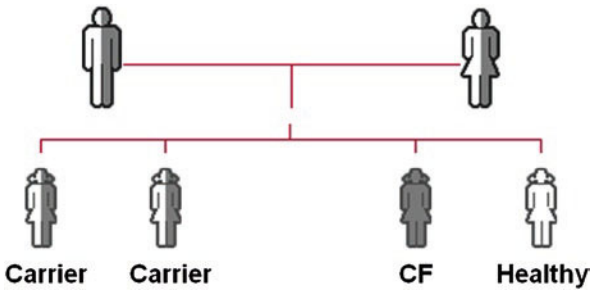
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_23

Differential Diagnosis

- Any immune deficiency disorder may present with pulmonary findings commonly seen in CF.

Pathophysiology and Etiology

- CF is transmitted genetically in an autosomal dominant pattern.



Cystic fibrosis inheritance pattern. This figure shows the inheritance pattern for children born with cystic fibrosis. If both the mother and father are carriers of the gene then they have a one in four chances of having a child with cystic fibrosis [Murphy AJ, Davies PSW. Anthropometry in Children with Cystic Fibrosis. In: Preedy VR, editor. Handbook of Anthropometry [Internet]. New York, NY: Springer New York; 2012 [cited 2015 Sep 14]. p. 1571–83. Available from: http://link.springer.com/10.1007/978-1-4419-1788-1_96] *Caption from original*

- The disorder is secondary to mutations in the cystic fibrosis trans membrane conductance regulator (CFTR) protein.
- The mutation impairs normal transport of chloride and other ions, leading to the production of thick viscous secretions commonly seen in target organs such as the lungs, liver, pancreas, and reproductive tract.

Presentation

Typical/"Classic"

- Most cases are detected by newborn screening and performance of sweat chloride testing in identified infants and children.
- There is a myriad of clinical manifestations of CF, including:

- Respiratory
  - Chronic cough
  - Sinusitis
  - Asthma
  - Bacterial colonization of the respiratory tract
- Clubbing of the digits

Clubbing of the fingers [Karkucak M, Erturk E, Capkin E, Akyazi H, Ozden G, Tosun M. Primary hypertrophic osteoarthropathy (pachydermoperiostosis): a case report. Rheumatology International. 2007 Jan 11;27(4):403–5.] *Caption from original*

- Nasal polyps

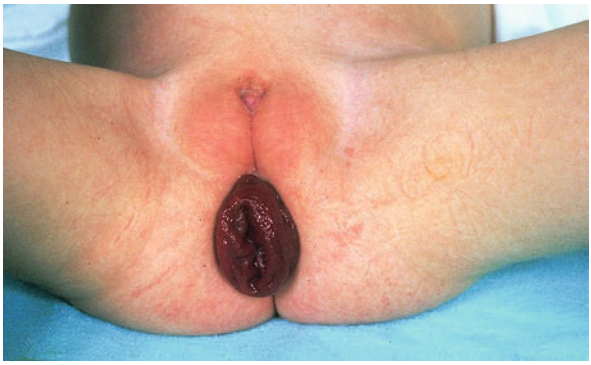
A pedunculated nasal polyp in a patient with cystic fibrosis. The polyp is obstructing the left nostril. Polyps commonly arise from the maxillary antrum. Chronic inflammation results in vasodilatation and edema of the mucosa. This initially

causes mucosal hypertrophy, resulting in irregular folds within the mucosa. As the mucosa enlarges, it may herniate into the nasal cavity, creating a pedunculated polyp that may completely occlude the middle meatus. [MacLusky I, Solomon M, Laxer R, Ford-Jones EL, Friedman J, Gerstle T. Atlas of Pediatrics, Volume IA, Chapter 14. In: Laxer RM, editor. The Hospital for Sick Children: Atlas of Pediatrics. Philadelphia, PA: Current Medicine Group; 2005. 519 p. ISBN 1-57340-188-9] *Caption from original*

- Gastrointestinal
  - Varying degrees of pancreatic insufficiency
  - Meconium ileus

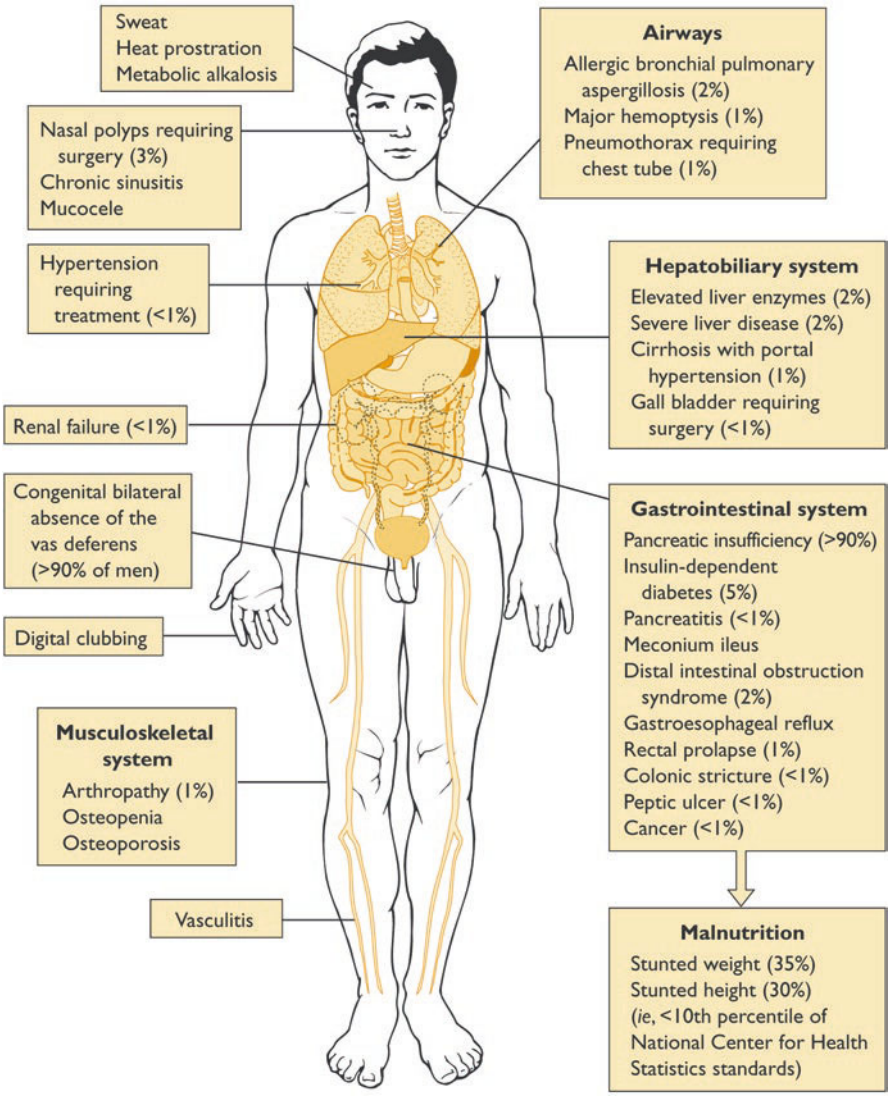
Meconium ileus in cystic fibrosis. The bowel lumen is plugged with meconium [Gilbert-Barness E, Spicer DE, Steffensen TS. Gastrointestinal (GI) System. Handbook of Pediatric Autopsy Pathology [Internet]. New York, NY: Springer New York; 2014 [cited 2015 Sep 14]. p. 355–75. Available from: http://link.springer.com/10.1007/978-1-4614-6711-3_10] *Caption from original*

- Secondary diabetes
- Pancreatitis
- Vitamin deficiencies
- Rectal prolapse



Rectal prolapse, which usually occurs during passage of a large bowel motion, can be a frightening condition for parents of young children. It is hardly ever associated with major medical complications and is easily reduced manually. This condition usually resolves spontaneously by 3 to 4 years of age. Surgical intervention is not advocated, unless the condition is persistent. [Durie P. Chapter 09. In: Hyman P, editor. Gastroenterology and Hepatology, Volume 04. Philadelphia: Current Medicine; 1996 (Feldman M, series editor) ISBN: 0-443-07852-1] *Caption from original*

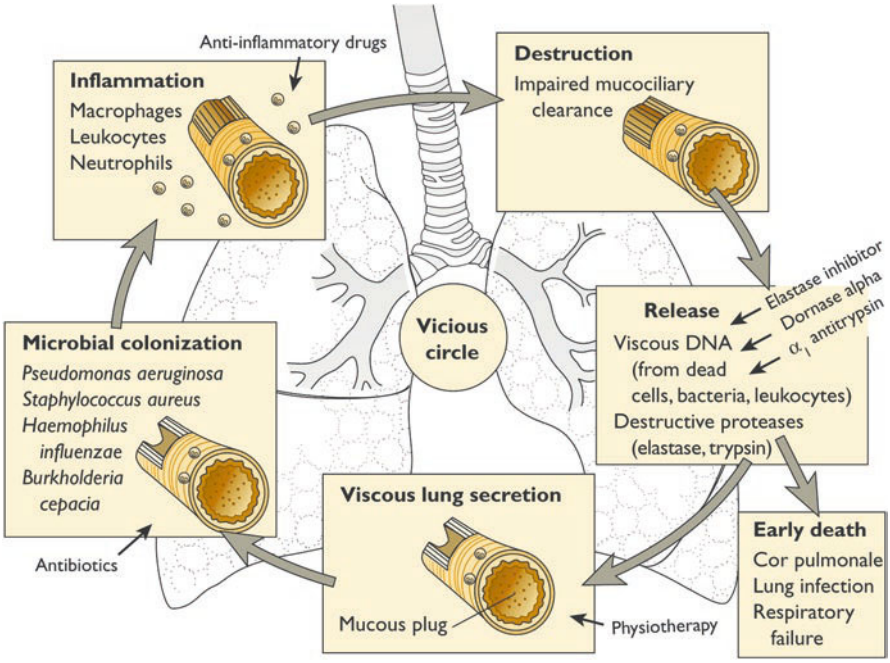
- Genitourinary
  - Male infertility



Clinical manifestations and co-morbidity of cystic fibrosis. Cystic fibrosis is associated with numerous complications and co-morbid conditions. As indicated in the figure, almost every patient with cystic fibrosis who lives long enough will eventually develop pulmonary symptoms. However, the age of onset, the rate at which cystic fibrosis progresses, and the incidence of co-morbid conditions are extremely variable. The 1999 incidence of some of these manifestations and co-morbid conditions, obtained from the Cystic Fibrosis Foundation Registry, are provided in parentheses. It is important to note that the incidence of most of these conditions increases significantly with age and disease progression. Thus, the prevalence of some

conditions (e.g., liver disease and diabetes mellitus) in a clinical setting that includes adolescents and young adults may be significantly higher than these figures suggest. [Coakley R. Boucher R. Fiel S. Schidlow D. Chapter 04. In: Crapo J, editor. Bone's Atlas of Pulmonary and Critical Care Medicine. 3rd ed. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-211-7] *Caption adapted from original*

- The most common clinical presentations are overwhelmingly pulmonary in nature, including chromic cough with sputum production, dyspnea, and signs of respiratory insufficiency.



The "vicious circle" of lung disease in cystic fibrosis. Cystic fibrosis is a genetic form of chronic bronchitis characterized by a vicious circle of obstruction, infection, and inflammation related to impaired local host-defense mechanisms. This produces progressive bronchiectasis and, ultimately, respiratory failure. Despite the identification of the CFTR gene and characterization of its role as an ion channel, intense efforts are still under way to understand how defective transepithelial electrolyte transport leads to the devastating consequences seen throughout the airways. [Coakley R. Boucher R. Fiel S. Schidlow D. Chapter 04. In: Crapo J, editor. Bone's Atlas of Pulmonary and Critical Care Medicine. 3rd ed. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-211-7] *Caption from original*

- Most infants and children will have already been diagnosed in the first few months of life.

Atypical

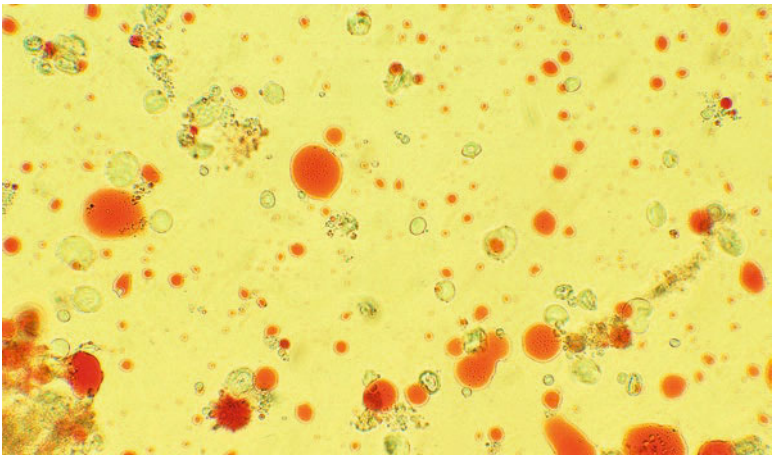
- Any of the aforementioned symptoms and signs may present.

Primary Differential Considerations

- Cystic fibrosis is a distinctive syndrome, but in early stages it may be confused with acute lung or sinus infections. Asthma and metabolic/nutritional disorders may also be differential considerations.

History and Physical Exam

- The history will reveal progressive symptoms and signs of respiratory compromise. The patient will most often have been diagnosed by abnormal screening and confirmatory testing.
- In older children, the cough is productive. In infancy, this finding is masked by the propensity of these children to swallow their secretions.
- Physical examination findings may include:
  - Poor weight gain
  - Clubbing
  - Dyspnea
  - Wheezing
  - Signs of pneumonia
  - Steatorrhea



Steatorrhea by fecal Sudan stain. This photomicrograph stool sample demonstrates the presence of large amounts of fat by Sudan stain. This test is qualitative and

should only be used as a screening tool for gross steatorrhea, but in this particular patient it reveals the presence of a large amount of fat in the stool. [Vanderhoof J. Chapter 06. In: Hyman P, editor. Gastroenterology and Hepatology, Volume 04. Philadelphia: Current Medicine; 1996 (Feldman M, series editor) ISBN: 0-443-07852-1] *Caption from original*

- Increased AP diameter
  - Typical symptoms suggesting the presence of CF include:
    - Meconeum ileus (25% of patients)
    - Respiratory symptoms (50% of patients)
    - Failure to thrive (25% of patients)

Findings That Confirm Diagnosis

- Abnormal sweat chloride and genetic testing

Factors That Suggest Diagnosis

- Any infant or child with failure to thrive and the early development of pulmonary compromise.

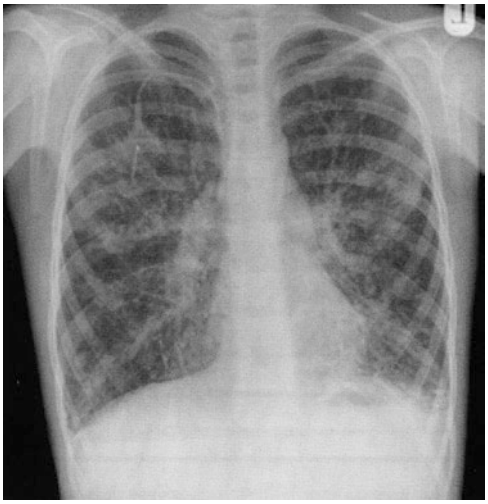
Factors That Exclude Diagnosis

- Normal screening tests

Ancillary Studies

Imaging

- Initial radiographs may be normal, with the eventual development of hyperinflation. Inevitably, the chronic nature of the disease will result in the development of bronchiectasis and cyst formation. In addition, pneumothoraces may develop.



Advanced cystic fibrosis (CF). This is a chest radiograph of a 14-year-old boy with advanced CF. It demonstrates the typical changes of end-stage CF. There is marked generalized hyperinflation. Both lungs demonstrate diffuse bronchial wall thickening, with "tram tracking" (parallel lines due to thickening and absence of tapering of the bronchial walls), most evident in the left lower lobe, indicative of bronchiectasis. There are also scattered peripheral acinar infiltrates, especially in the left apex and in both lung bases, as well as blunting of the left costrophenic sulcus, due to recurrent, long-standing pneumonia. The heart size is within normal limits given the degree of lung hyperinflation. A central line is in place to provide antibiotics. [MacLusky I, Solomon M, Laxer R, Ford-Jones EL, Friedman J, Gerstle T. Atlas of Pediatrics, Volume IA, Chapter 14. In: Laxer RM, editor. The Hospital for Sick Children: Atlas of Pediatrics. Philadelphia, PA: Current Medicine Group; 2005. 519 p. ISBN 1-57340-188-9] *Caption from original*

Electrocardiography

- With the development of chronic lung disease, signs of right-sided strain/hypertrophy will be evident.

Cardiac Enzymes

- Not indicated.

Special Populations

Age

- As discussed under Presentation, most cases are diagnosed in the first few weeks of life.

Co-morbidities

- The gene mutation in CF damages the hepatobiliary system. Diabetes may develop.

Pitfalls in Diagnosis

- Consider CF in all cases of chronic, progressive pulmonary dysfunction.

Critical Steps Not to Miss

- Early administration of bronchodilators
- Radiographic monitoring
- Cultures of expressed sputum
- Consultation with pediatric pulmonology

Mimics

- Any chronic lung disease

Time-Dependent Interventions

- Acute reversal of bronchospasm
- Provision of targeted antibiotics

Overall Principles of Treatment

- The primary goal in CF management is to maintain the patient's lung function to as high a level as possible, for as long as possible. Nutritional support is also important to both quality and quantity of life for patients with CF. Sound and prudent use of antibiotics both treats acute exacerbations and helps protect against antimicrobial resistance.

Organ System	Assessment	Therapy
Pulmonary	Clinical	Daily physiotherapy
	Routine spirometry	Antibiotics: based on sputum culture
	Chest radiography	Daily (inhaled vs oral)
	Routine sputum cultures	For acute exacerbations (oral vs IV)
	Throat swabs in infants or toddlers	Oxygen (if hypoxemic)
		Lung transplant for end - stage disease
Nutrition	Regular growth assessment: height vs weight	Pancreatic enzyme supplementation; high - protein; high-fat diet; caloric supplementation (nasogastric or gastrostomy tube feeds) if persisting malnutrition
	Skin-fold measurement	
	Fecal fat % (dietary intake)	
Gastroenterologic		
Meconium ileus	Clinical: neonate with vomiting, failure to pass meconium	Medical: N-acetylcysteine enema
	Abdominal radiography: gastric and small bowel distention ± “soap bubble” appearance in small bowel	Surgical: decompression - resection of obstructed segment, defunctioning ileostomy
	Contrast enema: meconium obstruction of terminal ileum	
DIOS	Clinical: symptoms or signs of chronic partial distal ileal or cecal obstruction	Exclude surgical complication (appendicitis, intussusception, volvulus)
	Mass in right lower quadrant	Daily mineral oil, balanced intestinal lavage (Golytely, Peglyte®)
	Radiologic: obstructing stool mass in distal ileum or cecum	
Hepatobiliary	Liver function tests	Pancreatic enzymes (increases enterohepatic circulation)
	Abdominal ultrasound (cirrhosis, portal hypertension)	Ursodeoxycholic acid therapy
		Sclerosis of esophageal varices
		Liver transplant for end - stage liver failure
Metabolic		
CF-related diabetes	Glucose tolerance test (ketosis rare unless type 1 diabetes)	Low-dose insulin (potential for hypoglycemia)
		Maintain adequate caloric intake
Sodium chloride depletion	Hyponatremia or metabolic alkalosis: blood electrolytes and gases; urinary electrolytes	Sodium chloride – water repletion
		Prevention: daily electrolyte supplements in hot weather or in high -risk populations (infants and athletes)

Clinical management of cystic fibrosis (CF). [MacLusky I, Solomon M, Laxer R, Ford-Jones EL, Friedman J, Gerstle T. Atlas of Pediatrics, Volume IA, Chapter 14. In: Laxer RM, editor. The Hospital for Sick Children: Atlas of Pediatrics.

Philadelphia, PA: Current Medicine Group; 2005. 519 p. ISBN 1-57340-188-9] *Caption from original*

Disease Course

- Unfortunately, most patients will develop irreversible lung disease in early adulthood.

Chapter 24
Diabetic Ketoacidosis

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Diabetic Ketoacidosis; DKA

Incidence/Epidemiology

- Diabetic ketoacidosis (DKA) is classically thought to occur only with type 1 diabetes mellitus, but it can also occur with type 2 diabetes in the setting of severe physiologic stress (infection, trauma, acute MI, or acute CVA).
- It can also occur as a presenting syndrome of type 2 DM, especially in patients of Hispanic or African American origin.
- It is more common in children and young adults than in adults.
- The annual incidence ranges from 4–8 cases per 1,000 patients with diabetes.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_24

- Hospital admissions for DKA have been increasing. There were about 80,000 discharge diagnoses of DKA in 1989, in 2009 there were 140,000 discharge diagnoses of DKA, an increase of 50 %.
- Hospital length of stay for DKA has fallen in the same period from about 6 days to 3.5 days.
- Overall mortality has been declining for the last 20 years and now averages less than 5 % for all patients. This is likely due to improved recognition and care.
- Mortality is still much higher for the extremes of age and illness. Mortality is greater than 20 % in the elderly.

Differential Diagnosis

- The differential diagnosis of DKA includes all the causes of an elevated anion gap metabolic acidosis. The classic mnemonic for the causes of an elevated anion gap acidosis is MUD PILES:
  - **M**ethanol
  - **U**remia (renal failure)
  - **D**KA**,** alcoholic ketoacidosis, and starvation acidosis
  - **P**araldehyde/phenformin ingestion (medications that are no longer available)
  - **I**ron/INH overdose
  - **L**actic acidosis (from multiple causes such as sepsis, metformin overdose)
  - **E**thylene glycol ingestion
  - **S**alicylate overdose
  - Paraldehyde and phenformin are medications that are no longer marketed.
  - Other ingestions/exposures that should be included in this list are: carbon monoxide, cyanide, and toluene.
  - Other diagnoses to consider in the setting of hyperglycemia include: hyperglycemic, hyperosmolar, and nonketotic (HHNK) coma (also referred to as hyperosmolar hyperglycemic state [HHS] or diabetic hyperosmolar state [DHS]). In this disorder the hyperglycemia tends to be more severe (>600 mg/dl), with little or no elevation in the anion gap. It tends to occur in older patients, have a more prolonged onset and course, and is usually associated with more pronounced mental status changes than DKA. The mortality in HHNK is also higher than in DKA.

Finding	Mild DKA	Moderate DKA	Severe DKA	HHS
Plasma glucose (mg/dL)	>250	>250	>250	>600
Arterial pH	7.25–7.30	7.00–7.24	<7.00	>7.30
Serum HCO_3^- (mEq/L)	15–18	10–15	<10	>15
Serum or urine ketones	Positive	Positive	Positive	Small
Beta-hydroxybutyrate	High	High	High	Normal or high
Effective serum osmolality[a] (mOsm/kg)	Variable	Variable	Variable	>320
Anion gap[b]	Upper limits of normal or > normal	>Normal	Significantly > normal	Variable
Sensorium	Alert	Alert or drowsy	Stupor/coma	Stupor/coma

[a]Effective serum osmolality = 2 × measured Na^+ (mEq/L) + BUN (mg/dL)/2.8 + glucose (mg/dL)/18, >320–330 mOsm/kg associated with neurologic deterioration
[b]Anion gap = $(Na^+ + K^+) - (Cl^- + HCO_3^-)$

Diagnostic criteria in DKA and HHS [Shah SJ. Diabetic Ketoacidosis in the Urgent Anesthesia Setting. In: Benumof JL, editor. Clinical Anesthesiology [Internet]. New York, NY: Springer New York; 2014 [cited 2015 Nov 5]. p. 407–14. Available from: http://link.springer.com/10.1007/978-1-4614-8696-1_49] *Caption from original*

- The differential diagnosis prior to the identification of the metabolic abnormalities is much broader and based upon the presenting symptoms. These may include: sepsis/shock/hypovolemic syndromes, abdominal pain associated with nausea and vomiting, change in mental status, and tachypnea.

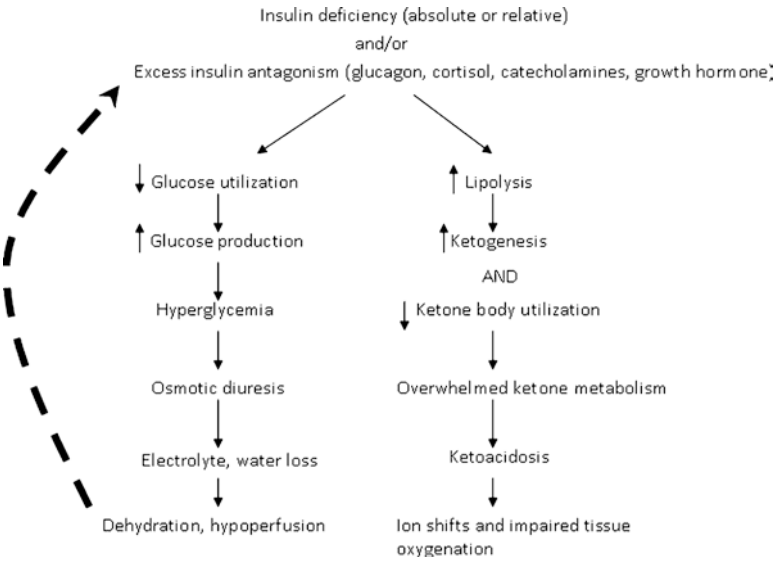
Pathophysiology and Etiology

- The primary pathophysiologic mechanism behind the development of DKA is an insulin deficiency, especially a lack of an appropriate insulin release to hyperglycemia.
- Cells require insulin to utilize glucose as a fuel source. In the absence of insulin, the body will seek alternative fuel sources. Catabolic (counterregulatory) hormones will be released that help break down and utilize protein and fat stores as fuel.
- The primary counterregulatory hormone is glucagon, but other involved counterregulatory hormones include catecholamines, cortisone, and growth hormone.
- The effect of these catabolic hormones is to increase gluconeogenesis and glycogenolysis, which in turn increases production of glucose and worsens hyperglycemia. Increasing both these processes also raises the production of byproducts and precursors such as free fatty acids and glycerol.

- Theses catabolic hormones also increase proteolysis. This boosts the amount of free glucogenic amino acids, which can be used with glycerol to produce glucose and worsen hyperglycemia.
- The free fatty acids that are produced during gluconeogenesis bind to albumin, and then are taken up by the liver, where they are converted to ketone bodies (beta-hydroxybutyrate [βHB], acetoacetic acid [AcAc], and acetone).
- Some body tissues can utilize ketone bodies for energy, but inefficiently. A low insulin level reduces the ability of brain, cardiac, and skeletal muscle to utilize ketones as an energy source, which increases the ketonemia.
- These ketone bodies are responsible for the metabolic acidosis of DKA.
- Under normal physiologic conditions, βHB and AcAc exist in a 1:1 equilibrium. During the increased lipolysis and ketogenesis of DKA, this ratio will approach 10:1. It is important to remember, however, that during insulin therapy, βHB will be metabolized at a faster rate than AcAc. This has important implications for monitoring therapy that will be discussed under the treatment section.
- Hyperglycemia causes an osmotic diuresis, resulting in profound fluid losses and volume depletion, which exacerbates hyperglycemia and ketonemia.
- The volume deficits can be profound and can lead to hypotension and shock.
- The osmotic diuresis also results in profound electrolyte losses (K, Na, Cl, PO2, Ca, Mg, and N).
- The acidosis causes a shift in potassium from intracellular to extracellular exacerbating total body potassium losses.
- In the setting of marked ketonemia, the kidney will exchange chloride for ketones, allowing the ketones to be excreted. The excretion of ketones leads to a decrease in potential bicarbonate, which leads in turn to less buffering capacity and then to worsening of the acidosis, which can lead to a hyperchloremic metabolic acidosis, in addition to the ketoacidosis.
- The breakdown of adipose tissue leads to an inflammatory response with the release of prostaglandins I2 and E2. These cause a peripheral vasodilation that can worsen hypotension and shock.
- Multiple factors and conditions are known to precipitate DKA. Many acute illnesses, as well as physiologic stress, can lead to hyperglycemia, and in the setting of insulin deficiency this leads to DKA.
- It is important to attempt to identify cause when a patient presents with DKA.
- In a significant minority of patients, no precipitating cause can be identified.
- The following list contains some of the common causes of DKA, but any acute illness and/or period of physiologic stress can initiate DKA, so this list is not exhaustive.

    - Reduction of or lack of daily insulin injections
    - Malfunction of insulin pump
    - Any acute infectious process
    - Acute MI
    - Stroke
    - Acute GI bleed

- Pregnancy
- Medications (especially steroids)
- Substance abuse (multifactorial, e.g., cocaine can cause hyperglycemia directly and then these patients forget or have no insulin available)
- Severe, acute illness or trauma



DKA pathophysiology. DKA is shown as unchecked lipolysis occurring alongside progressive water and electrolyte loss. Osmotic diuresis, progressive hypovolemia, and further reductions in glucose and ketone clearance in the absence of insulin creates a feed-forward loop that increases concentrations of antagonistic hormones and perpetuates the cycle [Steenkamp DW, Alexanian SM, McDonnell ME. Adult Hyperglycemic Crisis: A Review and Perspective. Current Diabetes Reports. 2013 Feb;13(1):130–7.] *Caption from original*

Presentation

Typical/"Classic"

- DKA develops acutely over a period of 24–48 hours.
- The early symptoms are often related directly to hyperglycemia with resultant osmotic diuresis and worsening volume loss (polydipsia/polyuria).
- As the metabolic abnormalities worsen and acidosis develops, tachypnea occurs as physiologic compensation to try and decrease the pCO2 to reduce the acidosis. Kussmaul respirations (a profound increase in the rate and depth of breathing) may develop.

- Diffuse, nonspecific abdominal pain associated with nausea and vomiting are common symptoms at presentation (especially in children). They are often related directly to DKA (prostaglandin release is felt to play a role) but can also indicate an underlying cause for the DKA.
- Vomiting contributes to the development of metabolic abnormalities, electrolyte losses, and the development of volume depletion and dehydration.
- As volume depletion worsens, the patient may develop clinical signs of shock with tachycardia, hypotension, and signs of poor perfusion (poor skin turgor, dry mucous membranes, peripheral cyanosis).
- Profound ketonemia (especially acetone) can cause a fruity odor on the breath.
- A change in mental status may occur, but is more common in HHNK. It is felt to be multifactorial and related to volume depletion, metabolic acidosis, hyperosmolarity, and hemodynamic abnormalities.

Atypical

- DKA is associated with multi-organ dysfunction. As such, it is associated with multiple, varying symptoms and presentations as above.
- Fever may be present due to an underlying infection, but it is important to remember that the absence of fever does not exclude underlying infection as a cause for DKA.
- DKA may present with the symptoms of the underlying causative disorder.
- Hypothermia may be present due to peripheral vasodilation from prostaglandin release.
- Abdominal pain with nausea and vomiting are frequent presenting symptoms of DKA as discussed in Typical/"Classic", above. However, abdominal pain and other abdominal symptoms may be due to the underlying cause. Acute pancreatitis can be both a cause and an effect of DKA. Lipase may be elevated in both situations, so it is often difficult to make the distinction.
- An alteration of decrease in the level of consciousness may occur, but is more commonly seen in HHNK. An altered level of consciousness seems to be more associated hyperosmolarity than with acidosis.

Primary Differential Considerations

- DFKA is a rather distinctive clinical entity. It is most likely to be confused with hyperosmolar nonketoic coma and alcoholic ketoacidosis. Other initial differential considerations might include:
    - Lactic academia
    - Septic shock
    - Acute pancreatitis
    - Salicylate toxicity

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical examination findings that are confirmatory for DKA.
- The diagnosis of DKA requires laboratory confirmation.

Factors That Suggest Diagnosis

- A history of reduced or no insulin use should suggest the diagnosis.
- Any patient with diabetes who presents with an acute illness or severe injury should have the diagnosis of DKA considered.
- Patients being treated for other acute illnesses need to have their metabolic status monitored and controlled to avoid precipitating DKA.

Factors That Exclude Diagnosis

- There are no historical or physical exam findings that can reliably exclude the diagnosis of DKA.
- DKA is only excluded by laboratory analysis documenting the lack of ketonemia.
- It is important to remember that while most patients with DKA will have marked hyperglycemia (400–800 mg/dL), it is possible to have DKA with only modest elevations in glucose (250–500 mg/dL).

Ancillary Studies

Laboratory

- The diagnosis of DKA requires laboratory confirmation.
- Patients with suspected or confirmed DKA need to have a complete laboratory analysis of electrolytes and acid-base status. This includes measurement of glucose, sodium, potassium, chloride, bicarbonate, calcium, phosphate, magnesium, renal function, liver function, arterial or venous pH, calculation of the anion gap, and determination of ketonemia. A urine dipstick should also be performed for ketonuria and glucosuria, and for evidence of urinary infection.

- These patients may also need further laboratory evaluation for a precipitating cause for DKA. This may require evaluation of cardiac biomarkers, pancreatic enzymes, and thyroid function.
- The diagnosis is generally confirmed by the presence of all the following findings:
  - a blood glucose >250 mg/dL
  - an anion gap >11 (usually greater than 20)
  - a bicarbonate <15 mEq/L, an arterial or venous pH<7.3
  - at least moderate ketonemia
- All diabetic patients should have a fingerstick glucose determination performed when being evaluated for any acute illness.
- The glucose in DKA is usually between 400 and 800 mg/dL. Higher levels, especially those above 1,000 mg/dL are more common in HHNK. Lower levels (250–500 mg/dL) may be seen, especially in the presence of starvation/inadequate food intake due to nausea or vomiting, alcohol abuse, and other intercurrent illnesses. It may also be lower in the presence of pregnancy, liver disease, and if insulin was given within several hours prior to evaluation.
- In DKA, the anion gap increases due to the presence of the unmeasured anions, beta-hydroxybutyrate (βHB) and acetoacetate (AcAc). When calculating the anion gap, use the measured serum sodium, not the corrected sodium (see sodium below).
- Venous blood gases can be used to assess the serum pH. There is a high degree of correlation between venous and arterial pH in DKA. The venous pH is about 0.03 lower than the arterial pH. Arterial blood gases are painful, and can cause severe complications such as arterial injury and thrombosis, so venous blood gases are currently recommended.
- The degree of acidosis can be assessed by both the serum pH and bicarbonate concentration. The pH and serum bicarbonate are usually both reduced. This is consistent with the metabolic acidosis. Patients with protracted, severe vomiting may also develop a metabolic alkalosis and have normal or slightly elevated bicarbonate levels. In this setting, an elevated anion gap may be the only indication that an underlying acidosis exists.
- Historically, serum and urine ketones were assessed by the use of the nitroprusside reagent. This is mostly a qualitative assay, but the strength of reaction (color change) may give an indication of the amount of ketone present. This reagent only reacts with AcAc, it does not detect βHB. In DKA, βHB is the predominant ketone body. βHB and AcAc exist in an equilibrium that favors βHB in acidic environments. So early in the course, if using the nitroprusside reagent, the level of ketonemia or ketonuria may seem lower than it actually is. As the patient is appropriately treated, and the acidosis improves, the equilibrium will favor the conversion of βHB to AcAc (prior to clearance of the ketone bodies). When using the nitroprusside reagent, there may seem to be a paradoxical increase in ketonemia or ketonuria as the patient improves.

Most hospital laboratories now have a direct, enzymatic assay for βHB that is reliable and quantitative. This is the preferred assay.

- Patients with DKA often have profound total body potassium deficits. Acidosis causes intracellular potassium to shift into the extracellular space. The osmotic diuresis causes the potassium to then be excreted in the urine. However, measured potassium is often normal or even elevated prior to treatment. This is due to the extracellular shift of potassium with acidosis, and the hemoconcentration/increased serum osmolarity associated with hyperglycemia. During the first several hours of treatment, the serum potassium can drop precipitously.
- Osmotic diuresis also leads to renal losses of sodium chloride. Hyperglycemia causes an increase in the measured serum sodium that is factitious. The serum sodium should be corrected for the level of hyperglycemia. The classic correction factor for serum sodium in the presence of hyperglycemia is 1.6. For every elevation of 100 mg of glucose above 100 mg/dL, you add 1.6 to the measured serum sodium for the true sodium concentration. Some authorities believe that the correction factor should be 2.4 when the serum glucose exceeds 400 mg/dL.
- The osmotic diuresis causes increased urinary losses and total body depletion of all electrolytes (including phosphorus, calcium, and magnesium). However, just like potassium, hemoconcentration may cause the initial levels to be elevated. And as with potassium, treatment can cause precipitous drops in these electrolytes.
- Serum creatinine is often elevated due to intravascular volume depletion from the osmotic diuresis.
- Liver functions and lipase are often elevated in DKA even the absence of significant liver or pancreas pathology. These values often improve with treatment. However, they can be associated with an underlying condition that may have precipitated the episode of DKA.
- DKA is often associated with leukocytosis, due to physiologic stress and hemoconcentration. However, significant bandemia (above 10 %) often accompanies an infectious process that may have precipitated DKA.

Electrocardiography

- An ECG should be performed on all patients with suspected or confirmed DKA.
- It can help in the identification of electrolyte abnormalities such as hypo- or hyperkalemia.
- Also, as DKA can be precipitated by an acute myocardial infarction, an ECG should be reviewed for any signs of ischemia or infarction.

Imaging

- Imaging is not helpful in the diagnosis of DKA.
- However, imaging is often necessary in the work-up, evaluation, and treatment of DKA to search for the cause of DKA.
- Most of these patients should have chest x-ray to assess for pneumonia, congestive heart failure, or other issues that can help explain the occurrence of DKA, or help in the safe and appropriate management of DKA.
- Abdominal pain is a difficult complaint to evaluate in DKA. It may be due to the DKA itself, but an abdominal issue may also be the precipitant of DKA. Many patients presenting in DKA with predominant abdominal complaints or with marked abdominal tenderness will require abdominal imaging to evaluate for an intra-abdominal process precipitating DKA. The usual study would be an abdominal/pelvic CT scan. Many of these patients will not tolerate oral contrast due to profound nausea and vomiting, and IV contrast will often be contraindicated due to an elevated creatinine from intravascular volume depletion. A completely non-contrast-enhanced CT scan can be useful in these patients to help exclude an intra-abdominal catastrophe.

Special Populations

Age

Children

- 30–40% of cases of new-onset diabetes in children will present with DKA.
- DKA as a presenting manifestation is more common in younger children (<5), and in those from socioeconomically disadvantaged backgrounds.
- Children are more likely to present initially with diffuse abdominal pain associated with nausea and vomiting.
- DKA in children is defined by the following biochemical abnormalities:
  - Blood glucose greater than 200 mg/dL; AND
  - A venous pH less than 7.3 or plasma bicarbonate less than 15 mEg/L; AND
  - Ketosis (presence of ketones in the urine).
  - Measurements of serum beta-hydroxybutyrate are more sensitive are more accurate indicators of ketosis (levels greater than 3 mmol/L)
- Other clues to the presence of new-onset diabetes in children include polyuria, polydipsia, increased nocturia, and especially daytime enuresis.
- Decreased urine output from dehydration is often not appreciated in children, due to the profound osmotic diuresis associated with DKA.
- DKA is the leading cause of morbidity and mortality in children with type 1 diabetes.

The Elderly

- The elderly are more likely to present with HHS/HHNK than DKA.
- The elderly are also more likely to present with mental status changes.
- Morbidity and mortality are also higher among the elderly.

During Pregnancy

- DKA occurring during pregnancy is associated with a fetal mortality rate approaching 30%.
- DKA can be precipitated by lower sugar levels during pregnancy.
- Several "normal" physiologic changes of pregnancy make pregnant women more likely to develop DKA.
    - Pregnant women have lower fasting plasma glucose levels. This leads to lower baseline insulin levels (a relative insulin deficiency) and increased baseline free fatty acid levels.
    - This is also an associated increase in counter-regulatory hormone levels.
    - There is a decrease in bicarbonate levels from the chronic respiratory alkalosis in pregnancy. This leads to a decreased buffering capacity.
- All the fluid and electrolyte changes that occur in the mother occur in the fetus. Maternal hyperglycemia causes fetal hyperglycemia with resultant osmotic diuresis. Maternal acidosis leads to fetal acidosis. Maternal hyperglycemia, diuresis, volume contraction, and acidosis cause decreased uterine blood flow and decreased fetal oxygenation. Fetal hypokalemia can cause fetal arrhythmias. All these changes lead to the increase in fetal mortality.
- Treatment priorities remain the same: fluids, correction of acidosis and hyperglycemia, and electrolyte repletion.

Co-morbidities

- Any significant medical co-morbidity can increase the morbidity and mortality associated with DKA.
- Significant cardiac, pulmonary, renal, and liver disease can complicate both the diagnosis and treatment of DKA. Any significant disorder of these systems can make fluid therapy challenging.
- Patients with history of severe CHF or end-stage renal disease may need central venous pressure monitoring for appropriate fluid management.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is important to consider the diagnosis in acutely ill patient with a history of diabetes.
- It is also important to consider the diagnosis in patients presenting acutely ill who are found to be academic and hyperglycemic even in the absence of a history of diabetes, as DKA can be the presenting issue with diabetes.
- It is critical to measure the all electrolytes, pH (a venous blood gas is often sufficient), and evaluate for ketosis.
- Appropriate resuscitative measures (especially fluid replacement) may need to be started prior to adequate confirmation of the diagnosis.
- A thorough search for a precipitating cause needs to be performed.

Mimics

- Many processes can mimic the presentation of DKA, as it is a multi-system disorder in which patients are critically ill.
- HHNK (hyperglycemic, hyperosmolar, non-ketosis) is an important mimic of DKA. Patients have ketosis, but usually little or no elevation in the anion gap. The glucose tends to be much higher (usually above 600) than those seen with DKA. These patients are usually older and have more profound mental status changes.
- Other causes of ketosis (such as alcoholic and starvation ketosis) can present similarly, but the glucose is usually normal or low at presentation.
- Patients with SIRS (systemic inflammatory response syndrome) can also present acutely ill with hypotension, acidosis (usually from lactate), and the two processes can co-exist. An acute infection can precipitate DKA.

Time-Dependent Interventions

- It is critically important to initiate fluid resuscitation early in the course of evaluation and treatment. Fluids should usually be started at the time of consideration of the diagnosis rather than after waiting for full laboratory confirmation.
- Immediate interventions on consideration of the diagnosis include aggressive fluid replacement, full monitoring including cardiac monitoring, continuous pulse ox, and frequent vital sign monitoring (blood pressure every 5 minutes

or more frequently). There should be a bedside, finger stick blood glucose check, a urine dipstick for ketones, at least two large-bore IV's, and a 12-lead ECG should be performed.

Overall Principles of Treatment

- Treatment should initially address three issues in the following order:
  - Fluid repletion
  - Potassium repletion
  - Insulin administration
- Fluid.
  - Adult patients with DKA usually have anywhere from a 5–10 liter free water deficit at presentation.
  - The first 2 liters of replacement should be given over the first 30–120 minutes of treatment. Continuing fluids can then be slowed with about 50 % of the total water deficit replaced over the first 12 hours and then subsequent 50 % over the next 12 hours.
  - Normal saline (NS) is the preferred fluid for initial resuscitation. NS helps increase intravascular volume and helps to prevent too rapid a fall in extracellular osmolarity. Too rapid a fall in extracellular osmolarity can lead to rapid transfer of free water into brain cells and cerebral edema.
  - After the initial resuscitation with 2 liters NS, most authorities recommend changing to 0.45 % (half normal) saline, if the corrected serum sodium is normal or elevated.
  - When the blood glucose falls below 250 mg/dl, the fluid should be changed to 5 % dextrose in 0.45 % NS to allow the continuation of insulin therapy.
- Potassium.
  - Patients with DKA almost universally have severe total body potassium deficits. Usually on the order of 3–5 mEq/kg.
  - The development of profound hypokalemia can be a life-threatening complication during the resuscitation and treatment of a patient with DKA.
  - However, the initial measured serum potassium is usually normal or high, due to the shift of intracellular potassium into the extracellular space in the presence of acidosis. Hypokalemia on presentation is urgently life-threatening and requires rapid and careful correction.
  - The primary goals of potassium replacement are to maintain normal extracellular potassium concentration during the acute phases of therapy when the most significant shifts are expected to occur. The intracellular deficit may be corrected over days instead of hours.
  - During initial resuscitation of DKA, the serum potassium may fall quickly due to the resolution of acidosis and insulin therapy, which both cause an

intracellular shift of potassium. This can lead to the precipitous development of profound extracellular hypokalemia with resulting cardiac arrhythmias, rhabdomyolysis, respiratory muscle paralysis, and paralytic ileus.
- The most rapid changes in potassium concentration occurs during the first several hours of therapy, so the potassium concentration needs to be measured frequently during this period (at least every 2 hours.)
- It is recommended that if the initial potassium concentration (prior to any fluids/insulin) is between 3.0 mEq/L and 5.5 mEq/L, then potassium replacement should be initiated at about 10 mEq/hour.
- If the initial potassium is below 3.0 mEq/L, the initial rate of replacement should be about 15 mEq/hour.
- If the initial serum potassium concentration is below 3.3–3.5 mEq/L, it is recommended that potassium replacement occur prior to initiation of insulin therapy, as insulin administration will cause the potassium to shift intracellularly and can precipitate profound, life-threatening extracellular hypokalemia.
- Potassium is usually given as potassium chloride in IV fluid. Potassium phosphate use is discouraged, as it can lead to profound hypocalcemia and the precipitation of calcium phosphate salt in tissues.

- Insulin.
  - There is nearly universal agreement that the administration of low dose (0.1 unit/kg/hour) intravenous short-acting insulin is the safest method for administering insulin in patients with DKA.
  - This method of insulin administration allows for a gradual reduction in plasma glucose of about 50 mg/dL/hour.
  - Multiple studies document that this method of insulin administration is associated with fewer complications (such as profound hypokalemia, hypophosphatemia, and hypoglycemia).
  - In adults, it is acceptable to give a loading dose of insulin at a dose of 1 unit/kg.
  - Children should not have a bolus dose of insulin. An IV-push loading dose has been shown to lead to more complications in children.
  - In general, insulin infusions should not be started until after an initial fluid bolus of 1–2 liters has been given.
  - Insulin therapy should be withheld in the setting of profound hypokalemia (initial serum potassium concentration less than 3.3–3.5 mEq/L) until potassium repletion has commenced. In this setting, insulin can cause profound hypokalemia by causing an intracellular shift of extracellular potassium.
  - In the first hours of treatment, the serum glucose should be measured at least every 2 hours.
  - The insulin infusion should be continued until the anion gap returns to normal and ketonemia resolves.

- Hyperglycemia often resolves before the anion gap normalizes and ketonemia resolves. It is recommended that the IV fluid be switched to fluid containing 5% dextrose when the serum glucose concentration falls below 250 mg/dL.
- Therapy with subcutaneous insulin should be initiated prior to stopping the insulin infusion. Subcutaneous insulin should be administered at least one hour prior to stopping the insulin infusion.

- Other electrolytes.
  - Phosphorus. Phosphorus (like potassium) is primarily intracellular, but shifts to the extracellular compartment in the setting of acidosis. As such, initial phosphorus concentrations are usually elevated in DKA but are not reflective of total body phosphorus. In DKA, total body phosphorus is usually depleted due to increased renal losses from the osmotic diuresis. However, phosphorus levels usually fall more gradually than potassium, and the levels often don't decrease until 24–48 hours into therapy. Intravenous replacement is not recommended unless the serum phosphorus falls below 1.0 mg/dL.
  - Magnesium. Magnesium concentrations may fall from the osmotic diuresis of DKA. Magnesium concentration doesn't usually fall until 24 hours into therapy. Magnesium repletion is recommended when the serum concentration falls below 2.0 mg/dL. Magnesium may be given intravenously as magnesium sulfate 2.0 grams over one hour. If the patient is tolerating orals, it can be given orally as magnesium oxide.
  - Calcium. Calcium homeostasis usually remains intact during DKA, but severe hypomagnesemia can lead to hypocalcemia (due to decreased parathyroid secretion). Patients with severe hypomagnesemia should have calcium levels followed and restored as necessary.
  - Bicarbonate. The administration of supplemental bicarbonate is contraindicated in the vast majority of cases of DKA. The acidosis will resolve spontaneously with resolution of ketogenesis. Bicarbonate therapy can be associated with and cause severe hypokalemia, worsen intracellular acidosis, worsen central nervous system acidosis, shift the oxyhemoglobin dissociation curve to the left, prolong ketogenesis, and precipitate cerebral edema.

Laboratory evaluation
After a brief history and physical examination, initial laboratory evaluation should include determination of complete blood count, blood glucose, serum electrolytes, blood urea nitrogen, creatinine, serum ketones, osmolality, arterial blood gases, and urinalysis. Admission ECG, chest radiograph, and cultures of blood, urine, and sputum may be ordered if clinically indicated. During therapy, capillary blood glucose should be determined every 1–2 hours at the bedside using a glucose oxidase reagent strip; and blood should be drawn every 4 hours for determination of serum electrolytes, glucose, blood urea nitrogen, creatinine, phosphorus, and venous pH
Fluids
1000 mL normal saline (0.9% sodium chloride) first hour, then normal or 0.45% saline at 250–500 mL per hour depending on serum sodium concentration and hydration status. When plasma glucose < 250 mg/dL, change to D5%1/2NS saline to allow continued insulin administration until ketonemia is controlled, while avoiding hypoglycemia
Insulin
0.1 U/kg body weight as intravenous bolus followed by 0.1 U/kg/h as a continuous infusion. The goal is to achieve a rate of decline of glucose between 50–100 mg per hour. When plasma glucose is < 250 mg/dL, reduce insulin rate to 0.05 U/kg per hour. Thereafter, adjust insulin rate to maintain glucose levels between 150–200 mg/dL until ketoacidosis is resolved. In patients with mild to moderate diabetic ketoacidosis, subcutaneous regular insulin or rapid-acting insulin analogs may be an alternative to intravenous insulin [037], [038]
Potassium
Serum K^+ > 5.0 mEq/L; no supplementation is required.
Serum K^+ = 4–5 mEq/L; add 20 mEq/L to each L of replacement fluid
Serum K^+ = 3–4 mEq/L; add 40 mEq/L to each L of replacement fluid
Serum K^+ < 3 mEq/L; hold insulin and give 10–20 mEq per hour until K^+ > 3.3, then add 40 mEq/L to each L of replacement fluid
Bicarbonate
Arterial pH < 7.0 or bicarbonate < 5 mEq; 50 mEq/L in 200 ml of H_2O over 1 hour until pH increases to > 7.0. Do not give bicarbonate if pH > 7.0
Phosphate
If indicated (serum levels < 1 mg/dL), 20–30 mmol potassium phosphate over 24 hours. Monitor serum calcium level
Transition to subcutaneous insulin
Insulin infusion should be continued until resolution of ketoacidosis (glucose < 200 mg/dL, bicarbonate > 18 mEq/L, pH > 7.30). When this occurs, start subcutaneous insulin regimen.
To prevent recurrence of diabetic ketoacidosis during the transition period to subcutaneous insulin, intravenous insulin should be continued for 1–2 hours after subcutaneous insulin is given [028]

Summary of management of patients with diabetic ketoacidosis, (028). Fisher JN, Shahshahani MN, Kitabchi AE. Diabetic ketoacidosis: low-dose insulin therapy by various routes. CO2—carbon dioxide; IV—intravenous; K+—potassium ion; NaCl—sodium chloride; NaHCO3—sodium bicarbonate; SQ—subcutaneous.

Insulin	Fluid Administration	Potassium repletion	Alkali
1. Give initial IV bolus of 0.2 U/kg actual body weight.	Shock absent: Normal saline (0.9% NaCl) at 7 mL/kg/h for 4 h, and half this rate thereafter	Potassium chloride should be added to the third liter of IV infusion and subsequently if urinary output is at least 30–60 mL/h and plasma [K^+] < 5 mEq/L.	Half-normal saline (0.45% NaCl) plus 1–2 ampules (44–88 mEq) $NaHCO_3$ per liter when blood pH < 7.0 or total CO_2 < 5 mmol/L; in hyperchloremic acidosis, add $NaHCO_3$ when pH < 7.20; discontinue $NaHCO_3$ in IV infusion when total CO_2>8–10 mmol/L.
2. Add 100 U of regular insulin to 1 L of normal saline (0.1 U/mL), and follow with continuous IV drip of 0.1 U/kg actual body weight per h until correction of ketosis.	Shock present: Normal saline and plasma expanders (*ie*, albumin, low molecular weight dextran) at maximal possible rate		
3. Give double rate of infusion if the blood glucose level does not decrease in a 2-h interval (expected decrease is 40–80 mg/dL/h or 10% of the initial value.)	Start a glucose-containing solution (*eg*, 5% dextrose in water) when blood glucose level decreases to 250 mg/dL.	Add K^+ to the initial 2 L of IV fluids if initial plasma [K^+] < 4 mEq/L and adequate diuresis is secured.	
4. Give SQ dose (10–30 U) of regular insulin when ketosis is corrected and the blood glucose level decreases to 300 mg/dL, and continue with SQ insulin injection every 4 h on a sliding scale (*ie*, 5 U if below 150, 10 U if 150–200, 15 U if 200–250, and 20 U if 250–300 mg/dL).			

Diabetic ketoacidosis (DKA) and nonketotic hyperglycemia (NKH) management. Administration of insulin is the cornerstone of management for both DKA and NKH. Replacement of the prevailing water, sodium, and potassium deficits is also required. Alkali are administered only under certain circumstances in DKA and virtually never in NKH, in which ketoacidosis is generally absent. Because the fluid deficit is generally severe in patients with NKH, many of whom have preexisting heart disease and are relatively old, safe fluid replacement may require monitoring of central venous pressure, pulmonary capillary wedge pressure, or both (001), Adrogué HJ, Madias NE. Management of life-threatening acid-base disorders. N Engl J Med. 1998; 338:26 -34, 107–111. (017), AdroguÈ HJ. Diabetic ketoacidosis and hyperosmolar nonketotic syndrome. Disease Course

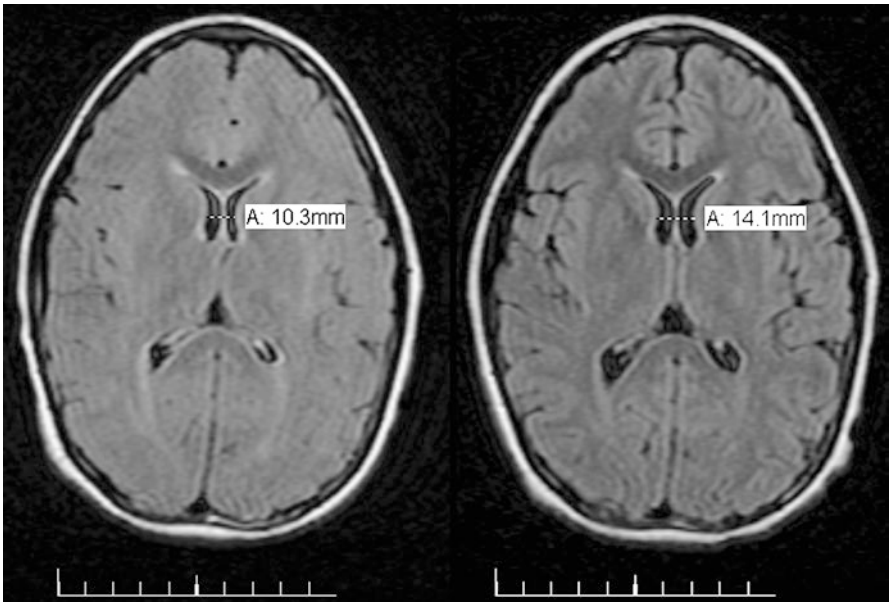
- With appropriate and aggressive treatment, most cases of DKA resolve over 24–72 hours.
- Advances in knowledge leading to improved and more aggressive treatment has reduced the mortality of DKA to less than 5 %.
- Currently, most mortality is seen in the very young and the very old.
- Overwhelming infection and acute myocardial infarction precipitating DKA are associated with increased mortality.
- In general, the sicker a patient is at presentation, the higher the mortality.
- Some complications related to therapy for DKA have previously been discussed (hypokalemia, hypophosphatemia, and hypoglycemia). Other complications of therapy include the adult respiratory distress syndrome, and cerebral edema.
- Adult respiratory distress syndrome (ARDS): This is a rare complication, generally felt to result in over-aggressive fluid repletion especially in patients with underlying pulmonary or cardiac disease.
- Cerebral edema. Cerebral edema is a feared complication of DKA in children. It tends to occur 4–24 hours after the initiation of therapy, and patients usually appear to be improving prior to its onset. Cerebral edema is associated with high morbidity and mortality. It is thought to result from free water diffusing into brain cells at a fast rate, causing cells to swell. The only known risk factors are young age and DKA being the presenting manifestation of diabetes. There are currently no identified presenting or treatment issues that reliably predict the onset of cerebral edema. Symptoms may include headache, incontinence, change in mental status, seizures, or other changes in autonomic or neurologic function. If the diagnosis of cerebral edema is being considered, therapy with intravenous mannitol (1–2 grams/kg IV) should be started immediately, without awaiting confirmatory studies.



A 12-year-old boy in DKA (left) and following recovery from the DKA episode (right). Axial FLAIR images (1.5 T) demonstrate that the intercaudate distance is smaller during DKA than after recovery, suggesting mild diffuse brain swelling. [Wootton-Gorges SL, Glaser NS. Imaging of the brain in children with type I diabetes mellitus. Pediatric Radiology. 2007 Jul 27;37(9):863–9.] *Caption adapted from original*

- Metabolic acidosis that does not respond to usual therapy is often due to lactic acidosis from unrecognized infection.
- Hypotension/shock refractory to fluid administration should prompt a consideration of concurrent gram-negative sepsis or myocardial infarction with cardiogenic shock.
- Venous thromboembolism (VTE) can occur as a late complication.
- Rhinocerebral mucormycosis is a rare, late, complication of DKA. It is an infection of the sinuses, nasal passages, oral cavity, and brain caused by saprophytic, aerobic fungi. It is associated with a very high mortality.

Chapter 25
Duchenne Muscular Dystrophy

Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Duchenne Muscular Dystrophy (DMD)

- A member of a group of diseases termed dystrophinopathies (includes Duchenne and Becker Muscular Dystrophy)
- Duchenne's is the most severe form

Incidence/Epidemiology

- Caused by a defective gene on the X chromosome.
- An X linked recessive trait.
- A population-based surveillance study of males 5–24 years old in four states found the overall prevalence of DMD/Becker muscular dystrophy (BMD) to be from 1.3 to 1.8 per 10,000.

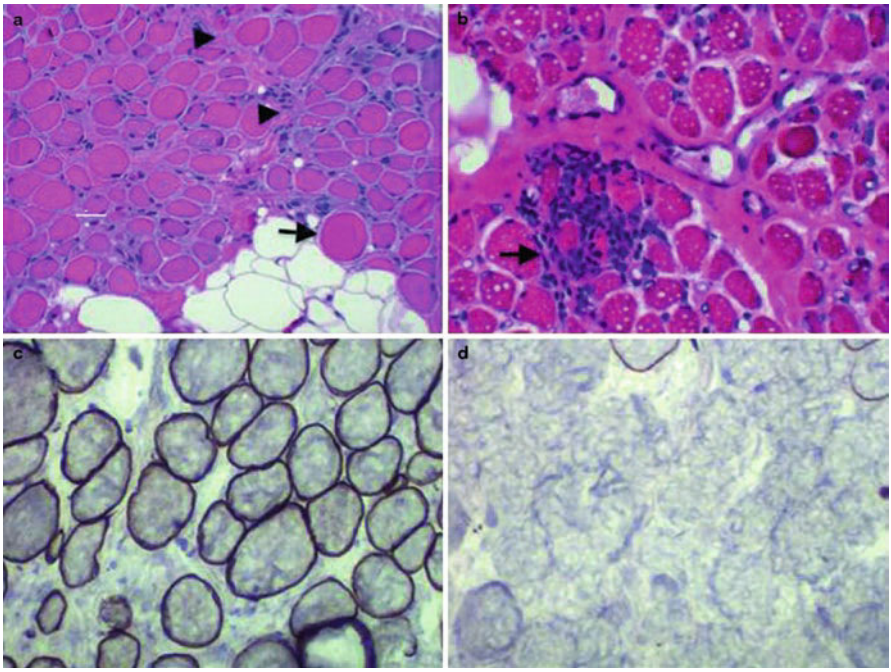
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_25

Differential Diagnosis

- The differential diagnosis of infants and children with muscle weakness is large.
- Some helpful clinical findings include:
  - Cranial nerve deficits are seen in neuromuscular junction dysfunction (myasthenia gravis, botulism, and tick paralysis).
  - Spinal cord dysfunction is heralded by loss of function below the level of the lesion (poor rectal tone, decreased cremasteric reflexes).
- Hyperesthesias are common in peripheral nerve disorders.
- The presence of ataxia and cerebellar signs favors a central anomaly.
- Hyporeflexia is common in Guillain-Barré syndrome, tick paralysis, and botulism.

Pathophysiology and Etiology

- The result of a defective gene located on the X chromosome that is responsible for the production of dystrophin.
- Dystrophin is responsible for stabilization of muscle proteins, protecting them from degradation.
- Damage to these proteins results in muscle fiber degeneration.



Duchenne muscular dystrophy. (a) On hematoxylin and eosin (H&E) staining, considerable fiber-type variation, including an occasional hypertrophic fiber (arrow) and fibrosis with fatty infiltration (arrow heads), is noted. (b) Also on H&E staining, lymphocytic infiltrates are demonstrated (arrow). (c) Normal dystrophin staining. (d) Loss of dystrophin staining in DMD [Russell JW, Weiss MD, Distad BJ, Castellani RJ. Muscle and Myotonic Diseases. In: Feldman EL, Grisold W, Russell JW, Löscher WN, editors. Atlas of Neuromuscular Diseases [Internet]. Vienna: Springer Vienna; 2014 [cited 2016 Aug 1]. p. 247–81. Presentation

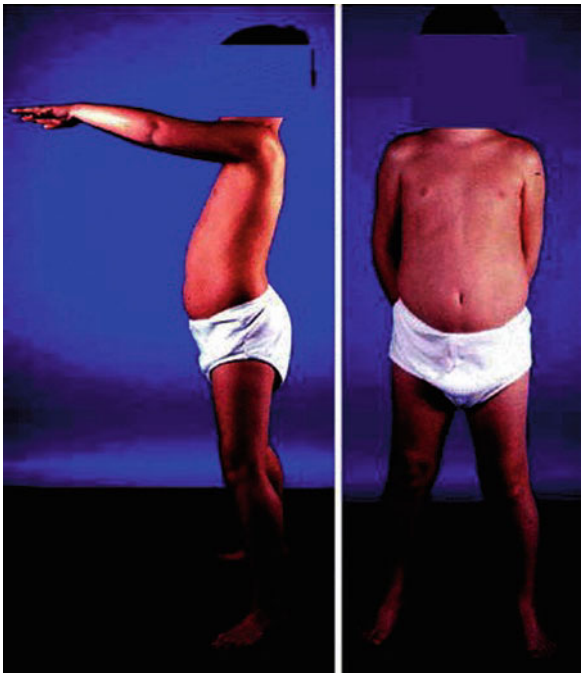
Typical/"Classic"

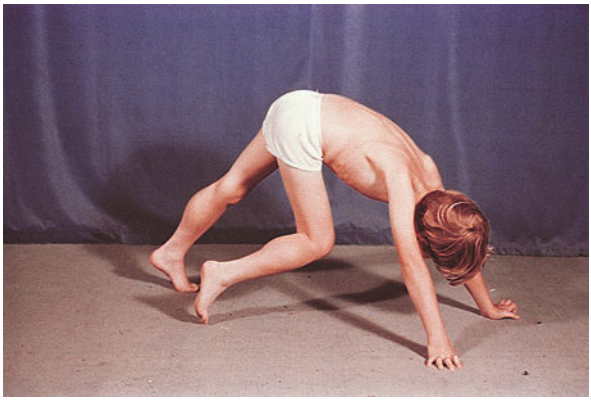
- Neuromuscular presentation is most common.
- Obvious clinical signs of weakness occur between 2 and 3 years of age.
- Lower extremity muscles are initially affected, specifically proximal limb musculature.

Duchenne dystrophy. Duchenne dystrophy is an X-linked progressive myopathy of childhood caused by mutations of the dystrophin gene. A,Lateral photograph of a boy with Duchenne dystrophy. Note the lumbar lordosis and enlarged calves [Pleasure D, Bird S, Scherer S, Sladky J, Schotland D. Neuromuscular Disease. In: Rosenberg RN, editor. Atlas of Clinical Neurology [Internet]. Current Medicine Group; 2003 [cited 2016 Aug 1]. p. 385–401. Available from: http://link.springer.com/chapter/10.1007/978-1-4757-4552-8_11] *Caption from original*.



Duchenne muscular dystrophy. Note the prominent abdomen and lumbar lordosis, calf pseudohypertrophy, and equinus at the ankles [Bleck EE, Robb JE. Hereditary and Developmental Neuromuscular Disorders. In: Benson M, Fixsen J, Macnicol M, Parsch K, editors. Children's Orthopaedics and Fractures [Internet]. London: Springer London; 2010 [cited 2016 Aug 1]. p. 249–64. Available from: http://link.springer.com/10.1007/978-1-84882-611-3_16] *Caption from original*

- There is impairment of running, jumping, and climbing stairs. Fractures from falls are common,
- Look for Gower's Sign—children will have to actively push up with their hands to attain a standing position.

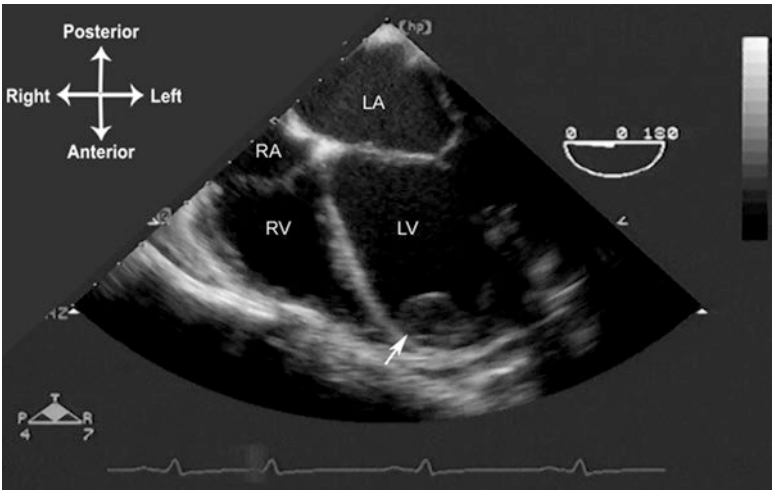


Duchenne's dystrophy, Gower maneuver [MacGregor DL. Neurology. In: Laxer R, Ford-Jones EL, Friedman J, Gerstle T, editors. The Hospital for Sick Children: atlas of pediatrics. Philadelphia: Current Medicine; 2005. Atlas of Pediatrics, Volume IA, Chapter 05;. ISBN: 1-57340-188-9] *Caption from original*

- Most patients are wheelchair-bound by early adolescence.

Atypical

- There may also be variable degrees of global developmental deficits.
- Cardiac presentations are less common than neuromuscular presentations.
- DMD causes a dilated cardiomyopathy.

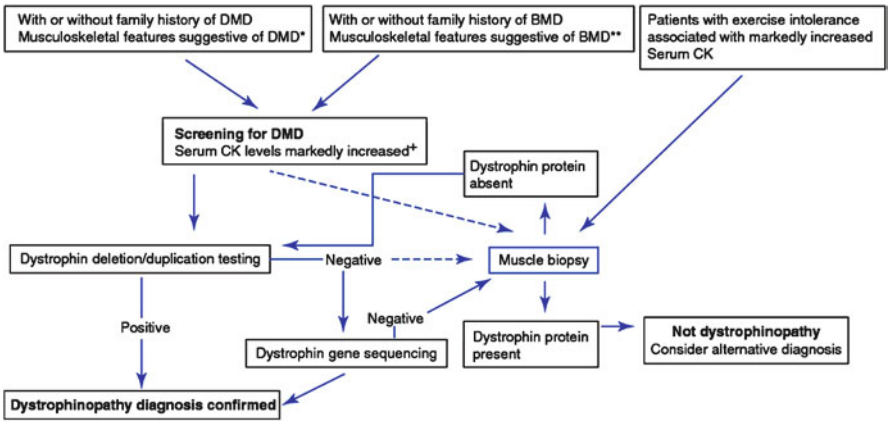


Thrombus (arrow) in the left ventricular apex of a patient with Duchenne muscular dystrophy and dilated cardiomyopathy. Mid-esophageal four-chamber view, multiplane angle 0°. LA left atrium, LV left ventricle, RA right atrium, RV right ventricle [Wong PC. Additional Applications of Transesophageal Echocardiography. In: Wong PC, Miller-Hance WC, editors. Transesophageal Echocardiography for Congenital Heart Disease [Internet]. London: Springer London; 2014 [cited 2016 Aug 1]. p. 399–436. Available from: http://link.springer.com/10.1007/978-1-84800-064-3_16] *Caption from original*

- Conduction abnormalities may be present (resulting in mostly supraventricular disorders).
- The progression of cardiac disease is gradual, with full expression after 18 years of age.
- Most children, by virtue of their lack of strenuous activity, are asymptomatic.
- Most children with DMD develop scoliosis.

Primary Differential Considerations

- Other muscular dystrophies must be considered; the most common is Becker muscular dystrophy. Muscle biopsy can differentiate among these and other diagnoses.



Algorithm to guide diagnostic workup in suspected DMD/BMD patients for confirmation of dystrophinopathy diagnosis. For patients diagnosed by muscle biopsy, dystrophin genetic testing is also necessary. For patients diagnosed by genetic testing, muscle biopsy is not necessary, and if at all possible, defer muscle biopsy until patient participates in a later clinical trial. DMD Duchenne muscular dystrophy, BMD Becker muscular dystrophy, CK creatine kinase [Sahenk Z, Rodino-Klapac LR. Dystrophinopathies. In: Katirji B, Kaminski HJ, Ruff RL, editors. Neuromuscular Disorders in Clinical Practice [Internet]. New York, NY: Springer New York; 2014 [cited 2016 Aug 1]. p. 1207–29. Available from: http://link.springer.com/10.1007/978-1-4614-6567-6_56] *Caption adapted from original*

History and Physical Exam

Findings That Confirm Diagnosis

- Common findings include a wide-based gait, lumbar lordosis, pseudohypertrophy of the calf muscles, shortening of the Achilles tendons, and hyporeflexia or areflexia.
- Depending on the degree of scoliosis, respiratory function may be compromised.

Factors That Suggest Diagnosis

- Most children will have already been diagnosed prior to their first Emergency Department encounter.

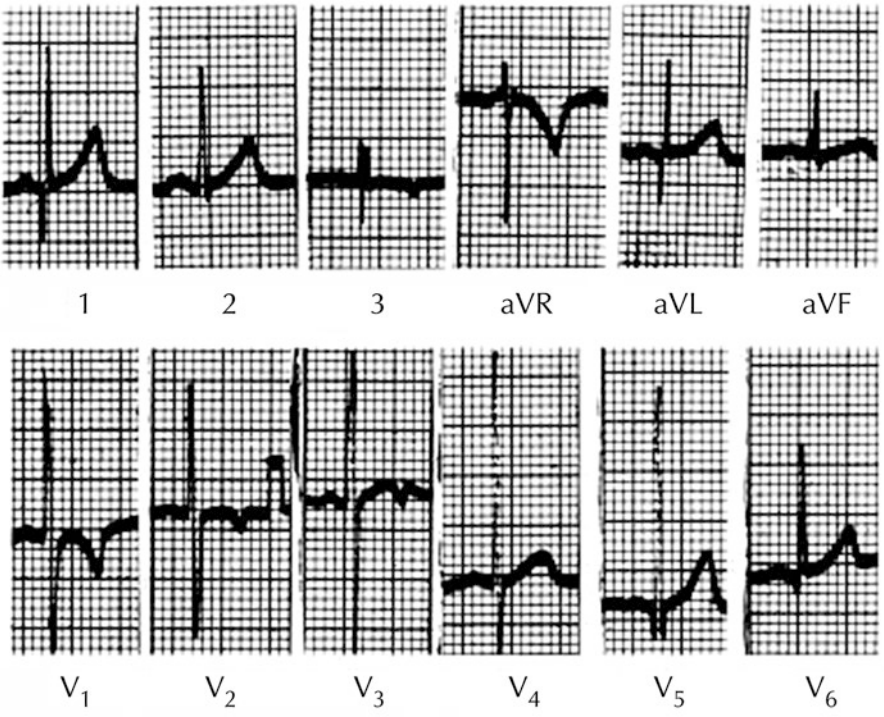
Factors That Exclude Diagnosis

- No clinical findings can exclude DMD in patients with suggestive findings. A muscle biopsy is required.

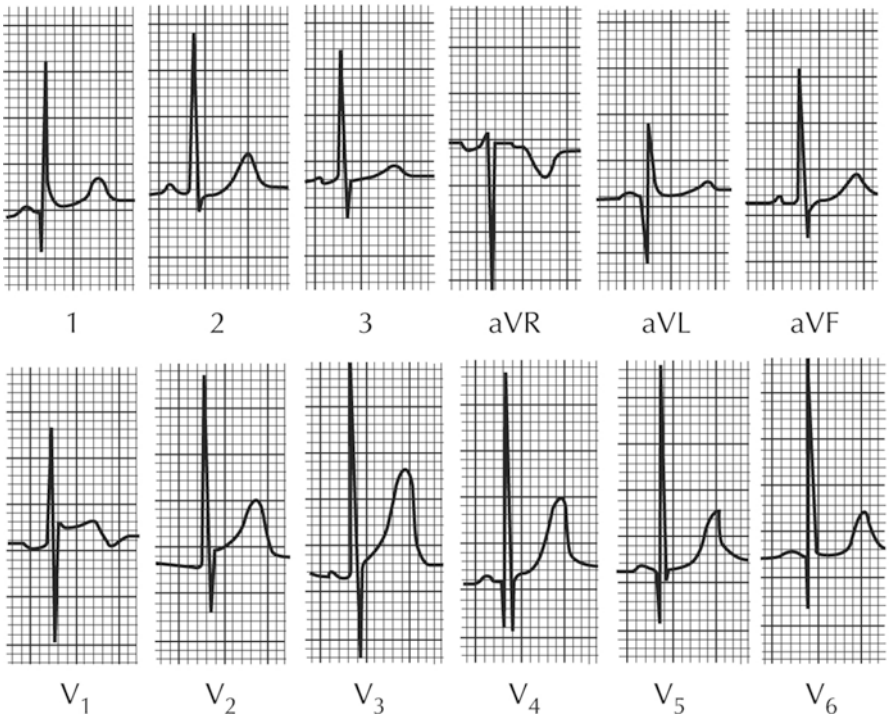
Ancillary studies

Electrocardiography

- As previously mentioned, a variety of arrhythmias may occur, particular supraventricular.



Electrocardiogram of female carrier of Duchenne dystrophy gene [Perloff J, Abelmann W. Chapter 6. In: Lee RT, Braunwald E, editors. Atlas of cardiac imaging. Philadelphia: Current Medicine; 1998. ISBN: 0-443-07567-0] *Caption from original*



Electrocardiogram of Duchenne dystrophy in 10-year-old boy [Perloff J, Abelmann W. Chapter 6. In: Lee RT, Braunwald E, editors. Atlas of cardiac imaging. Philadelphia: Current Medicine; 1998. ISBN: 0-443-07567-0] *Caption from original*

Laboratory

- Patients with DMD will have elevated levels of serum creatine kinase.
- These elevations may occur prior to the appearance of clinical disease.
- Levels peak in early childhood but may actually normalize as damaged muscle fibers are replaced by fibrotic change.

Special Populations

Age

- DMD is identified in early life. The usual life expectancy of patients with DMD is about 25 years.

Co-morbidities

- None significant

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is most important to anticipate the variable forms of target organ dysfunction that accompany DMD patients.
- Complications of respiratory compromise are the most frequent etiologies of emergency department visits.
- Aspiration pneumonia and cases of primary bacterial pneumonia are commonly encountered.
- Use extreme caution when providing sedation and analgesia to DMD patients.
- DMD patients are susceptible to the development of malignant hyperthermia, specifically associated with administration of succinylcholine and inhalational agents.

Mimics

- In general, these patients are already diagnosed prior to ED presentation.

Time-Dependent Interventions

- Depending on the particular complication, early administration of fluids and broad-spectrum antibiotics are indicated.

Overall Principles of Treatment

- As mentioned, most ED cases necessitate pulmonary support and attention to obvious complications.

Disease Course

- Sadly, most children with DMD are confined to a wheelchair by early adolescence.
- Death usually occurs by early adulthood, and is caused by cardiopulmonary insufficiency.

Chapter 26
Epiglottitis

Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

- Epiglottitis (Supraglottitis)

Incidence/Epidemiology

- There has been a marked decrease in cases since the introduction of the Hib vaccine.
- According to current estimates, in the United States 1.6 cases occur per 100,000 adults, and 0.5 cases occur per 100,000 children.
- As a result of immunization practices, the median age of children presenting with epiglottitis has increased from 3 years to 6–12 years of age.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_26

Differential Diagnosis

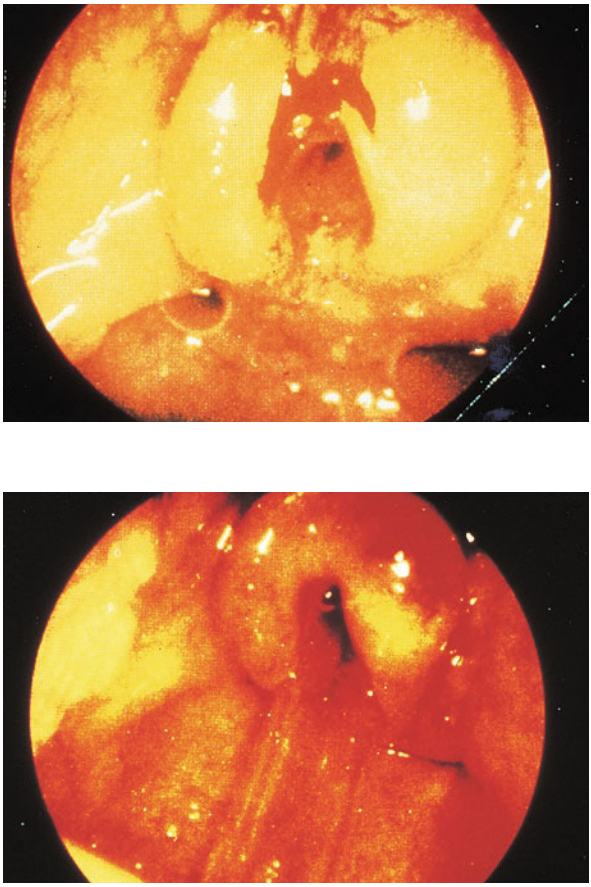
- Other causes of acute upper airway obstruction must be considered:
  - Croup
  - Bacterial tracheitis
  - Peritonsillar abscess
  - Retropharyngeal abscess
  - Upper airway foreign body
  - Congenital upper airway anomalies

	Croup	Epiglottitis
Cause	Viral	Bacterial
Age	6 mo to 3 y	4–6 y
Site of obstruction	Subglottic	Supraglottic
Clinical features		
Onset	Gradual (days)	Sudden (hours)
Fever	With or without low grade fever	High fever (> 102°F)
Dysphagia, drooling		Present
Cough	Barking, dry cough	Not common
Respiratory rate	↑	Normal
Position	Normal	Sitting upright
Appearance	Mild distress	Toxic appearing
Quality of voice	Hoarseness	Muffled
Primary Treatment	Supportive:	Secure airway:
Hydration	Needed	Needed
Antibiotics	Not Needed	Needed to treat *Haemophilus* influenza
Airway support	Not Needed	Always needed
Extubation	Not Needed	When temperature decreases and with leak around the endotracheal tube

Differential diagnosis of croup vs epiglottitis. The two most common infectious causes of upper airway obstruction in children, croup and epiglottitis, differ in etiology, patient demographics, and symptomatology. [Rasmussen G, Deshpande J. Pediatric anesthesia. In: Muravchick S, editor. Subspecialty care. Philadelphia: Current Medicine; 1998. 236 p. (Miller RD editor, Atlas of anesthesia; vol. 5). ISBN: 0-443-07905-6] *Caption from original*

Pathophysiology and Etiology

- Epiglottitis is essentially a cellulitic process secondary to bacteremic spread.
- The onset of edema is rapid and usually does not involve subglottic structures.



Severe epiglottitis. Two patients with severe epiglottitis. A, The characteristic edema of the epiglottis and laryngeal structures and purulent material. B, Extent that advanced edema can become, so that by the time many patients present, they are breathing through an extremely small aperture. [Rasmussen G, Deshpande J. Pediatric anesthesia. In: Muravchick S, editor. Subspecialty care. Philadelphia: Current Medicine; 1998. 236 p. (Miller RD editor, Atlas of anesthesia; vol. 5). ISBN: 0-443-07905-6] *Caption from original*

- Most cases are bacterial in origin, usually from *Haemophilus influenza* type b (Hib).
- Other causes in children include streptococci and *Staphylococcus aureus* (including MRSA strains).

Presentation

Typical/"Classic"

- Look for the "3 D's": distress, drooling, and dysphagia.
- Unlike croup, there is generally no prodromal URI.
- Most children become ill within 24 hours, often with a toxic appearance.
- Younger children will assume a "sniffing posture," in which the chin is thrust forward and the neck hyperextended in order to maximize airway patency.

	Children	Adults
Age at acquisition	3–5 yrs	—
Location of pathology	Supraglottic	Supraglottic
Onset	Rapid	Most have a mild illness with prolonged course, painful dysphagia, and pharyngitis
Fever	High	Variable
Appearance	Toxic	Usually not toxic
Stridor	+++	Not usual
Cough	Not usual	—
Drooling	Often	—

Clinical features of acute epiglottitis [Tristram D. Chapter 07. In: Brook I, editor. Atlas of Upper Respiratory and Head and Neck Infections, 2e. Philadelphia: Current Medicine; 2000. (Mandell GL, editor. Atlas of infectious diseases; vol. 4). ISBN: 1-57340-140-4]

Atypical

- Older children and adults may only complain of a sore throat, and generally do not appear toxic

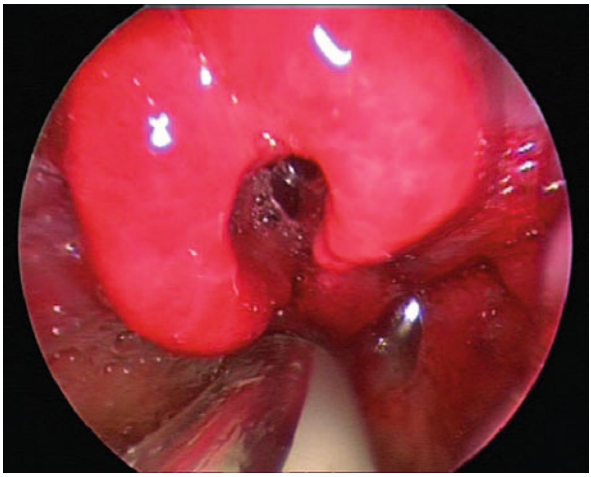
Primary Differential Considerations

- Early consideration in patients with symptoms referable to epiglottitis should also be given to the following differential diagnoses:
  - Peritonsillar or retropharyngeal abscess
  - Angioedema
  - Laryngitis
  - Tonsillitis
  - Laryngeal diphtheria

History and Physical Exam

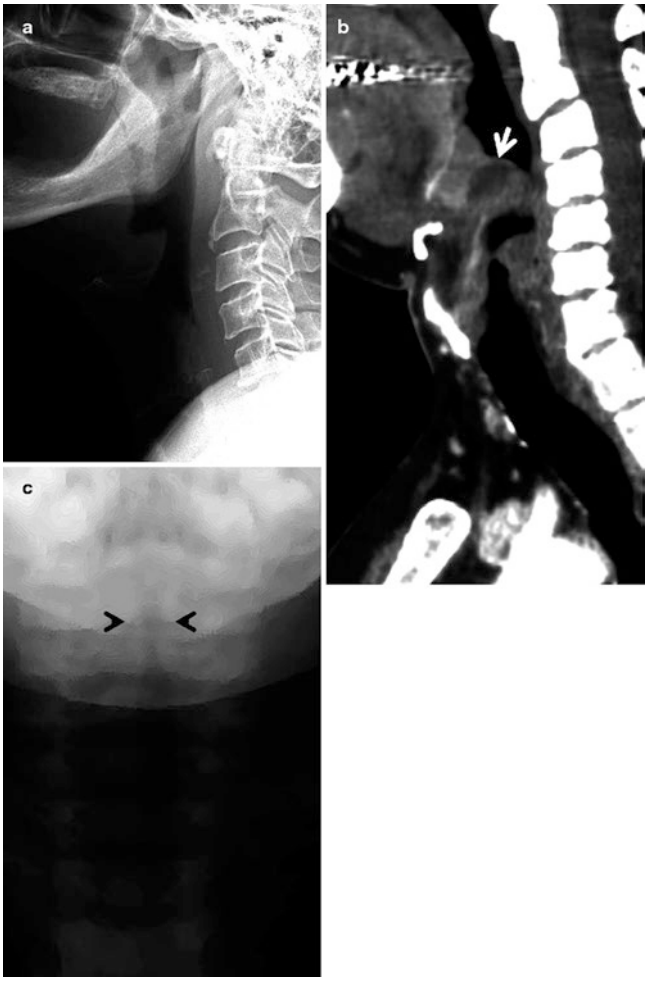
Findings That Confirm Diagnosis

- In the purest sense, the diagnosis is confirmed by direct visualization of the epiglottis in the operating room.



Direct laryngoscopy findings in a 10-year-old presenting with epiglottitis [Hughes AL, Karter N, Swanson DS. Laryngeal Infections. In: Valdez T, Vallejo J, editors. Infectious Diseases in Pediatric Otolaryngology [Internet]. Cham: Springer International Publishing; 2016 [cited 2016 Aug 3]. p. 151–61. Available from: http://link.springer.com/10.1007/978-3-319-21744-4_11] *Caption from original*

- Indirect diagnosis may be obtained by visualization of a swollen epiglottis on lateral neck radiographs (“thumb print sign”).



(a, b) Acute epiglottitis. Note the swollen epiglottis with a thumb-like appearance. Radiography is unnecessary in acute epiglottitis and must not be undertaken lightly but occasionally may be performed to exclude a foreign body. It is best performed with the patient in a sitting position to keep the airway open. Epiglottitis can be life-threatening and resources to secure the airway must be available at all times. The CT image shows an edematous epiglottis containing an abscess (arrow). CT is unnecessary for acute epiglottitis. (c) Croup – "steeple" like narrowing of the subglottic airway (arrowheads) [Raghavan P, Shonka DC, Wintermark M, Mukherjee S. Larynx and Hypopharynx. In: Raghavan P, Mukherjee S, Jameson MJ, Wintermark M. Manual of Head and Neck Imaging [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2016 Aug 2]. p. 109–36. Available from: http://link.springer.com/10.1007/978-3-642-40377-4_5] *Caption from original*

Factors That Suggest Diagnosis

- Many studies have highlighted the following findings:
  - Difficulty breathing (80 %)
  - Stridor (80 %)
  - Muffled or hoarse voice (79 %)
  - Pharyngitis (73 %)
  - Fever (57 %)
  - Sore throat (50 %)
  - Difficulty swallowing (26 %)
  - Change in voice (20 %)

Symptom	No. of patients	Percent
Sore throat	272	94
Dysphagia	252	88
Odynophagia	178	62
Fever	118	41
Dyspnea	85	30
Hoarseness	40	14
Foreign body sensation	23	8
Cough	19	7
Muffled voice	18	6
Otalgia	11	4
Stridor	4	1
Drooling	4	1
Heartburn	4	1
Vomiting	2	1
Tripod position	0	0

Patients may have more than one presenting symptom

Presenting symptoms and signs in 288 acute supraglottitis adult patients [Ovnat Tamir S, Marom T, Barbalat I, Spevak S, Goldfarb A, Roth Y. Adult supraglottitis: changing trends. European Archives of Oto-Rhino-Laryngology. 2015 Apr;272(4):929–35.] *Caption from original*

Factors That Exclude Diagnosis

- A normal epiglottitis on direct view in the surgical suite is the only way to exclude the diagnosis fully in patients suspected of having epiglottitis.

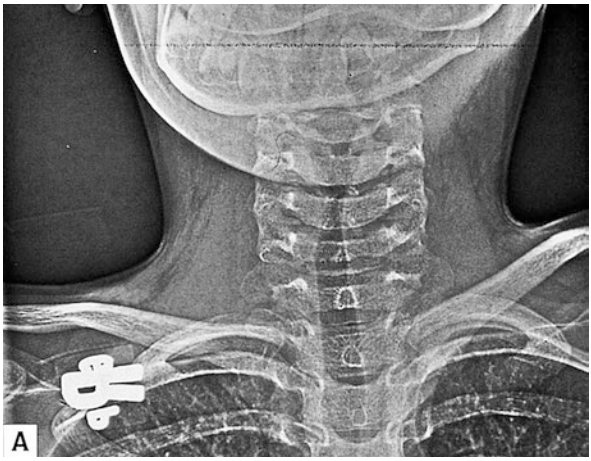
Ancillary Studies

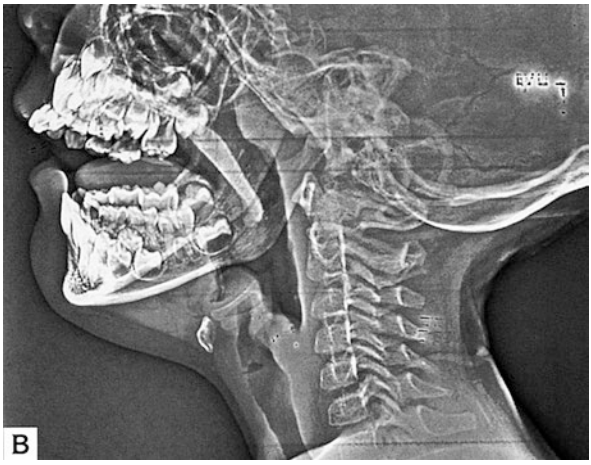
Laboratory

- Note: It is advisable to wait until definitive equipment and personnel are at the bedside (or in the OR) before negatively stimulating the child.
- Although the diagnosis is a clinical one, leukocytosis is common, as are positive blood cultures.

Imaging

- Radiographs should only be obtained at no risk to the child.
- No patient should leave the Emergency Department without adequate airway personnel and equipment.





Epiglottitis as seen by xeroradiography. A, Anteroposterior view of the neck of a child with documented epiglottitis shows narrowing in the diameter of the trachea, which can be confused with acute viral croup. The lateral neck view is preferable because it can demonstrate the enlarged epiglottis, or "thumb sign." B, Xeroradiograph showing a lateral neck view of the same child demonstrates the acute epiglottic and aryepiglottic swelling seen in acute epiglottitis. Direct visualization in the operating room revealed a markedly swollen epiglottis. [Tristram D. Chapter 07. In: Brook I, editor. Atlas of Upper Respiratory and Head and Neck Infections, 2e. Philadelphia: Current Medicine; 2000. (Mandell GL, editor. Atlas of infectious diseases; vol. 4). ISBN: 1-57340-140-4] *Caption from original*

Epiglottitis. Lateral radiograph of the neck demonstrates gross enlargement of the epiglottis (arrowhead) as well as the aryepiglottic fold, resulting in narrowing of the supraglottic laryngeal airway [Singh A. Imaging of Neck Emergencies. In: Singh A, editor. Emergency Radiology [Internet]. New York, NY: Springer New York; 2013 [cited 2016 Aug 2]. p. 183–98. Available from: http://link.springer.com/10.1007/978-1-4419-9592-6_15] *Caption from original*

Special Populations

Age

- Epiglottitis can present at all ages. Adult epiglottitis is generally less acute and is certainly less life-threatening than the pediatric issue.
- Pediatric epiglottitis is much less common in areas where the Hib vaccine is widely given; kids who are not immunized are at higher risk.

Co-morbidities

- Immune-compromised patients are at higher risk of developing epiglottitis. This is particularly true in adult cases.

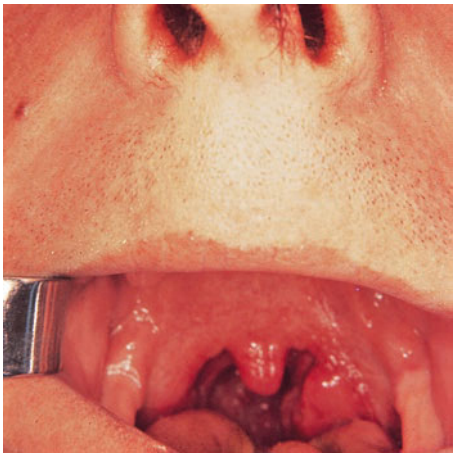
Co-morbidity	Number of patients	Percent
None	108	38
Smoking	121	42
Cardiovascular disease	87	30
Gastroesophageal reflux	37	13
Diabetes mellitus	29	10
Immunosuppression	20	7
Others	124	43

Patients may present with several co-morbidities

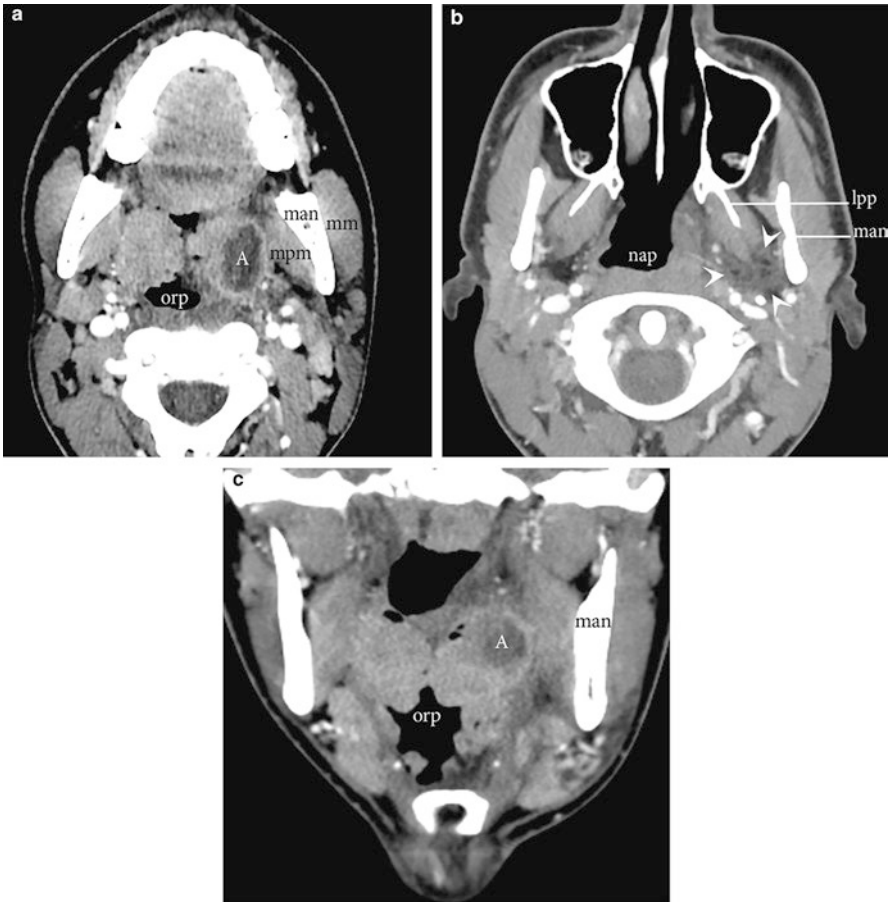
Most common co-morbidities among 288 acute supraglottitis adult patients [Ovnat Tamir S, Marom T, Barbalat I, Spevak S, Goldfarb A, Roth Y. Adult supraglottitis: changing trends. European Archives of Oto-Rhino-Laryngology. 2015 Apr;272(4):929–35.] *Caption from original*

Pitfalls in Diagnosis

- The two most significant pitfalls in diagnosis are:
  - failing to consider the diagnosis altogether
  - being cavalier in the workup and sending a child suspected of epiglottitis to radiology without definitive airway assistance.
- Failing to consider significant differential diagnoses such as peritonsillar abscess is a problem.



Peritonsillar abscess [Endicott J, Seper J. Chapter 10. In: Brook I, editor. Atlas of Upper Respiratory and Head and Neck Infections, 2e. Philadelphia: Current Medicine; 2000. (Mandell GL, editor. Atlas of infectious diseases; vol. 4). ISBN: 1-57340-140-4]



Peritonsillar abscess. Axial (***a***, ***b***) and coronal (***c***) CECT images demonstrate a rim-enhancing left-sided peritonsillar abscess (A) in this child with odynophagia and fever. There is resultant narrowing of pharynx and "kissing" appearance of the enlarged tonsils. There is infiltration of left parapharyngeal fat (white arrows). Medial pterygoid muscle (mpm, ***a***), mandible (man, ***a***, ***b***, ***c***), masseter muscle (mm, ***a***), oropharynx (orp, ***a***, ***c***), lateral pterygoid plate (lpp, ***b***), nasopharynx (nap, ***b***) [Pawha P, Jiang N, Shpilberg K, Luttrull M, Govindaraj S. Gross and Radiographic Anatomy. In: Levine AI, Govindaraj S, DeMaria, S, editors. Anesthesiology and Otolaryngology [Internet]. New York, NY: Springer New York; 2013 [cited 2016 Aug 2]. p. 3–33. Available from: http://link.springer.com/10.1007/978-1-4614-4184-7_2] *Caption from original*

Critical Steps Not to Miss

- If a diagnosis of epiglottitis is suspected, all efforts should be directed toward obtaining the personnel and equipment necessary for intubation.
- Without question, intubation is best carried out in the OR by medical caregivers expert in Pediatric airway management (i.e., ENT or Anesthesia).

Mimics

- Most other causes of upper airway disease in children do not present in a manner similar to that of epiglottitis.

Time-Dependent Interventions

- Early confirmation of the diagnosis and expectant airway management by expert operators is essential to good outcomes in acute epiglottitis.

Overall Principles of Treatment

- The management of epiglottitis has 3 phases:
  - Recognition
  - Intubation
  - Intravenous antibiotics

Disease Course

- The prognosis is excellent if surgical correction is carried out.

Chapter 27
Esophageal Rupture

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Esophageal Rupture

- Esophageal Perforation, Boerhaave's Syndrome

Incidence/Epidemiology

- Esophageal rupture is a rare but life-threatening event.
- Current mortality of 30 %.
- There are many causes of esophageal rupture (described below). Iatrogenic causes are the most common, accounting for about half of all cases. Classic Boerhaave's syndrome accounts for another 15 %, foreign bodies for 14 %, trauma (penetrating, blunt, caustic ingestion) for 10 %, and other miscellaneous causes for the remainder of cases seen.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_27

Differential Diagnosis

- Esophageal rupture usually causes acute onset of chest pain, so all the causes of acute chest pain need to be considered in the differential. These include; acute coronary syndrome, aortic dissection, pulmonary embolism, pneumonia, pneumothorax, other intra-abdominal catastrophes, amongst others.
- Esophageal rupture has many causes. Usually the history will lead to recognition of the cause of the rupture once identified.

Pathophysiology and Etiology

- Rupture of the esophagus allows for the direct contamination/communication of esophageal contents into the mediastinum. The esophagus has no serosal mucosal covering, so there is no anatomic mechanism for containment. The parietal pleura is very thin and weak, so the local inflammatory response allows for easy disruption of the parietal pleura and passage of contents into the pleural space.
- The left, posterior, distal esophagus just above the esophagogastric junction is the weakest point in the esophagus and the most common place for spontaneous rupture and rupture from gastrointestinal endoscopic procedures.
- Complications from tracheal and pharyngeal procedures may lead to rupture of the cervical esophagus at the level of the cricopharyngeal muscle just distal to the esophageal introitus, an anatomic narrowing point of the esophagus. Cervical ruptures often are better localized and not as serious as distal ruptures.
- There are multiple causes of esophageal rupture.
    - Iatrogenic, which is the most common, accounting for about 50 % of cases
        - Esophageal rupture complicates about 0.2–1 % of endoscopies. It is more likely in the setting of pre-existing esophageal disease such as caustic burns, tumors, eosinophilic esophagitis, and other causes of esophageal scarring.
        - Esophageal dilatation.
        - Endotracheal procedures/intubations, and with esophageal obturator airway placement.
    - Spontaneous “Boerhaave’s syndrome”
        - Causes about 15 % of all cases.
        - First described by Boerhaave in the early 1700s.
        - Very high mortality if not recognized early. The forces required to rupture the esophagus also force the spread of esophageal contents throughout the mediastinal space, leading to massive mediastinal contamination.

- The usual site of perforation is the distal esophagus in the left posterior region, just above the gastroesophageal junction.
- Usually occurs after episodes of sudden, forceful vomiting (about 75 % of these cases), but also may occur after severe coughing, straining, seizures, and childbirth (25 % of cases). Therefore, 25 % of cases do not have the typical history of forceful vomiting.
- A history of alcoholism, recent heavy drinking, and/or overindulging in food is found in most of the cases due to forceful vomiting.

- Foreign bodies
  - Cause 10 % of esophageal perforations.
  - Usually from pills, batteries, buttons.
  - Caused by either direct laceration or pressure or chemical necrosis.
  - Usually occurs at either the cervical or lower esophagus.
- Trauma
  - Causes about 10 % of cases.
  - May be from caustic (alkali or acid) burns, penetrating trauma, or blunt trauma.
  - Perforation more likely from alkali burns than acid burns.
  - Penetrating wounds to the neck, chest, and abdomen associated with only about a 0.5 % incidence of esophageal perforation.
  - Often overlooked initially as more obvious injuries are treated.
  - Blunt trauma is a very rare cause.
  - Miscellaneous causes (remaining 15 %)
  - Esophageal tumors, esophageal disease (achalasia, Barrett's esophagus, eosinophilic esophagitis), infectious (rare), aortic pathology (aortic aneurysm, aberrant right subclavian artery).

Presentation

Typical/"Classic"

- Acute onset of severe, constant, sharp, substernal chest pain immediately following an appropriate procedure or an episode of forceful vomiting. Pain is often pleuritic and radiates in an esophageal pattern (neck into chest and upper abdomen). Pain often worsens with swallowing.
- Usually the patient appears ill and uncomfortable. He or she also may complain of shortness of breath and be diaphoretic.
- If the patient presents early in the course, physical exam findings may be normal.
- If presenting 1–2 hours into the course, the patient may appear septic, with fever, tachycardia, hypotension, and hypoxia.

- "Hamman crunch": crunching sound heard on auscultation during systole as the result of air in the mediastinum surrounding the pericardium.
- Classically described subcutaneous emphysema (feeling of crunchiness [crepitus] under skin due to air tracking through subcutaneous tissues) in neck is present in only about 25 % at time of presentation.
- Chest x-ray (CXR) may be normal early in course, but over time pneumomediastinum, left more often than right pleural effusion, pneumothorax, hydropneumothorax, and/or a widened mediastinum may develop. CXR also may demonstrate subcutaneous air.

Atypical

- About one-third of cases will present atypically.
- May present as back pain only.
- Remember that about 25 % of patients with spontaneous esophageal rupture do not give a history of forceful vomiting.
- Many of the classically described physical and radiologic findings may not develop until several hours into the clinical course, so a high index of suspicion must be maintained by the treating physician.
- Pneumomediastinum is demonstrated in only about 40 % on plain CXR, even well into the clinical course.

Primary Differential Considerations

- Patients who present with signs and symptoms consistent with esophageal rupture also should be evaluated for these differential diagnoses:
  - Acute coronary syndrome
  - Aortic dissection
  - Peptic ulcer disease
  - Acute pancreatitis

History and Physical Exam

Findings That Confirm Diagnosis

- Esophageal rupture is a rare disease, and a high index of suspicion must be maintained by the treating physician.
- CT is the most common confirmatory study.

- Contrast esophagoscopy and endoscopy also may be used, but less commonly.
- Endoscopy may be falsely negative.
- The combination of contrast esophagoscopy and endoscopy approaches 100 % sensitivity for diagnosis.

Factors That Suggest Diagnosis

- The development of severe chest or upper abdominal pain after an ENT or GI procedure, after an episode forceful vomiting, after penetrating trauma, or in a patient with known esophageal disease should suggest the diagnosis, and a high index of suspicion should be maintained by the treating physician.
- Finding a pneumomediastinum on CXR in the appropriate clinical setting (s/p procedure, or after forceful vomiting) makes the diagnosis likely enough that appropriate treatment can proceed while confirmation is sought.
- It is important to remember that pneumomediastinum takes 1–2 hours to develop, especially in perforation of the lower esophagus, so its absence does not exclude the diagnosis.
- Pneumomediastinum may be present in only about 40 % of cases.
- Other suggestive findings on CXR include pleural effusions (left-sided more common than right), pneumothorax, hydropneumothorax, subcutaneous emphysema, or pneumoperitoneum.

Factors That Exclude Diagnosis

- The finding of another cause for the acute chest pain (e.g., acute myocardial infarction, aortic dissection) essentially excludes the diagnosis.
- Radiographic studies may all be normal early (first 1-4 hours) in the course of the disease, so in an appropriate clinical setting, suspicion must be maintained even if initial studies are unrevealing.

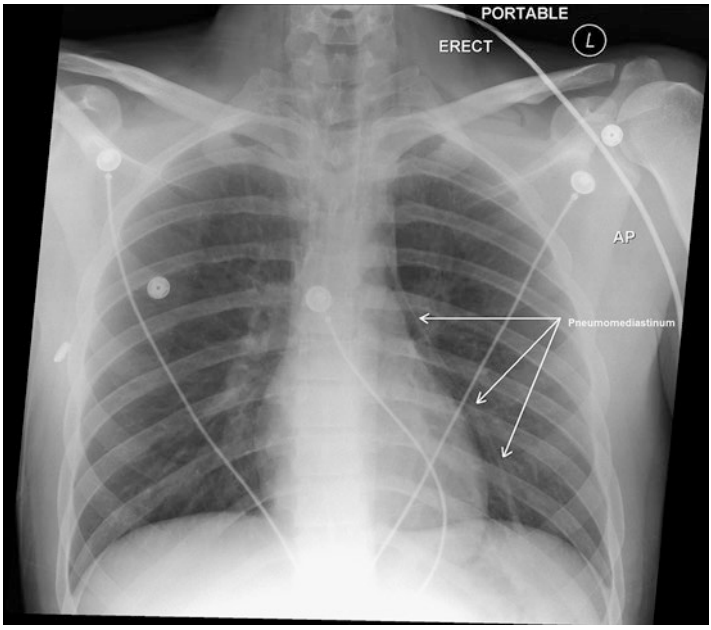
Ancillary Studies

Laboratory

- There are no laboratory tests that are specific to the diagnosis.
- Patients often manifest laboratory values consistent with an acute, severe, infectious, or inflammatory condition, such as leukocytosis, acidosis, or elevated lactate.

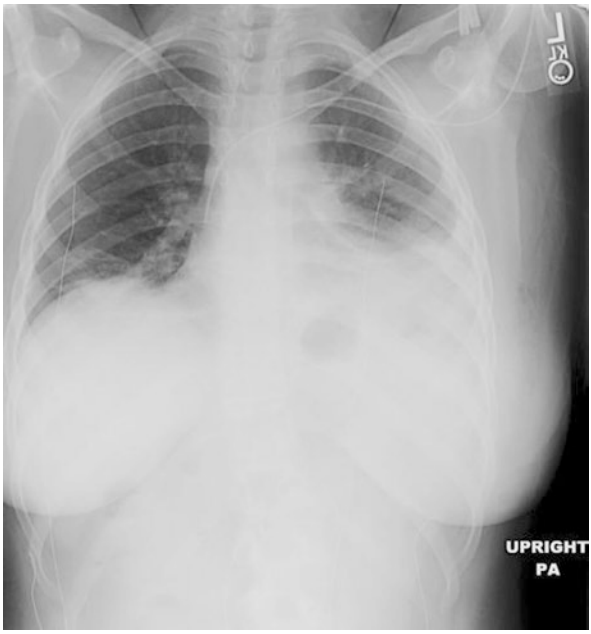
Imaging

- The plain CXR often is normal early in the disease course.
- Classically, the CXR may show multiple findings (alone or in combination):
  - Pneumomediastinum (seen in 40 %) with or without subcutaneous emphysema



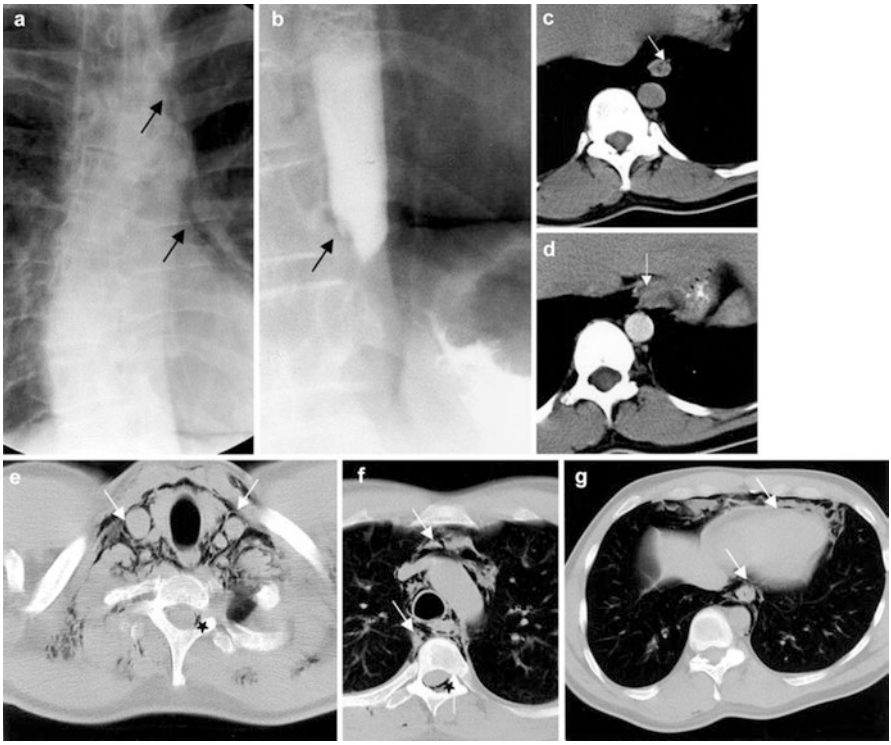
Chest X-ray showing pneumomediastinum. [From article: Pneumomediastinum from nasal insufflation of cocaine. International Journal of Emergency Medicine. 2010 Dec;3(4):435–7. https://doi.org/10.1007/s12245-010-0205-9, at http://link.springer.com/article/10.1007%2Fs12245-010-0205-9; by Brian T. Kloss, Claire E. Broton, Elliot Rodriguez, © Springer-Verlag London Ltd 2010; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption adapted from original*

- Left-sided pleural effusion



CXR demonstrating a left-sided pleural effusion. [Kohler JA, Ellis AR. Libman-Sacks Endocarditis in Pediatric Patient With Systemic Lupus Erythematosus. Pediatric Cardiology. 2012 Dec;33(8):1466–8.]

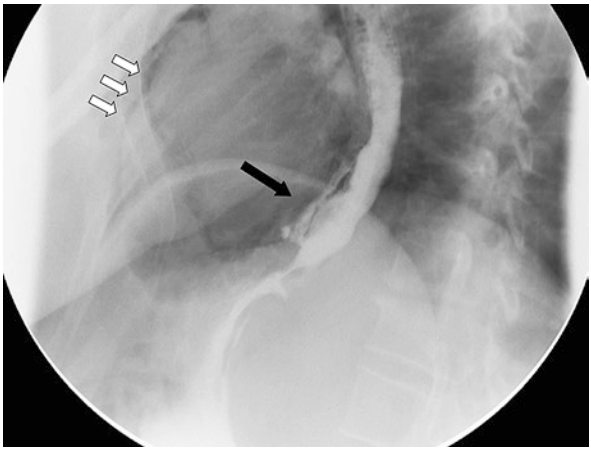
- Pneumothorax or hydropneumothorax
- Widened mediastinum
- CT scan of the chest often demonstrates the esophageal perforation and is more sensitive than CXR for detecting mediastinal air. Chest CT is the diagnostic study of choice.



a Chest radiography demonstrating pneumomediastinum (arrows). There were no infiltrates, atelectasis, or pleural effusion apart from the subcutaneous emphysema. b Esophagography with water-soluble contrast medium depicted a small but visible right-sided submucosal tear representing a contained esophageal perforation (arrow). No contrast medium extravasation through the esophagus was seen. c Nonenhanced CT demonstrated high attenuation of the supradiaphragmatic wall at a typical site, suggesting an intramural hematoma. c, d Nonenhanced and contrast-enhanced CT revealed an esophageal wall thickening which is a nonspecific finding. e–g CT at the level of the thyroid gland showed extensive pneumomediastinum and subcutaneous emphysema. Intraspinal air collections were seen at multiple levels in the spinal canal as visualization of air tracks (*). In addition to a large quantity of air in the anterior and posterior mediastinum, local periesophageal extraluminal air collections were observed indicating extraluminal complications of Boerhaave's syndrome. CT scan depicted air tracks (arrows) extending from the esophagus into the anterior lower mediastinum (g). [Radiological findings in Boerhaave's syndrome - Springer. [cited 2015 May 19]; Available from: http://link.springer.com/article/10.1007%2Fs10140-002-0264-1/fulltext.html] *Caption adapted from original*

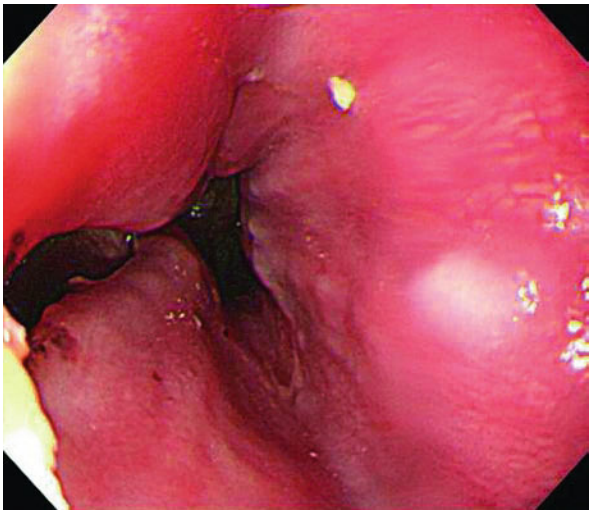
- Contrast esophagoscopy also may demonstrate the esophageal defect. It should be performed initially with a water-soluble contrast agent (Gastrografin), as barium-containing contrast agents, if extruded into the sur-

rounding tissues, may incite an inflammatory response. However, water-soluble contrast has a higher false-negative rate, so a negative water-soluble study should then be confirmed by a barium contrast study if the clinical suspicion remains high.



Water-soluble contrast radiograph of a patient with a distal esophageal perforation. The white arrows indicate free air in the mediastinum; the black arrow indicates extravasation of esophageal contrast. [Sánchez-Pernaute A, Aguirre EP, Talavera P, Valladares LD, de la Serna JP, Mantilla CS, de León AR, Torres A. Laparoscopic approach to esophageal perforation secondary to pneumatic dilation for achalasia. Surgical Endoscopy. 2009 May;23(5):1106–9.] *Caption from original*

- Esophagogastroduodenoscopy (EGD, upper endoscopy) also can directly demonstrate the esophageal defect. However, endoscopy may also miss a small defect. The combination of contrast esophagoscopy and endoscopy approaches 100 % sensitivity for the diagnosis.



Boerhaave syndrome. Perforation site was observed in the left side of the esophagus. [Park JM. Miscellaneous Esophageal Diseases. In: Chun HJ, Yang S-K, Choi M-G, editors. Clinical Gastrointestinal Endoscopy [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2015 May 19]. p. 87–98. Available from: http://link.springer.com/10.1007/978-3-642-35626-1_7] *Caption from original*

Special Populations

Age

- Esophageal rupture is slightly more common inmiddle-aged and older populations.

Co-morbidities

- Esophageal rupture is associated with chronic alcohol use and with other esophageal diseases that cause strictures or scarring of the esophagus.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the critical step. It also is critical to continue to consider the diagnosis, as physical and radiographic findings may take several hours to develop after the rupture.

Mimics

- Anything that causes acute chest or upper abdominal pain can mimic esophageal rupture. These include but are not limited to acute myocardial infarction, pulmonary embolism, aortic dissection, spontaneous pneumothorax, perforated peptic ulcer, pancreatitis, acute cholecystitis, and mesenteric thrombosis.

Time-Dependent Interventions

- Early diagnosis is important. Time is critical in decreasing morbidity and mortality. If primary closure of the defect occurs within the first 24 hours, there is 80–90 % survival. If repair occurs greater than 24 hours after rupture, survival falls below 50 % and may reach 30 %.
- Any patient with hemodynamic instability should be resuscitated, as would any patient in shock.

Overall Principles of Treatment

- Rapid resuscitation with intravenous fluids, empiric broad-spectrum antibiotics, and appropriate management of complications such as pneumothorax or hydropneumothorax should begin as appropriate, even if the diagnosis is not certain.
- Early primary surgical repair of the defect is definitive treatment. Some contained cervical esophageal ruptures may be managed conservatively and nonoperatively.

Disease Course

- Esophageal rupture may be rapidly fatal if not identified and treated early.
- Patients often present in extremis or have a rapidly progressive course.

Chapter 28
Esophagitis

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Esophagitis

Incidence/Epidemiology

- Esophagitis has been implicated as the cause of chest pain in 20–60 % of patients with chest pain not having an acute myocardial infarction.

Differential Diagnosis

- Esophagitis may cause acute chest pain, so the initial differential diagnostic considerations include all the acute causes of chest pain.
- Once the esophagus is believed to be the source of the chest pain, the differential diagnosis may focus on the causes of acute esophagitis, including inflammatory and infectious esophagitis, each of which has multiple causes.

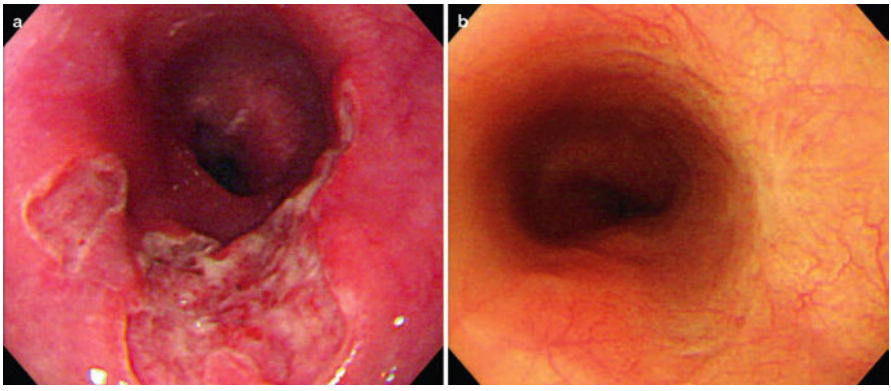
Pathophysiology and Etiology

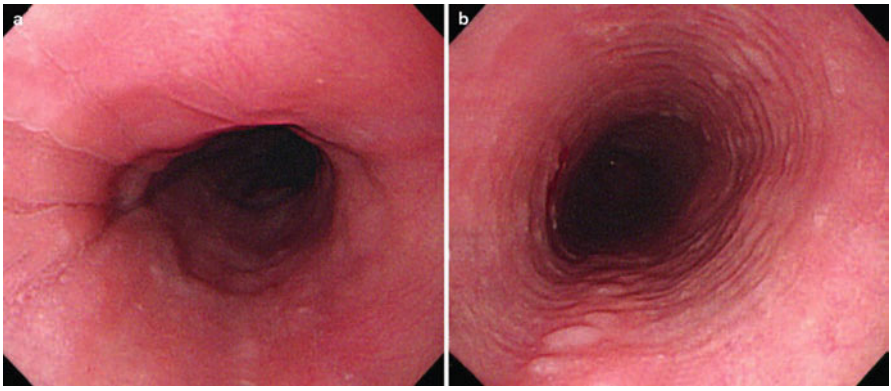
- The final common pathway of pathophysiology is inflammation of the esophageal mucosa. The pathologic changes may progress to include inflammation and ulceration of both the mucosal and muscular layers of the esophagus. Both may lead to permanent scarring with strictures and narrowing of the esophagus.
  - This inflammation may result from multiple insults:
    - Inflammatory:
      - The best example is severe gastroesophageal reflux leading to inflammation, ulceration, scarring, and strictures.
      - "Pill" esophagitis results from pills remaining in contact with the esophageal mucosa. The most common location for pills to get stuck is at the level of the aortic arch, an anatomic narrow point in the esophagus. This may occur with any medication, but the most commonly implicated are nonsteroidal drugs; potassium tablets; antibiotics, such as clindamycin, doxycycline, and tetracycline; and bisphosphonates. Pill esophagitis usually causes dysphagia and odynophagia in addition to chest pain. Risk factors for the development of pill esophagitis include poor pill-taking practices, such as incorrect head position and insufficient water intake with the medication; swallowing of large tablets; and the extremes of age.



Pill-induced esophagitis. (a) Three days after ingestion of an unknown medication, a small and a neighboring, large well-demarcated ulcer with intact surrounding mucosa are noted at mid-esophagus. (b) Scar change of the ulcer after 2 months [Park KS. Infectious and Noninfectious Esophagitis. In: Chun HJ, Yang S-K, Choi M-G, editors. Clinical Gastrointestinal Endoscopy [Internet]. Berlin, Heidelberg:

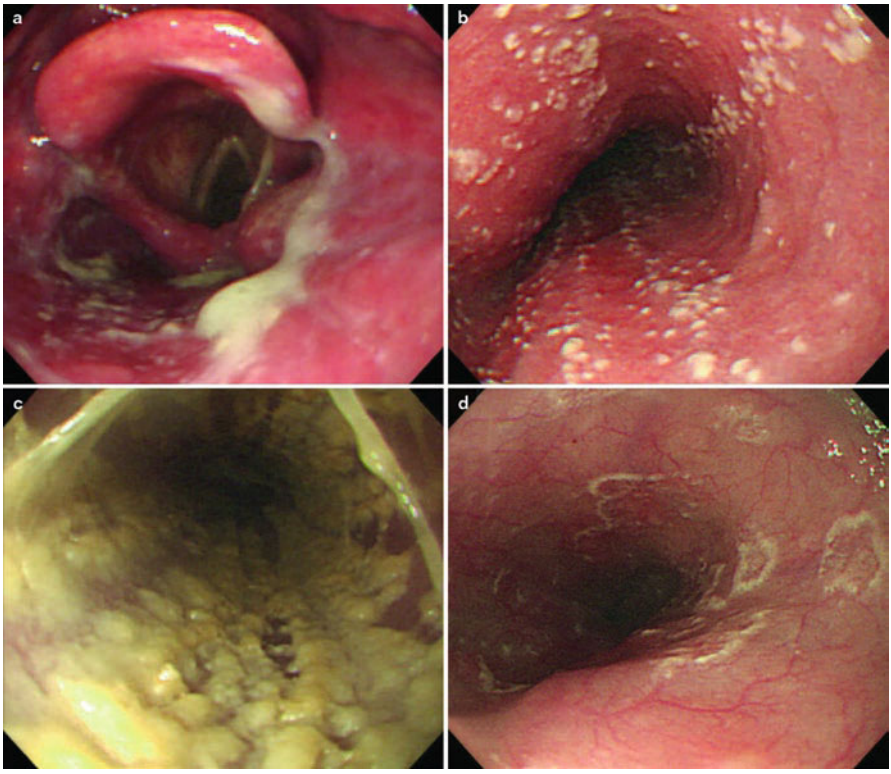
Springer Berlin Heidelberg; 2014 [cited 2015 May 14]. p. 17–30. Available from: http://link.springer.com/10.1007/978-3-642-35626-1_3] *Caption from original*

- Eosinophilic esophagitis. Caused by sequestration and localization of eosinophils within the esophageal mucosa, leading to inflammation and narrowing of the esophageal lumen, with subsequent fibrosis and scarring. Usually causes dysphagia and odynophagia, and is a common cause of esophageal food impaction. Believed to be the result of an allergic response within the esophageal mucosa.



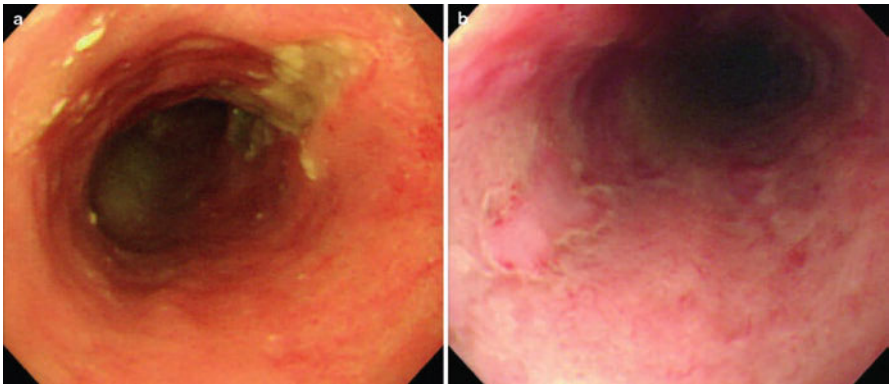
Eosinophilic esophagitis. (a) Linear furrows, (b) multiple rings [Park KS. Infectious and Noninfectious Esophagitis. In: Chun HJ, Yang S-K, Choi M-G, editors. Clinical Gastrointestinal Endoscopy [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2015 May 14]. p. 17–30. Available from: http://link.springer.com/10.1007/978-3-642-35626-1_3] *Caption from original*

- Corrosive esophagitis. Occurs after alkali (or less likely, acid) ingestion, with initial inflammation and ulceration and subsequent scarring and stricture formation.
- Radiation esophagitis. A long-term sequela of mantle radiotherapy for cancer.
- Infectious: Infectious esophagitis usually is associated with underlying immunosuppression (such as from HIV, cancer, severe diabetes). Diagnosing infectious esophagitis in an otherwise healthy patient should prompt a search for underlying immunosuppression.
- Candida albicans is the most common cause.

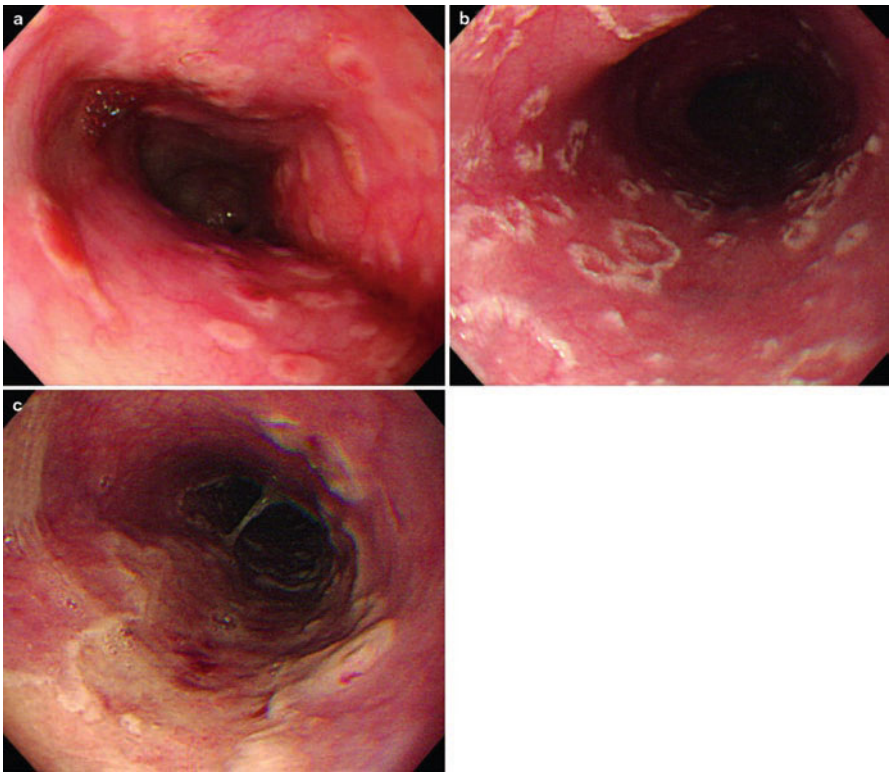


Candida esophagitis. (a) Coexisting pharyngeal lesions help to diagnose Candida esophagitis. (b) Multiple white plaques. (c) Diffuse membranous white material. (d) Atypical lesions which resemble herpetic esophagitis [Park KS. Infectious and Noninfectious Esophagitis. In: Chun HJ, Yang S-K, Choi M-G, editors. Clinical Gastrointestinal Endoscopy [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2015 May 14]. p. 17–30. Available from: http://link.springer.com/10.1007/978-3-642-35626-1_3] *Caption from original*

- Viral causes include cytomegalovirus and herpes simplex virus.



CMV esophagitis. (a) Longitudinal deep ulcer, (b) multiple shallow ulcers mimicking herpes esophagitis [Park KS. Infectious and Noninfectious Esophagitis. In: Chun HJ, Yang S-K, Choi M-G, editors. Clinical Gastrointestinal Endoscopy [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2015 May 14]. p. 17–30. Available from: http://link.springer.com/10.1007/978-3-642-35626-1_3] *Caption from original*



Herpes esophagitis. (a) Multiple vesicular lesions, (b) shallow ulcers with prominent demarcation, (c) large ulcer formation by confluence of small ulcers [Park KS. Infectious and Noninfectious Esophagitis. In: Chun HJ, Yang S-K, Choi M-G, editors. Clinical Gastrointestinal Endoscopy [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2014 [cited 2015 May 14]. p. 17–30. Available from: http://link.springer.com/10.1007/978-3-642-35626-1_3] *Caption from original*

Presentation

Typical/"Classic"

- Chest pain, often described as burning. There is no historical or examination feature sensitive or specific enough to exclude cardiac causes of chest pain; therefore, a cardiac workup should be performed before or during evaluation for esophagitis.

- Certain symptoms may be helpful if present:
  - Odynophagia: pain with swallowing or pain exacerbated by swallowing
  - Dysphagia: difficulty swallowing. It may be described as a sensation of food or liquid getting stuck.

Atypical

- Any complaint of chest pain may be caused by esophagitis, so there is no typical or atypical presentation.

Primary Differential Considerations

Early in the evaluation of patients with symptoms of esophagitis, consider the following important differential diagnoses:

- Acute coronary syndrome
- Aortic dissection
- Acute pericarditis
- Pneumothorax
- Pleurisy
- Pneumonia
- Esophageal rupture
- Peptic ulcer disease

History and Physical Exam

Findings That Confirm Diagnosis

- The only findings that can completely confirm the diagnosis are typical findings on esophagogastroduodenoscopy (EGD/endoscopy).

Factors That Suggest Diagnosis

- Chest pain associated with pain with swallowing (odynophagia) and/or difficulties swallowing (dysphagia) strongly suggest the diagnosis.

Factors That Exclude Diagnosis

- A normal EGD excludes esophagitis.

Ancillary Studies

Laboratory

- No laboratory studies are helpful in suggesting or confirming the diagnosis of esophagitis. Laboratory studies may help exclude the diagnosis, e.g., positive cardiac biomarkers in a patient with chest pain. Remember that esophagitis may coexist with other diagnoses.

Imaging

- Plain chest x-ray usually is unremarkable.
- CT of the chest may demonstrate esophageal wall thickening, but this is often an incidental finding during studies performed for other reasons, such as evaluation for pulmonary embolism. It also may suggest the diagnosis, but it does not confirm the diagnosis.

Special Populations

Age

- Esophagitis may occur at any age. Certain diagnoses within the category may have age predilections, such as eosinophilic esophagitis, which is more likely in children and young adults.
- Clinical manifestations in children include:
  - Emesis
  - Feeding problems
  - Dysphagia
  - Abdominal pain
  - Food impaction
- In the pediatric population, there is a definite association with other forms of allergic disease (asthma, allergic rhinitis, urticaria, eczema)

Co-morbidities

- Common co-morbidities include obesity, diabetes, immunosuppression, alcohol abuse, and cigarette smoking.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is important.
- However, it is more important to make sure the cause of chest pain is not a more immediately life-threatening condition.

Mimics

- The entire constellation of diagnoses underlying chest pain syndrome can mimic the pain and overall presentation of esophagitis.
- Esophagitis is more often considered a "mimic" of cardiac causes of chest pain.

Time-Dependent Interventions

- Check the ECG immediately for signs of acute myocardial ischemia. Remember that a normal ECG does not exclude acute coronary syndrome!
- If the patient has signs of GI bleeding, initiate stabilization and resuscitation immediately.

Overall Principles of Treatment

- Treatment depends on identifying the underlying cause of the esophagitis.
- Inflammatory causes of esophagitis often improve with acid suppression, usually from proton-pump inhibitors.
- Infectious causes need to be treated with the appropriate anti-infective agents.
- Eosinophilic esophagitis may be treated with elimination diets for removal of putative causative agents or with topical or systemic corticosteroids.
- The use of acid suppression with proton-pump inhibitors is prescribed nearly universally for all causes of esophagitis.

- If the esophagus becomes scarred or develops strictures, endoscopically guided esophageal dilatation may be necessary.

Disease Course

- Most cases of esophagitis from almost any cause will improve within several weeks of initiation of appropriate treatment.

Chapter 29
Foreign Body Aspiration

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Foreign Body Aspiration (esophageal/tracheal)

Incidence/Epidemiology

- Swallowed and inhaled foreign bodies both may cause chest pain with or without shortness of breath.
- Both swallowed and inhaled foreign bodies are more common among young children, but esophageal food bolus impaction may occur at any age and is more common in the elderly, often presenting as chest pain.
- Foreign body aspiration may be life threatening at any age; cases in which food is the aspirated agent are referred to as "café coronary."

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_29

Symptoms can include choking, coughing, wheezing, upper airway obstructive breathing, and if severe, cyanosis.
The foreign body can be lodged in the esophagus and compress the trachea, it can lie in the trachea itself, or it can lie in a mainstem bronchus.
The foreign body may be of various materials, including chunks of food, pieces of toys, coins, and—worst of all—a peanut, which may increase in size as it absorbs secretions.
Bronchoscopy usually is performed to remove the foreign body. The anesthetic plan must be tailored to the type of foreign body and the amount of the patient's distress.
Anesthetic induction: An inhalational technique may need to be performed to avoid muscle relaxation and prevent the foreign body from changing position with relaxation. The dilemma is inducing the patient having a full stomach with an inhalational technique. If intravenous access has been obtained, rapid sequence induction may be considered; however, avoid cricoid pressure, which may compress the object and cause tracheal or esophageal lacerations.

Features associated with aspiration of a foreign body. This is a common emergency situation in a child with a foreign body that becomes lodged in either the trachea or the esophagus that can result in airway compromise. The patients undergo bronchoscopy to retrieve the foreign body and are generally kept spontaneously ventilating in order to remove the object. [Rasmussen G, Deshpande J. Pediatric anesthesia. In: Muravchick S, editor. Subspecialty care. Philadelphia: Current Medicine; 1998. 236 p. (Miller RD editor, Atlas of anesthesia; vol. 5). ISBN: 0-443-07905-6] *Caption from original*

[b] Stands for the percentage of one kind of the foreign body

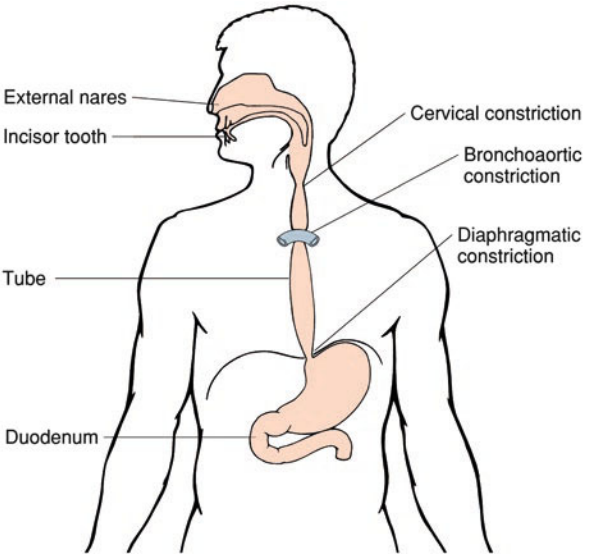
Foreign bodies, sex, age and clinical manifestations of 121 cases with dangerous esophageal foreign bodies. [Peng A, Li Y, Xiao Z, Wu W. Study of clinical treatment of esophageal foreign body-induced esophageal perforation with lethal complications. Eur Arch Otorhinolaryngol. 2012 Sep;269(9):2027–36.] *Caption from original*

Differential Diagnosis

- The differential diagnosis is limited in cases of acute presentation, because the patient usually reports what has happened. Large foreign body aspiration in an unresponsive patient may be identified during direct laryngoscopy for rescue endotracheal intubation. Patients with an esophageal food bolus impaction may present with lower chest pain and retching, suggesting an atypical acute coronary syndrome.

Pathophysiology and Etiology

- Foreign body aspiration in patients above toddler age generally is accidental. Symptoms are driven by the size of the foreign body, which in turn determines the location of "lodging."
- Esophageal food bolus impaction generally is associated with inadequate chewing and often occurs in the setting of concomitant alcohol consumption.



Esophageal foreign bodies. In the last several decades, endoscopy has become the method of choice in the management of esophageal foreign bodies, although a trial of sublingual nitroglycerin and intravenous glucagon is warranted. At times this will allow the offending bolus to pass. The most common location of the impaction is the distal esophagus at the level of the diaphragm; however, compressions at the level of the cricopharyngeus, aortic arch, and left main-stem bronchus may also be the site of impaction. It is also helpful to identify foreign bodies as sharp or dull, pointed or blunt, and toxic or nontoxic (eg, batteries). Also, food-related impactions should be distinguished. If the foreign body is known, in vitro simulation may be helpful in choosing the right accessory for use during the procedure. [Bozymski EM, Kenney CM. Esophageal therapeutics. In: Orlando RC, editor. Atlas of esophageal diseases. 2nd ed. Philadelphia: Current Medicine; 2002. 248 p. ISBN: 1-57340-181-1] *Caption from original*

Type and location of esophageal foreign bodies. [Russell R, Lucas A, Johnson J, Yannam G, Griffin R, Beierle E, Anderson S, Chen M, Harmon C. Extraction of esophageal foreign bodies in children: rigid versus flexible endoscopy. Pediatr Surg Int. 2014 Apr;30(4):417–22.] *Caption from original*

Presentation

Typical/"Classic"

- Aspirated foreign bodies typically present as choking, coughing, and/or shortness of breath

  - Dyspnea
  - Audible wheezes may be present.
  - Large proximal aspirated foreign bodies may present as cardiac arrest.
- Esophageal foreign bodies typically present as lower chest pain and an inability to swallow; the patient often is spitting out saliva.
  - There often is a history of achalasia or previous similar episodes.

Atypical

- Especially in children, no reliable history may be available, making the etiology of typical symptoms more obscure.
- Smaller aspirated foreign bodies may not cause symptoms until days or week later, when secondary inflammation or infection has developed.

Primary Differential Considerations

- For aspirated foreign bodies, consider:
  - Epiglottitis
  - Retropharyngeal or peritonsillar abscess
  - Caustic ingestion
  - Anxiety
- For esophageal foreign bodies, consider:
  - Esophageal injury
  - Anxiety (“globus hystericus”)
  - Caustic ingestion

History and Physical Exam

- Except in toddlers, the history usually is very helpful.
- On physical exam, assessing patency of the airway and adequacy of oxygenation is the priority.

Findings That Confirm Diagnosis

- Visualization of the foreign body
- History of aspiration and subsequent coughing/gagging/choking

- History of swallowing incompletely chewed food and subsequent inability to handle oral secretions

Factors That Suggest Diagnosis

- Suggestive history

Factors That Exclude Diagnosis

- Clinically difficult to exclude, even with few symptoms; passage of time with diminishing symptoms is helpful.

Ancillary Studies

Laboratory

- No diagnostic laboratory findings

Electrocardiography

- Useful only if myocardial ischemia is a diagnostic consideration

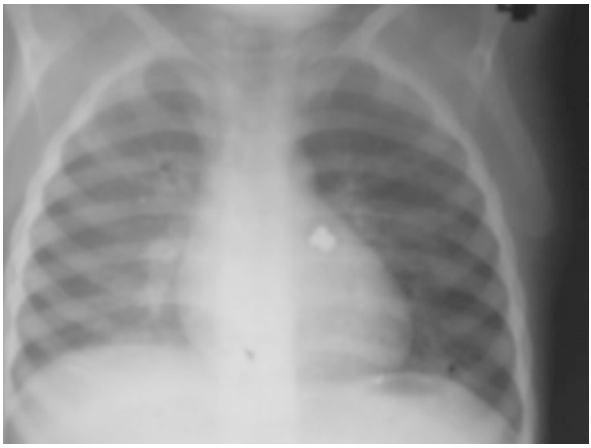
Imaging

- Aspirated foreign bodies:
  - Plain chest radiography may be helpful in patients with bronchial foreign bodies, when asymmetric lung volumes may be appreciated.
  - Chest CT may be helpful in localizing more distal foreign bodies.

Radiological findings	No of cases; *n* (%)
Obstructive emphysema	15 (20.5%)
Collapse	34 (41.65%)
Normal	20 (24.3%)
Pneumonitis	6 (7.3%)
Consolidation	4 (5%)
Foreign body visualised	2 (2.43%)
Abscess	1 (1.25%)

Radiographic findings in patients with airway foreign body. [Jaswal A, Jana U, Maiti PK. Tracheo-bronchial foreign bodies: a retrospective study and review of literature. Indian J Otolaryngol Head Neck Surg. 2014 Jan;66(S1):156–60.] *Caption from original*

Foreign body in right main bronchus. [Tsikoudas A, Sheikh S. An interesting case of a wandering foreign body in the tracheobronchial tree. Eur Arch Otorhinolaryngol. 2005 May;262(5):426–7.] *Caption from original*



Chest radiograph showing foreign body in left main bronchus with obstructive emphysema of left lung. [Jaswal A, Jana U, Maiti PK. Tracheo-bronchial foreign bodies: a retrospective study and review of literature. Indian J Otolaryngol Head Neck Surg. 2014 Jan;66(S1):156–60.] *Caption from original*

- Esophageal foreign bodies:
  - Plain chest radiography is not useful for food bolus impactions.
  - Barium swallow may be challenging for the patient but will be diagnostic.
  - More proximal foreign bodies may be visualized on plain radiography.

Esophageal foreign bodies (FBs). Ingested FBs may become impacted at any level but are typically held up at the three sites of natural narrowing: the cricopharyngeus muscle, the level of the aortic arc, and the gastroesophageal junction. The most common esophageal FBs are coins. They usually lodge at the cricopharyngeus, resulting in marked dysphagia even for liquids. Anteroposterior (from base of skull

to pelvic outlet) and lateral radiographs are recommended if a coin ingestion is suspected because the presence of multiple coins may not be appreciated on a single anteroposterior view. Sharp FBs are particularly treacherous because they may perforate the esophagus, resulting in mediastinitis or major vessel injury and life-threatening hemorrhage. This radiograph shows a metallic foreign body lodged in the midesophagus of a 4-year-old boy who had stopped eating solid foods 2 months previously, precisely at the time his older brother's toy tractor steering wheel disappeared. Removal at esophagoscopy was complicated because the foreign body was deeply embedded in the esophageal wall. [Papsin BC, James A, Friedberg J, Forte V, Crysdale WS. Otolaryngology—head and neck surgery. In: Laxer RM, editor. The Hospital for Sick Children: atlas of pediatrics. Philadelphia: Current Medicine; 2005. p. 231-250.] *Caption from original*

Other Studies

- Endoscopy often is indicated.

Special Populations

Age

- Aspiration of foreign bodies may occur at any age but is most common in toddlers.

Dysphagia
Sedative or hypnotic drug use
Poor dentition
Altered Sensorium
Chronic aspiration
Parkinson's disease
Primary neurologic disorders with impairment of swallowing or mental status
Trauma with loss of consciousness
Seizure
General anesthesia
Alcohol intoxication
Polypharmacy and difficulty swallowing large pills
Eating while lying supine or just before falling asleep

Risk factors for foreign body aspiration in elderly patients. [Folch E, Majid A. Foreign body aspiration in the elderly patient. Curr Geriatr Rep. 2015 Jun;4(2):192–201.] *Caption from original*

- Esophageal food bolus impaction is more common in older patients.
- Commonly aspirated FBs in children include nuts, seeds, popcorn, food particles, hardware, and fragments of playthings.
- Coins are aspirated more commonly by older children.
- Fatal aspirations usually involve toy balloons or similar items.
- In one study, common anatomic sites in childhood aspiration included the larynx (3 %), trachea/carina (13 %), right hemithorax (60 %), left hemithorax (23 %), and bilateral bronchial tree (2 %).
- In the pediatric patient, the diagnosis often is delayed. Children may present with wheezing, dyspnea, recurrent pneumonia, or chronic cough. Aggressive investigations beyond plain radiography, especially bronchoscopy, are warranted in patients with recurrent or otherwise unexplained symptoms.

Co-morbidities

- Achalasia

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Evaluation for satisfactory airway
- Evaluation for satisfactory oxygenation

Mimics

- Asthma

Time-Dependent Interventions

- Immediate evaluation for adequate airway and gas exchange

Overall Principles of Treatment

- Identify and remove foreign body.
- In cases of esophageal food bolus impaction, consider using glucagon before endoscopy; the use of meat tenderizer, advocated in the past, no longer is recommended.

Disease Course

- The course is determined by the acuity of presentation and underlying etiology, as well as the rapidity with which the foreign body is removed.
- The vast majority of foreign body cases are not life threatening.

Chapter 30
Gastroesophageal Reflux Disease

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Gastroesophageal Reflux Disease

- GERD, Reflux, Indigestion, Heartburn, Pyrosis

Incidence/Epidemiology

- Six to 7 % of the US population reports daily, persistent heartburn.
- Twenty to 40 % report monthly heartburn.
- GERD is responsible for a significant amount of morbidity and has substantial economic consequences.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_30

Differential Diagnosis

- GERD may present with the acute onset of chest pain similar to acute cardiac pain, so acute myocardial infarction (MI) and the other causes of acute chest pain have to be considered in the differential diagnosis.
- The presentation of GERD also may be similar to that of esophagitis, peptic ulcer disease (PUD), biliary disease, pancreatitis, hepatitis, and gastrointestinal motility disorders.

Pathophysiology and Etiology

- Reflux of gastric contents into the esophagus occurs several times a day in most people as a normal physiologic event. It becomes abnormal, and considered GERD, when it is associated with symptoms or pathologic changes within the gastrointestinal or respiratory tracts. The Montreal Classification defines GERD as "A condition that develops when the reflux of stomach contents causes troublesome symptoms and/or complications."
- The lower esophageal sphincter (LES) is the main physiologic barrier to reflux.
- When reflux does occur, both mechanical (gravity) and physiologic (peristalsis, saliva, esophageal secretions) forces can help push gastric contents back into the stomach.
- GERD may be caused or worsened by anything that reduces LES pressure, decreases esophageal motility or gastric emptying time, or directly irritates the esophageal mucosa, as well as by mechanical means.
- Factors that may reduce LES pressure include drugs (anticholinergic agents, benzodiazepines, calcium-channel blockers, progesterone), foods (chocolate, caffeine, high-fat foods, peppermint, nitrates), nicotine, and alcohol.
- Conditions that decrease esophageal motility include achalasia, diabetes, and scleroderma.
- Factors and conditions that may decrease gastric emptying time include anticholinergic medications, diabetic gastroparesis, and gastric outlet obstruction.
- Substances that may act as direct irritants to the gastric mucosa include caffeine, citrus products, and tomato-based products.
- Mechanical factors include stooping, bending forward, the Valsalva maneuver, and the supine position.
- GERD is much more common in obese patients.
- Hiatal hernia (prolapse of a portion of the stomach through the diaphragmatic esophageal hiatus) also is considered a risk factor for GERD.

Presentation

Typical/"Classic"

- The most common complaint is heartburn, a burning sensation from the subxyphoid region radiating into the neck or pharynx.
- Typically, symptoms worsen after large meals or with recumbency.
- Symptoms usually are relieved with antacids; however, this effect is not pathognomonic and does not reliably exclude cardiac causes of pain.
- Other common presenting complaints include regurgitation and nausea, but usually these are associated with heartburn.
- An uncommon but somewhat specific symptom of GERD is water brash, a vagally mediated increase in saliva production often perceived by patients as "foaming at the mouth."
- GERD also may cause extraesophageal symptoms, including asthma (or worsening asthma) from reflux associated with aspiration, chronic cough, hoarse voice, recurrent laryngitis or sore throat, frequent throat clearing, and dental problems.

Atypical

- It is important to remember that GERD symptoms can mimic those of acute MI. Patients may describe the acute onset of chest pressure, dull chest pain, or squeezing. The radiation pattern can mimic that of acute MI and radiate to the back, jaw, or arm.
- Dysphagia (difficulty swallowing) and odynophagia (painful swallowing) are uncommon symptoms for GERD and should prompt further evaluation for other causes.
- Globus is a perception of fullness or a lump in the throat, unrelated to swallowing. It is not a usual symptom of GERD, and its presence should prompt a search for other causes. It often is thought to be related to emotional stress or to have a functional basis.

Primary Differential Considerations

- Prompt consideration also should be given to the possible diagnosis of:
  - Acute coronary syndrome
  - Esophageal spasm
  - Biliary colic
  - Gastritis
  - Hiatal hernia

History and Physical Exam

Findings That Confirm Diagnosis

- Because the diagnosis of GERD can be applied only for symptoms, there are no tests that are confirmatory. A classic history of heartburn, worse after large meals, and recumbency relieved by antacids is enough to make a presumptive diagnosis of GERD.
- The physical exam is often unremarkable and not helpful in making the diagnosis.

Factors That Suggest Diagnosis

- A classic presentation as above suggests the diagnosis.
- The diagnosis of GERD should be kept within the differential when evaluating a patient for new-onset or worsening asthma not explained by other factors, as a cause of chronic cough or laryngitis, and for patients with unexplained hoarseness.

Factors That Exclude Diagnosis

- GERD may exist even in the absence of symptoms; there is no factor that excludes the diagnosis.
- Normal endoscopy does not exclude the diagnosis of GERD.

Ancillary Studies

Laboratory

- Lab tests are unhelpful in the diagnosis of GERD and often are used only to evaluate for other causes of the patient's symptoms.

Imaging

- Imaging usually is not helpful or indicated for the diagnosis of GERD.
- Patients may need imaging or endoscopy to exclude other diagnoses.

- Patients with symptoms such as dysphagia, odynophagia, weight loss, or other constitutional symptoms may need endoscopy to exclude malignancy and other serious causes of their symptoms.

Special Populations

Age

- GERD occurs in all age groups, including infants and children.
- In children, the term *gastroesophogeal reflux disease* applies when the reflux results in untoward complications, such as esophagitis, respiratory events, or growth failure.
  - There is some evidence that severe reflux in infancy predisposes children to GERD later in life.
- GERD and asthma often overlap in children and adolescents, but current data do not suggest that control of one has a significant clinical impact on the other.

Co-morbidities

- GERD may coexist with any other condition.
- Conditions that may make GERD more likely include obesity, diabetes, achalasia, motility disorders, and hiatal hernia.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is critical to consider the more immediately life-threatening causes of chest and abdominal pain.

Mimics

- GERD is a classic mimic of acute MI.
- GERD also can mimic PUD, all the causes of esophagitis, biliary disease, pancreatitis, and esophageal and gastric motility disorders.

Time-Dependent Interventions

- The only time-dependent intervention is to exclude more serious causes of pain.

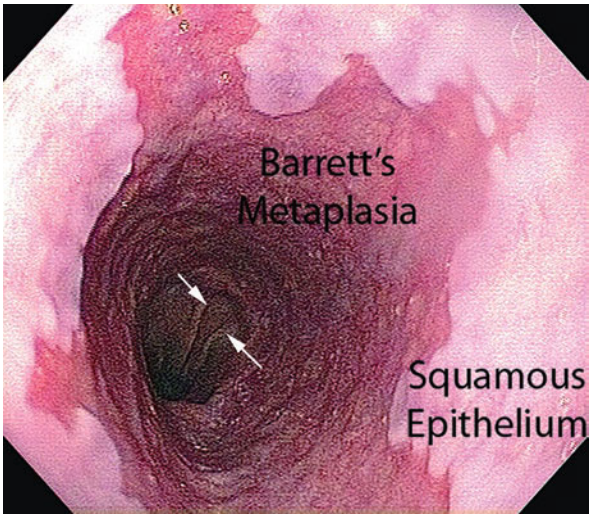
Overall Principles of Treatment

- Patients with a suggestive history, as well as those in whom more serious causes of the symptoms have been excluded, often are treated empirically with acid suppression and lifestyle changes.
- Lifestyle changes include decreasing or stopping known exacerbating substances, weight loss, and elevating the head of the bed.
- Acid suppression usually is attempted with either H2-blockers or proton-pump inhibitors (PPIs). H2-blockers have been shown to promote esophageal healing in mild esophagitis. PPIs suppress acid more effectively than H2-blockers and are more efficacious both in relieving symptoms and in promoting esophageal mucosal healing. However, PPIs are much more expensive than H2-blockers.
- Anywhere from 40–90 % of patients will report symptom improvement from PPIs.
- However, symptom improvement is not a diagnostic criterion for GERD.
- Patients whose symptoms are refractory to treatment may need further evaluation, although this group of patients usually constitutes a small minority. This is especially true for patients with worrisome symptoms such as dysphagia and odynophagia.
- Further evaluation may include esophagogastroduodenoscopy (EGD), esophageal manometry, and ambulatory pH monitoring.
- It is worth remembering that EGD may be normal in GERD, and this study usually is performed to exclude other diagnoses.
- Esophageal manometry and ambulatory pH monitoring are invasive tests; patients should be evaluated by a specialist before undergoing these studies.

Disease Course

- GERD is a chronic condition. It often requires long-term medical therapy for control.
- A minority of patients have long-term relief from lifestyle changes.
- GERD may be associated with several long-term complications, many of them serious.

- GERD may be associated with chronic esophageal mucosal changes, starting with thinning and inflammation and then scarring. These events may lead to esophageal strictures, which may cause dysphagia, odynophagia, food impactions, etc.
- The most serious complication of GERD is damage to the normal esophageal stratified squamous epithelium by acid, leading to replacement with metaplastic columnar epithelium. This condition, known as *Barrett's esophagus*, is associated with a higher incidence of esophageal adenocarcinoma. Currently, it is believed that 1–10 % of people with Barrett's esophagus will develop esophageal adenocarcinoma. Patients with Barrett's esophagus require endoscopic surveillance with biopsies to look for cancerous changes.



Endoscopic photograph of long-segment Barrett's esophagus. The arrows mark the proximal extent of the gastric folds, which is the location of the gastroesophageal junction. Note that Barrett's metaplasia extends well above the GEJ to line the distal esophagus. The reddish-pink (salmon) color and velvet-like texture of Barrett's epithelium contrasts sharply with the pale and glossy appearance of the esophageal squamous epithelium. [Spechler SJ. Barrett's Esophagus. In: Shaker R, Belafsky PC, Postma GN, Easterling C, editors. Principles of Deglutition [Internet]. New York, NY: Springer New York; 2013 [cited 2015 May 14]. p. 723–38. Chapter 31
Goiter

Christopher J. Rees, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Goiter

Incidence/Epidemiology

- Dietary deficiency of iodine is the most common cause of goiter worldwide. There are estimated to be about 200 million cases of iodine-deficient goiter worldwide.
- In the United States (where significant dietary deficiency of iodine only occurs in new immigrants), the most common cause of goiter is multinodular goiter.
- The female: male ratio is 4:1.
- Goiter is distributed equally among races.
- The incidence of goiter increases with age.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_31

Differential Diagnosis

- Goiters often present as an anterior neck mass on physical examination. The differential diagnosis of anterior neck masses is broad, but generally falls into several categories:
  - Inflammatory masses (such as lymphadenopathy)
  - Neoplastic masses (both primary and metastatic)
  - Congenital (vascular anomalies, thyroglossal duct cysts)
- Some goiters extend into the thoracic cavity (substernal goiters) and present as mediastinal masses (most often anterior mediastinal masses) found on an imaging study (CXR, CT chest) performed for other reasons. The most common causes of a mediastinal mass (in decreasing order of frequency) are:
  - Substernal goiter
  - Neurogenic tumors
  - Thymoma
  - Pericardial or bronchogenic cysts
  - Lymphoma
  - Teratoma

Pathophysiology and Etiology

- A goiter refers to an abnormally enlarged thyroid gland.
- Goiters can be classified as diffuse or nodular, toxic or non-toxic, and either benign or malignant. A toxic goiter overproduces thyroid hormone.
- The most common pathophysiologic reason for goiter formation is increased secretion of thyroid stimulating hormone (TSH) by the anterior pituitary gland. This occurs as the thyroid becomes unable to synthesize adequate amounts of T3 and T4. This can have multiple causes, such as iodine deficiency and thyroid cell inflammation and destruction from autoimmune thyroiditis (Hashimoto's Thyroiditis).
- Goiters can also form when TSH secretion is normal. This can result from the action of multiple growth factors acting on thyroid cells over a long period of time, usually in the presence of a genetic predisposition to goiter formation. This leads to nontoxic, multinodular goiters.
- Patients with Graves' disease produce TSH receptor antibodies. These autoantibodies stimulate the TSH receptor and lead to thyroid growth and overproduction of thyroid hormones.
- As stated in the Incidence/Epidemiology section, iodine deficiency is the leading cause of goiter worldwide. However, iodine deficiency is mostly unheard of in the United States and Western Europe. In these areas iodine deficiency is usually only found among recent immigrants.

- In most Western countries, multinodular goiter, Hashimoto's disease (autoimmune thyroiditis), and Graves' disease are the most common causes of goiter.
- Less common causes of goiter include thyroiditis (of any cause), thyroid tumors, and infiltrative diseases of the thyroid.

Presentation

Typical/"Classic"

- It is important to review the anatomy of the thyroid gland, as the presenting symptoms of goiter can be related to compression of neighboring structures.
  - The thyroid sits just below the larynx; it has 2 lobes connected by a small bridge of thyroid tissue termed the isthmus. The thyroid partially encircles the anterolateral aspects of the trachea. It is bordered posteriorly by the trachea and esophagus, and laterally by the carotid sheaths. Anteriorly, the thyroid is covered only by the thin strap muscles anterolaterally, and then connective tissue, subcutaneous tissue, and skin. As a result of this minimal anterior anatomic coverage, the thyroid mostly enlarges outward and does not usually compress any lateral or posterior structures.

- In goiters that grow asymmetrically, however, enlargement of one lobe is predominant. Asymmetrical goiters can also enlarge circumferentially around the trachea, which can cause compression of the jugular veins, tracheal narrowing, and/or impingement of the esophagus.
- Goiters can also extend caudally into the thoracic inlet. The thoracic inlet is an oval-shaped area about 5 cm (anteroposteriorly) by 10 cm (laterally). It is bordered anteriorly by the sternum, laterally by the first ribs, and posteriorly by the first thoracic vertebra. Structures within the thoracic include the trachea, esophagus, and major vascular structures. As the borders of the thoracic inlet are all bony, there is no room for expansion. If a goiter extends caudad through the thoracic inlet, the goiter is referred to as substernal (or retrosternal). Substernal goiters are more likely to cause compression than purely cervical goiters. Substernal goiters are thought to account for anywhere from 2–20 % of all goiters.
- Most goiters grow very slowly, do not cause thyroid dysfunction, and are asymptomatic. They are usually found on routine physical examination, and on imaging studies being performed for other reasons.
- Most goiters are painless.
- Once a goiter is detected, an evaluation should be performed with three major goals:
  - Identify the underlying cause.
  - Evaluate for the presence of obstructive symptoms.
  - Evaluate for the presence of features suspicious for malignancy.

Atypical

- As most goiters are asymptomatic, any symptomatic goiter can be considered the "atypical" presentation of goiter.
- However, goiters may be associated with either hypo- or hyperthyroidism, and patients can present with symptoms of those disorders.
  - Hypothyroidism. A goiter due to long-standing, burned-out Hashimoto's (autoimmune) thyroiditis, and severe iodine deficiency, can be associated with hypothyroidism. Those symptoms are protean and can include profound fatigue, unintentional weight gain, constipation, and cold intolerance.
  - Hyperthyroidism. Some causes of goiter can be associated with hyperfunctioning thyroid tissue (multinodular goiter with autonomously functioning nodules), and Graves' disease. Patients with goiter from these conditions may present with symptoms of hyperthyroidism, such as unexplained weight loss, palpitations, and dyspnea on exertion.

- Goiters may present with symptoms of obstruction or compression of neighboring structures. This occurs most commonly from substernal goiters, but can also occur from large cervical goiters. It can also happen acutely, if there is acute enlargement of the thyroid. This can happen from acute thyroiditis, and also, rarely, from hemorrhage into a thyroid nodule (these situations are also associated with pain in the thyroid.)
    - Exertional dyspnea is the most common compressive symptom from goiters, present in 30–60 % that have compressive symptoms. The development of exertional dyspnea usually indicates that the tracheal diameter has been reduced to less than 8 mm. When the tracheal diameter is reduced below 5 mm, patients will typically have wheezing or stridor.
        - In the early stages, the dyspnea may be intermittent and positional, occurring when lying down, or when reaching or bending (reaching and bending force the thyroid further into the thoracic inlet.)
    - Cough is also a common symptom of obstruction, present in 10–30 % of patients with compressive symptoms.
    - Other, less common obstructive/compressive symptoms include:
        - Dysphagia from extrinsic narrowing of the esophagus.
        - Hoarseness from compression of the recurrent laryngeal nerve with vocal cord paralysis (can be transient or permanent).
        - Venous engorgement of the face, neck, and upper anterior chest from jugular vein compression. This can also lead to thrombosis of the jugular vein.

Photograph of a woman who has a large retrosternal goiter with signs of compression of the venous system. She has engorged superficial veins on her anterior neck

and chest. [Medeiros-Neto G. Chapter 3. In: Surks MI, editor. Volume 1: Thyroid Diseases. 1 edition. Philadelphia: Current Medicine Group; 1999. (Korenman SG, editor. Atlas of Clinical Endocrinology). ISBN: 0-632-04397-0]

- Horner's syndrome. Horner's syndrome results when the goiter causes compression of the cervical sympathetic nerve supply to the eye. Horner's syndrome is rare, and it is especially rarely caused by goiter. The classic triad of Horner's consists of (all on the affected side);
  - Miosis (constricted pupil).
  - Partial ptosis, drooping eyelid from partial paralysis of the superior tarsal muscle.
  - Hemifacial anhidrosis, loss of sweating on the affected half of the face.

Photograph of the eyes showing the left ptosis and miosis of Horner's syndrome. [Mutalib M, Vandervelde C, Varghese A, Sallomi DF, Silva P de, Casey JMH, Howlett DC. Horner's syndrome secondary to asymptomatic pneumothorax in an adolescent. Eur J Pediatr. 2006 Sep 19;166(5):507–8.] *Caption from original*

Primary Differential Considerations

- Patients who present with an exam consistent with goiter should be also be evaluated for other possible diagnoses, including:
  - Other thyroid pathology, such as nodules, thyroiditis, or malignancy
  - Parathyroid cyst or malignancy
  - Lipoma or fibroma
  - Branchial cleft cyst or cystic hygroma

History and Physical Exam

Findings That Confirm Diagnosis

- The diagnosis can be confirmed by the direct palpation of the goiter. A goiter can usually be distinguished from other anterior neck masses (such as fatty tissue, redundant skin, etc.) as the thyroid will go up and down with swallowing. It is often helpful to ask the patient to swallow a sip of water and just observe the anterior neck for this up and down motion.

Diffuse goiter: Hashimoto's thyroiditis [Gharib H. Chapter 4. In: Surks MI, editor. Volume 1: Thyroid Diseases. 1 edition. Philadelphia: Current Medicine Group; 1999. (Korenman SG, editor. Atlas of Clinical Endocrinology). ISBN: 0-632-04397-0] *Caption adapted from original*

Large goiter in a 57-year-old man. [Giovanella L. Nontoxic Multinodular Goiter. In: Giovanella L, Treglia G, Valcavi R, editors. Atlas of Head and Neck Endocrine Disorders [Internet]. Cham: Springer International Publishing; 2016 [cited 2015 Dec 17]. p. 67–72. Available from: http://link.springer.com/10.1007/978-3-319-22276-9_10] *Caption adapted from original*

- In patients with short and thick necks it can be difficult to adequately palpate the thyroid. These patients may require some form of imaging to be certain a goiter is present.

Factors That Suggest Diagnosis

- Patients with a family history of thyroid disease, recent immigrants from areas of the world considered iodine-deficient, those with a history of head and neck irradiation, or other radiation exposure, should be considered to be at higher risk for goiter.
- All patients in whom the diagnosis is being considered should be directly questioned about the presence of hyper- or hypothyroid symptoms, and for the presence or absence of obstructive symptoms.
- The presence of a substernal thyroid can be suggested by:
  - The inability to directly palpate the inferior thyroid margin on either side.
  - Pemberton's maneuver. In this provocative physical exam test, the examiner holds the patient's arms directly above the head for about one minute. This maneuver forces the thyroid into the thoracic inlet and can exacerbate obstructive symptoms and signs. These include dyspnea, distension of the neck veins, facial flushing or cyanosis, or the inability to swallow.

Pemberton's sign. The presence of a retrosternal goiter causes facial flushing and distended superficial veins. Mild flushing is noted with the arms by the side indicating some baseline obstruction at rest. [Sharma N, Watkinson JC. Retrosternal Goiter.

In: Watkinson JC, Scott-Coombes DM, editors. Tips and Tricks in Endocrine Surgery [Internet]. London: Springer London; 2014 [cited 2015 Dec 17]. p. 161–6. Available from: http://link.springer.com/10.1007/978-1-4471-2146-6_20] *Caption from original*

- Kocher's test. This is a physical examination maneuver that can be used to test for the presence of tracheal compression. In a positive test, compression of the lateral lobes of the thyroid will produce stridor from tracheal compression.

Factors That Exclude Diagnosis

- No historical or physical examination factors can adequately exclude the diagnosis.
- In patients with short and thick necks it can be difficult to adequately palpate the thyroid. These patients may require some form of imaging to be certain a goiter is either present or absent.

Ancillary Studies

Laboratory

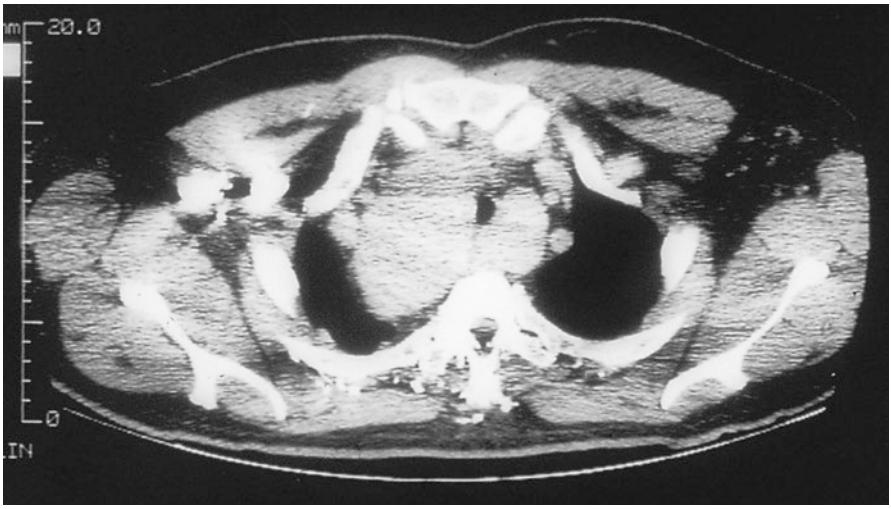
- Thyroid stimulating hormone (TSH). All patients with goiter should have their thyroid function evaluated by measurement of their serum TSH. Serum TSH is often normal (euthyroid), but can also be low (suppressed) with hyperthyroidism, and high with hypothyroidism.
  - If the TSH is low, the serum-free thyroxine (T4) and total triiodothyronine (T3) should also be measured to assess for an autonomously functioning multinodular goiter or Graves' disease.
  - If the TSH is high, free T4 should be measured as part of the evaluation for likely Hashimoto's disease.
- Thyroid peroxidase antibodies (TPO). Patients with Hashimoto's (autoimmune) thyroiditis almost always have elevated TPO. Patients with goiter and hypothyroidism in the United States will most likely have Hashimoto's thyroiditis as the cause of their goiter. This can be confirmed by elevated TPO.
- TSH receptor antibodies. These should be measured when Graves' disease is being considered in the differential diagnosis of the goiter. This is mostly in the setting of a goiter associated with hyperthyroidism.

Imaging

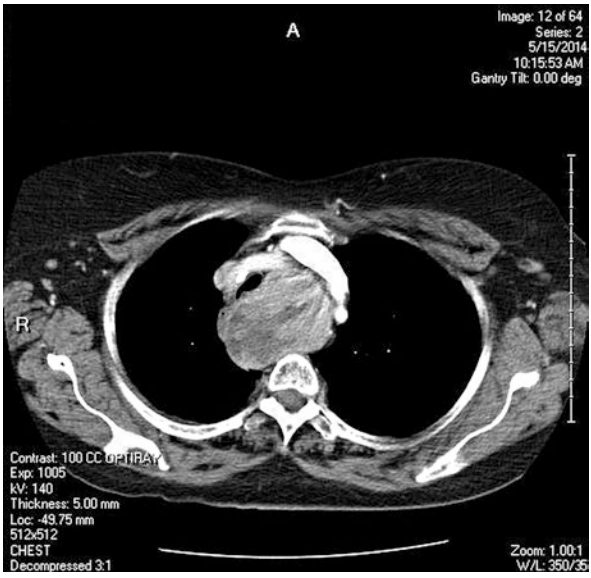
- Thyroid ultrasound should be obtained in most patients with goiter. Thyroid ultrasound can be used to evaluated thyroid size and volume; it can also help assess thyroid function. Thyroid ultrasound can also help in the evaluation of a goiter with features that may be consistent with thyroid cancer. These "worrisome" features include a rapidly growing goiter, asymmetric thyroid enlargement, firm consistency to focal areas of the thyroid, and tenderness to palpation.
- Chest x-ray. Substernal goiters are often found incidentally on a CXR being performed for other reasons. They can appear as a mass that causes tracheal deviation or narrowing, or as superior mediastinal widening, or a mediastinal mass.

Chest radiograph in substernal goiter. There is an anterior mediastinal mass, which was thought to be compatible with a substernal goiter. Note the deviation of the trachea to the left and the presence of a mass in the upper anterior mediastinum. [Singer P. Chapter 12. In: Surks MI, editor. Volume 1: Thyroid Diseases. 1 edition. Philadelphia: Current Medicine Group; 1999. (Korenman SG, editor. Atlas of Clinical Endocrinology). ISBN: 0-632-04397-0] *Caption adapted from original*

- CT scan. Goiters may be incidentally noted on CT scans of the neck and chest being performed for other reasons, but a CT chest can also be an important test in the evaluation of large cervical goiters and suspected substernal goiters. CT can help delineate the extent of the goiter. To fully evaluate the goiter, a CT of the neck and chest may be necessary.



Computed tomography in substernal goiter. Note the predominantly right-sided mass with tissue to the left of the trachea as well. The trachea is not significantly narrowed. [Singer P. Chapter 12. In: Surks MI, editor. Volume 1: Thyroid Diseases. 1 edition. Philadelphia: Current Medicine Group; 1999. (Korenman SG, editor. Atlas of Clinical Endocrinology). ISBN: 0-632-04397-0] *Caption adapted from original*



Substernal goiter Substernal goiter (SG) leading to significant tracheal deviation and compression with symptomatic dyspnea on exertion[Wilhelm SM. Multinodular Goiter. In: Pasieka JL, Lee JA, editors. Surgical Endocrinopathies [Internet]. Cham:

Springer International Publishing; 2015 [cited 2015 Dec 17]. p. 57–63. Available from: http://link.springer.com/10.1007/978-3-319-13662-2_11] *Caption from original*

Image from a computed tomography of a patient with a massive intrathoracic goiter. The goiter is clearly below the aortic arch[Rolighed L, Rønning H, Christiansen P. Sternotomy for substernal goiter: retrospective study of 52 operations. Langenbeck's Archives of Surgery. 2015 Apr;400(3):301–6.] *Caption from original*

- Thyroid radionuclide imaging may be necessary to identify any nodules or areas of autonomous functioning within the thyroid.

Other

- Flow-Volume Loop. Any patient with symptoms or signs consistent with an obstructive goiter should have pulmonary function tests with a flow-volume loop. If another imaging study reports a tracheal diameter less than 10 mm, the patient should also have a flow-volume loop performed. A fixed, mechanical obstruction in the trachea will show a blunted or "notched" flow-volume loop. A positive flow-volume loop may influence treatment and suggest the need for surgery.
- Fine needle aspiration (FNA) biopsy. FNA biopsy may be necessary to evaluate suspicious areas of goiter, or suspicious nodules for cancer. Suspicious findings include:
  - Rapid growth of the goiter
  - Pain or tenderness
  - Asymmetry in the consistency of the thyroid on examination

Special Populations

Age

- Goiter is most common in the middle-aged to older adult population. The incidence of goiter rises with age.
- Although rare, goiters can occur in infants and children. They can be congenital or acquired.
    - Congenital Goiter. Goiters can occur in infants from congenital causes. Congenital goiters may not be evident at birth, but will usually develop over the first several months of life. The causes of congenital goiter include:
        - Inborn errors of thyroid hormone production
        - Mother's with Hashimoto's or Graves' can have transplacental transfer of maternal antibody leading to goiter
        - Maternal ingestion of antithyroid drugs
        - Inborn mutations of thyroid hormones and receptors
        - Thyroid tumors
    - Acquired Goiter. Acquired goiters in children follow a similar distribution as adults. In iodine-deficient parts of the world, iodine-deficient goiters are the most common cause. In areas of the world where iodine-deficiency is uncommon, common causes of goiter include:
        - Hashimoto's Thyroiditis
        - Graves' Disease
- Colloid Goiter. This is a unique form of goiter that occurs in adolescent girls. The cause is unknown. Thyroid function is usually normal. It usually improves over time with no treatment.

Co-morbidities

- Goiters can occur in patients with multiple other co-morbid illnesses. Significant cardiac and pulmonary disease can complicate the management of goiters. As one of the primary treatments for goiter may be surgical, patients with multiple co-morbid conditions may not be good candidates for surgery.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is critical to take a complete history, including a family history and exposure to radiation history, to help determine the cause for a goiter and to guide the appropriate work-up and treatment.
- It is critical to assess for a substernal goiter, by asking about obstructive symptoms, performing a thorough examination, and ordering appropriate imaging studies.

Mimics

- There are no significant mimics of goiter.
- There are other causes of anterior neck masses, but thorough physical examination, and/or an appropriate imaging study, can determine the etiology of the mass.

Time-Dependent Interventions

- Goiters are usually very slow-growing and can be dealt with over time.
- Substernal goiters may cause acute symptoms from tracheal compression. This can be due to continued growth of the thyroid, acute hemorrhage into a large nodule, or from acute swelling from thyroiditis. These symptoms usually include dyspnea, associated with wheezing or stridor.
- In these situations, an adequate airway must be obtained. Temporary measures can include humidified oxygen, positive pressure ventilation such as continuous positive airway pressure (CPAP), and use of heliox (a helium/oxygen mixture). All of these are temporizing measures however, and a secure airway will need to be obtained. This usually requires the involvement of a surgeon with experience in these matters.

Overall Principles of Treatment

- The treatment goals for goiters differ based upon the cause of the goiter, whether the goiter is symptomatic or asymptomatic, and whether the goiter is cervical or substernal.

- Goiters that are not associated with hyperthyroidism and are non-obstructive (such as Hashimoto's): The primary goals are to treat any underlying hypothyroidism, decrease the size of the goiter, and prevent further growth. If there is significant hypothyroidism, treatment with thyroid replacement hormone can decrease the size of the goiter. If the patient is asymptomatic, the goiter can be followed. If the goiter is large, surgery or radioiodine ablation (RIA) may be appropriate. Surgery is indicated for large goiters, especially those that are continuing to grow over time. RIA can be an alternative to surgery for those patients that are not good surgical candidates.
- Substernal (or cervical) Goiter with obstructive symptoms:
    - Once obstructive symptoms occur, the patient requires treatment. There is a small incidence of spontaneous hemorrhage into an enlarged thyroid. This can cause an acute increase in thyroid size leading to acute compression that can be fatal.
    - The usual treatment is surgical resection of the thyroid gland.
    - If the patient is unable or unwilling to have surgery, RIA can be considered.
- Asymptomatic Substernal Goiter:
    - These patients can be observed over time for the development of obstructive symptoms.
    - These patients can also be offered definitive surgical treatment.
    - Early, definitive surgical treatment should be considered, for the following reasons:
        - Most goiters will continue to enlarge.
        - Surgery will become more technically difficult as the goiter enlarges.
        - A significant minority (up to 40%) of patients with asymptomatic substernal goiter have abnormal flow-volume loops.
        - There is a small risk of cancer developing in the goiter. The risk of cancer developing in a goiter is about the same as the risk of cancer developing in any thyroid nodule.
        - There is a small risk of acute hemorrhage into the thyroid with potentially fatal acute airway obstruction.
    - Patients are considered safe to observe, rather than to undergo surgery, when any of the following conditions is met:
        - They have a normal flow-volume loop.
        - The substernal component ends at or above the brachiocephalic vein.
        - The patient is a poor surgical candidate.
    - Patients being observed should be followed closely for the development of obstructive symptoms, and should have a CT scan every year until stability is documented.

- Goiters with associated hyperthyroidism: These are usually associated with Graves' disease. These patients need to have their primary disease process treated. Goiters associated with Graves' will often become smaller owing to treatment of the Graves'.

- Any goiter or thyroid nodule that has features or findings concerning for malignancy should have a fine needle aspiration (FNA) biopsy performed.
- Radioiodine ablation works best in large, hyperfunctioning (hyperthyroid), multinodular goiters. In this setting there can be a 30–40% reduction in the size of the goiter.

Disease Course

- Goiters usually grow slowly.
- Most will continue to increase in size over time, but a minority may remain stable in size.

Chapter 32
Heart Failure

Charles V. Pollack, Jr. and Victoria G. Riese

Name and Synonyms

Heart Failure; Congestive Heart Failure

Incidence/Epidemiology

- Heart failure is a clinical state in which perfusion of tissues and/or venous return to the heart is impaired because of inadequate pumping functionality of the cardiac muscle, or when perfusion can only be maintained from an abnormally high diastolic volume.
- There are multiple ways to characterize heart failure:
  - Systolic vs diastolic
    - In systolic failure, the ventricles are unable to contract normally.
    - In diastolic failure, the ventricles fail to relax and fill properly.
    - Patients who have both dilated and hypertrophic ventricles may have both systolic and diastolic failure
  - Right-sided vs left-sided
    - Left-sided heart failure leaves blood in the lungs and therefore usually presents as pulmonary edema.

- Right-sided heart failure leaves blood in the periphery and therefore usually presents with edema and liver congestion.
- Long-standing heart failure usually manifests findings of both left- and right-sided failure

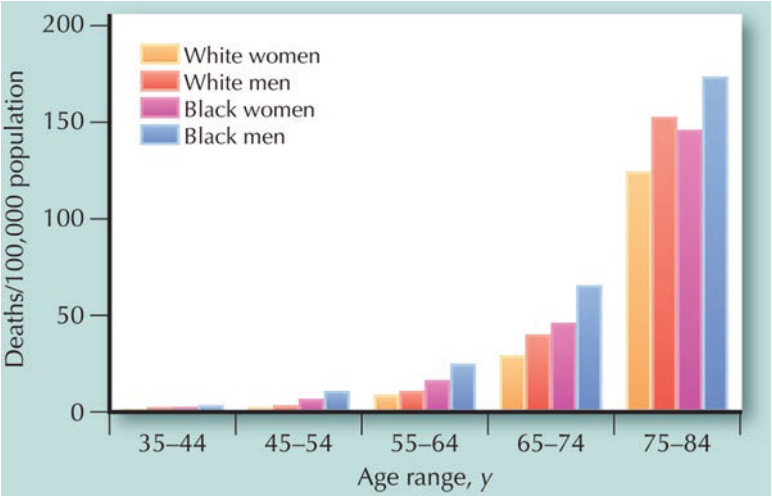
- Acute vs chronic
  - Acute heart failure usually develops immediately after a large myocardial infarction or rupture of a heart valve.
  - Chronic heart failure develops more slowly and is often due to systemic hypertension, dilated cardiomyopathy, or multivalvular disease.

Chronic heart failure	Chronic heart failure is a clinical syndrome characterized by complex and variable symptoms and signs. The cardinal manifestations of heart failure are dyspnea and fatigue, which may limit exercise tolerance, and fluid retention, which may lead to pulmonary congestion and peripheral edema. Chronic heart failure is often punctuated by acute decompensation.
Acute heart failure	New onset of decompensated heart failure or decompensation of chronic, established heart failure with symptoms sufficient to warrant hospitalization. Cardiac dysfunction can be related to systolic or diastolic dysfunction, to abnormalities in cardiac rhythm, or to preload and after-load mismatch.
Heart failure with reduced LVEF (also referred to as systolic heart failure or heart failure with reduced systolic function)	A clinical syndrome characterized by signs and symptoms of heart failure and reduced LVEF. Most commonly associated with left ventricular chamber dilation.
Heart failure with preserved LVEF (also referred to as diastolic heart failure or heart failure with preserved systolic function)	A clinical syndrome characterized by signs and symptoms of heart failure with preserved LVEF. Most commonly associated with a nondilated left ventricle. May be the result of valvular disease or other causes.

Classification of the heart failure syndrome. Heart failure is often classified as heart failure with abnormal systolic function versus heart failure with preserved systolic function. These classifications often consider normal systolic function and normal ejection fraction to be the same. Heart failure with preserved left ventricular ejection fraction (LVEF) is variably defined as an LVEF greater than 40%, greater than 45%, or greater than 50%. Heart failure with preserved LVEF is not a distinct condition, but rather a syndrome with numerous possible causative or comorbid conditions, including hypertension, diabetes mellitus, vascular stiffness, renal impairment, and atrial fibrillation. There is no current consensus about nomenclature for heart failure with preserved systolic function. The clinical classification of patients with acute decompensated heart failure continues to evolve and reflects ongoing changes in the understanding of the pathophysiology of this syndrome. Worsening renal function, persistent neurohormonal activation, and progressive deterioration in myocardial function all seem to play a role. Decompensation also commonly occurs without a fundamental worsening of underlying cardiac structure or function. Failure to adhere to prescribed medications or an inadequate medical regimen may

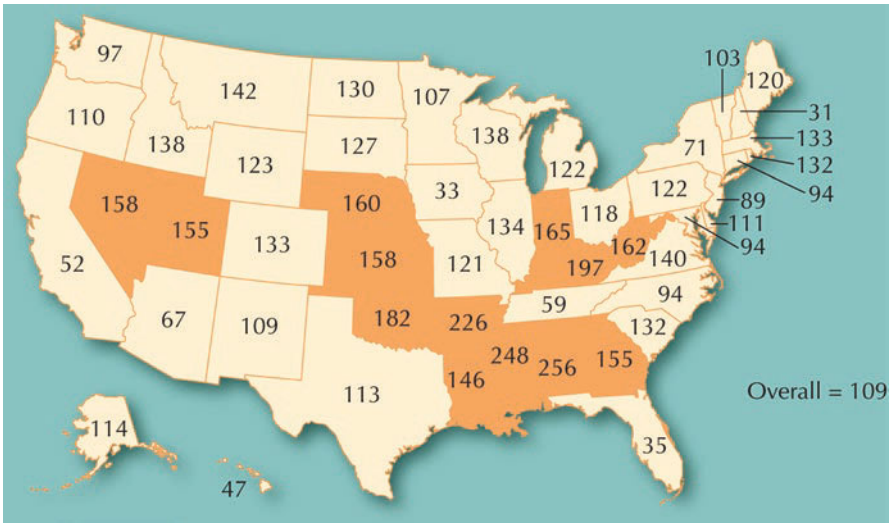
lead to hospitalization without a worsening of underlying circulatory function. Other descriptive terms used for heart failure include right- and left-sided heart failure referring to syndromes presenting predominately with congestion of the systemic or pulmonary vascular beds. Mild, moderate, and severe heart failure are used as clinical symptomatic descriptions instead of or in addition to New York Heart Association functional classification. [Kittleson MM, Fonarow GC. Clinical Syndromes of Acute and Chronic Heart Failure. In: Colucci WS, editor. Atlas of heart failure, 5th ed. Philadelphia: Current Medicine Group; 2008. 344 p. ISBN: 1-57340-261-3] *Caption adapted from original*

- Black males have the highest incidence of heart failure per capita.



US heart failure deaths by age, sex, and race. Among all age groups, black men experienced the highest rates of heart failure death. In all age groups except ages 75 to 84 years, black women experienced the next highest rates of heart failure death followed by white men. In the age group of 75 to 84 years, white men had higher rates of heart failure–-related death than black women. In all age groups, white women experienced the least heart failure–related mortality (American Heart Association: Heart Disease and Stroke Statistics —2007 Update.. Dallas: American Heart Association; 2007). [Parikh NI, Vasan RS. The Epidemiology of Heart Failure. In: Colucci WS, editor. Atlas of heart failure, 5th ed. Philadelphia: Current Medicine Group; 2008. 344 p. ISBN: 1-57340-261-3] *Caption from original*

- There is a “heart failure belt” across middle America



Geographic heterogeneity in US heart failure death rates. Numbers reflect state-specific, age-adjusted death rates per 100,000 persons for men and women > 65 years of age for the period from 1990 to 1996. The 13 highlighted states have the highest heart failure death rates. Possible explanations for the apparent "heart failure belt" across middle-America are 1) higher prevalence of hypertension and myocardial infarction in the belt, 2) varying access to early diagnosis, 3) regional differences in congestive heart failure treatment, or 4) differing practices of diagnostic coding for heart failure in death certificates (Changes in mortality from heart failure: United States, 1980-1995. MMWR Morb Mortal Wkly Rep. 1998; 47:633 -637). [Parikh NI, Vasan RS. The Epidemiology of Heart Failure. In: Colucci WS, editor. Atlas of heart failure, 5th ed. Philadelphia: Current Medicine Group; 2008. 344 p. ISBN: 1-57340-261-3] *Caption from original*

- Heart failure is classified by multiple scales, but the most commonly used is from the New York Heart Association (NHYA) and is symptom-driven.

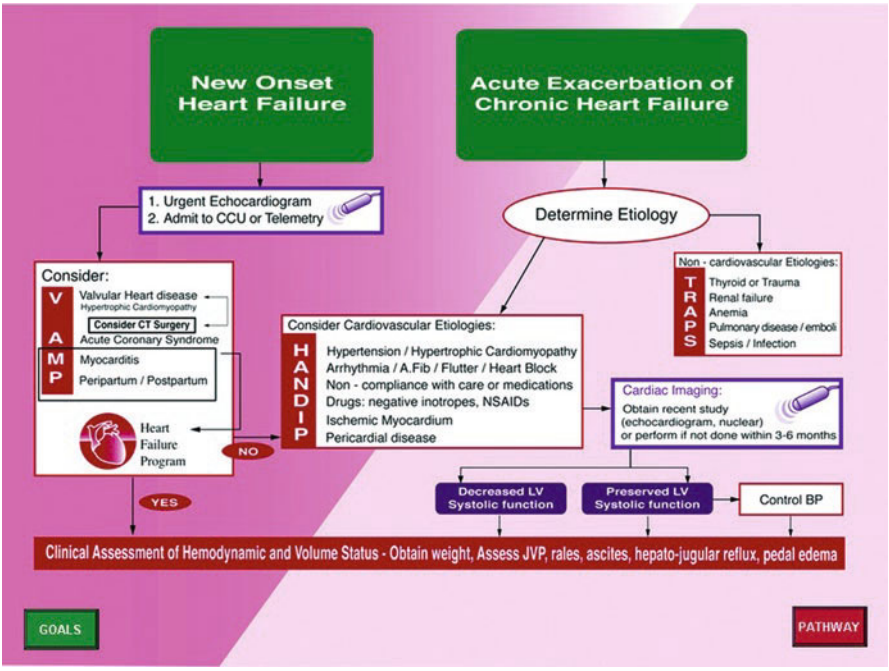
Class I	No limitation of daily physical activity.
Class II	Slight limitation of activity. Comfortable at rest but ordinary physical activity produces fatigue and dyspnea.
Class III	Marked limitation of physical activity. Fatigue and dyspnea results from minimal physical activity.
Class IV	Severe physical limitation. Dyspnea at rest and unable to carry on physical activity without severe symptoms.

New York Heart Association classification of heart failure. The functional classification of patients with congestive heart failure developed by the New York Heart Association is based on the amount of activity tolerated by patients before the onset of symptoms. Despite the limitations of this subjective classification, it is a useful

descriptive system and remains the standard by which patients with heart failure are compared (Boston: Little, Brown; 1964; 114). [O'Connor C, Tuman K. Chapter 7. In: Miller RD, Reves JG, editors. Atlas of Anesthesia: Cardiothoracic Anesthesia, Volume 8, 1e. Philadelphia: Current Medicine Group; 1999. 256 p. ISBN: 0-443-07974-9] *Caption from original*

Differential Diagnosis

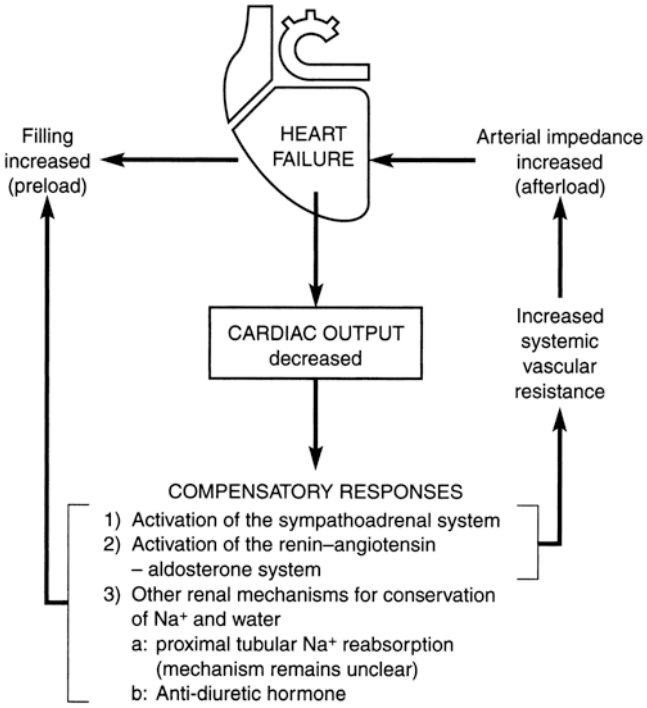
- The differential diagnosis of heart failure is to some extent dependent upon the type of failure being manifest. In general, the differential includes:
  - Acute exacerbation of COPD



Differential diagnosis between new onset heart failure and acute exacerbation of chronic heart failure with timing of imaging and consideration of precipitating pathophysiology. [Wild D, Herzog E, Aziz E, Kukin M. Pathway for the Management of Heart Failure Complicating Acute Coronary Syndrome. In: Herzog E, Chaudhry F, editors. Echocardiography in Acute Coronary Syndrome [Internet]. London: Springer London; 2009 [cited 2015 Jun 4]. p. 365–76. Available from: http://link.springer.com/10.1007/978-1-84882-027-2_25] *Caption from original*

- Pulmonary embolism
- Pneumonia
- Acute renal failure
- Noncardiogenic pulmonary edema
- Myocardial infarction
- Respiratory failure

Pathophysiology and Etiology



Pathophysiology of heart failure. [Khan MG. Heart Failure. Cardiac Drug Therapy, 8e [Internet]. Totowa, NJ: Humana Press; 2015 [cited 2015 Jun 4]. p. 369–421. Available from: http://link.springer.com/10.1007/978-1-61779-962-4_12] *Caption from original*

Common
Coronary heart disease
Hypertension
Idiopathic
Diabetes mellitus
Valvular disease
Less common
Anemia
Connective tissue disease
Viral myocarditis
Hemochromatosis
Human immunodeficiency virus infection
Hyperthyroidism, hypothyroidism
Hypertrophic cardiomyopathy
Infiltrative disease (including amyloidosis and sarcoidosis)
Mediastinal radiation
Peripartum cardiomyopathy
Restrictive pericardial disease
Tachyarrhythmia
Toxins (including drugs and alcohol)
Trypanosomiasis (Chagas' disease)

Etiologies of heart failure. [Marín-García J. Diagnosis of Heart Failure: Evidence-Based Perspective. Heart Failure [Internet]. Totowa, NJ: Humana Press; 2010 [cited 2015 Jun 4]. p. 353–63. Available from: http://link.springer.com/10.1007/978-1-60761-147-9_18] *Caption from original*

- There are many contributing factors to the development of heart failure, including:
  - Increased metabolic demand on the heart, such as:
    - Infection
    - Anemia
  - Other demand for increased cardiac output, such as:
    - Pregnancy
    - Thyrotoxicosis
    - Sepsis
    - Hypovolemia
  - Physical demand on the heart, such as:
    - Hypertension
    - Endocarditis
    - Pulmonary embolism
    - Salt and volume retention

- Injury to heart muscle, such as:
  - Myocardial infarction
  - Myocarditis
- Arrhythmia
- Toxic exposures
- Chagas' disease

Presentation

Typical/"Classic"

- Most patients with acute heart failure present with shortness of breath.
- Dyspnea on exertion and orthopnea are common.
- Chest pain and palpitations are not uncommon.
- Patients with right-sided failure only will complain of dependent edema, weight gain, and swelling of the abdomen.

Atypical

- Patients may present only with weight gain or nocturia.
- Chest pain or palpitations without dyspnea would be unusual.

Primary Differential Considerations

- Patients who present with signs and symptoms of heart failure should also be evaluated for these potential diagnoses:
  - Acute coronary syndrome
  - Pulmonary embolism
  - COPD exacerbation
  - Pneumonia

History and Physical Exam

- In the history, focus on symptoms of fluid overload and pump failure, such as:
  - Dyspnea (specifically asking about dyspnea at rest vs only with exertion, and about nocturnal dyspnea/orthopnea)

- Peripheral edema and ascites (socks leaving indentations, having to loosen belt)
- Nocturia and insomnia
- Fatigue
- Generalized weakness
- Abdominal pain (which may result from hepatic congestion)

- On physical examination, there are a number of findings associated with heart failure that should be sought:
  - Pulmonary rales

http://www.easyauscultation.com/rales

Rales. [Rales Lung Sounds; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

- Peripheral edema

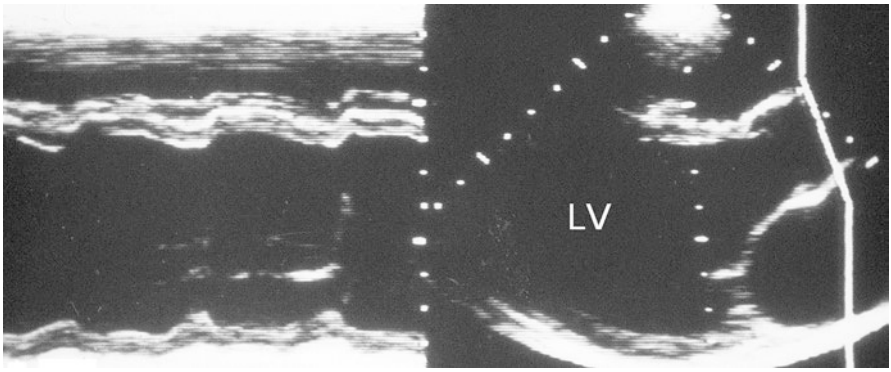
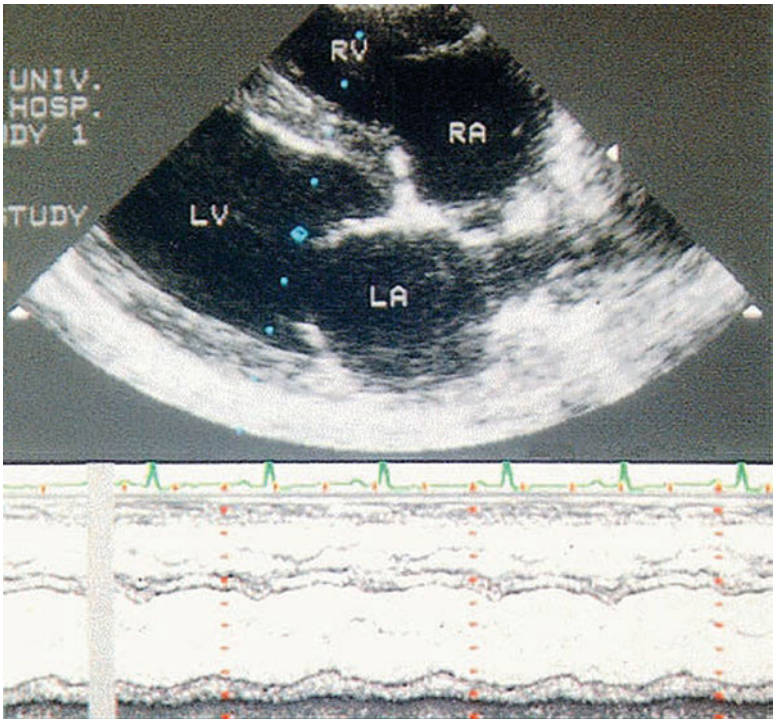
- Neck vein distention

Findings that Confirm Diagnosis

- More than two or three of the signs and symptoms are strongly suggestive of heart failure. Confirmation of the diagnosis (and important prognostic information) is obtained by echocardiography.



M-mode echocardiogram (left) and parasternal long-axis view from a patient with marked alcohol consumption and heart failure. The echocardiographic pattern is that of dilated cardiomyopathy with reduced contraction. [Nihoyannopoulos P. Cardiomyopathies. In: Nihoyannopoulos P, Kisslo J, editors. Echocardiography [Internet]. London: Springer London; 2009 [cited 2015 Jun 4]. p. 399–434. Available from: http://link.springer.com/10.1007/978-1-84882-293-1_20] *Caption from original*



Two-dimensional M-mode echocardiogram of a dog with congestive heart failure induced by rapid pacing. Note the generalized cardiac dilatation and decreased left

ventricular shortening fraction. LA—left atrium; LV—left ventricle; RA—right atrium; RV—right ventricle. [Gwathmey J, Abelmann W. Chapter 11. In: Lee RT, Braunwald E, editors. Atlas of Cardiac Imaging, 1e. Philadelphia: Current Medicine; 1998. 248 p. ISBN: 0-443-07567-0] *Caption from original*

Factors that Suggest Diagnosis

- More than two of the signs and symptoms listed above are suggestive and warrant specific evaluation

Factors that Exclude Diagnosis

- A normal echocardiogram and a normal brain-type natriuretic peptide (BNP level) exclude heart failure. It may not be possible to exclude the diagnosis fully on clinical grounds alone.

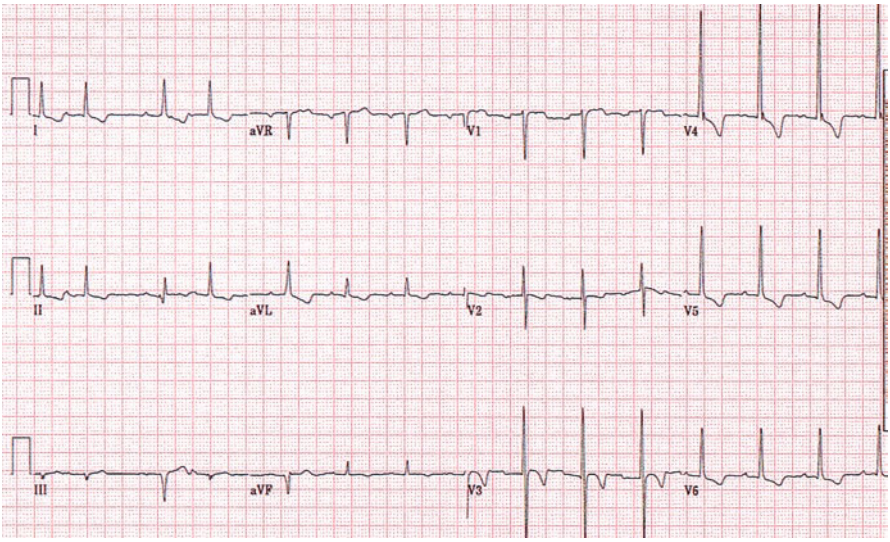
Ancillary Studies

Laboratory

- Baseline CBC (to exclude anemia) and renal function should be evaluated
- Urine should be checked for protein, blood, and glucose
- Serum electrolytes (especially potassium) should be checked
- A BNP level should be checked

Electrocardiography

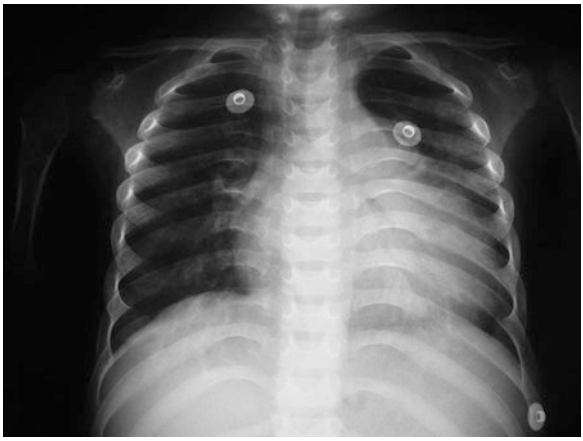
- Electrocardiogram should be obtained to evaluate rhythm and to look for left ventricular hypertrophy or Q-waves. There are no pathognomonic findings for heart failure on ECG.



A 12-lead electrocardiogram demonstrating left ventricular hypertrophy with a "strain" pattern. [Fleisher L. Chapter 3. In: Miller RD, Lichtor JL, editors. Atlas of Anesthesia: Preoperative Preparation and Intraoperative Monitoring, Volume 3, 1e. Philadelphia: Current Medicine; 1997. 251 p. ISBN: 0-443-07902-1] *Caption adapted from original*

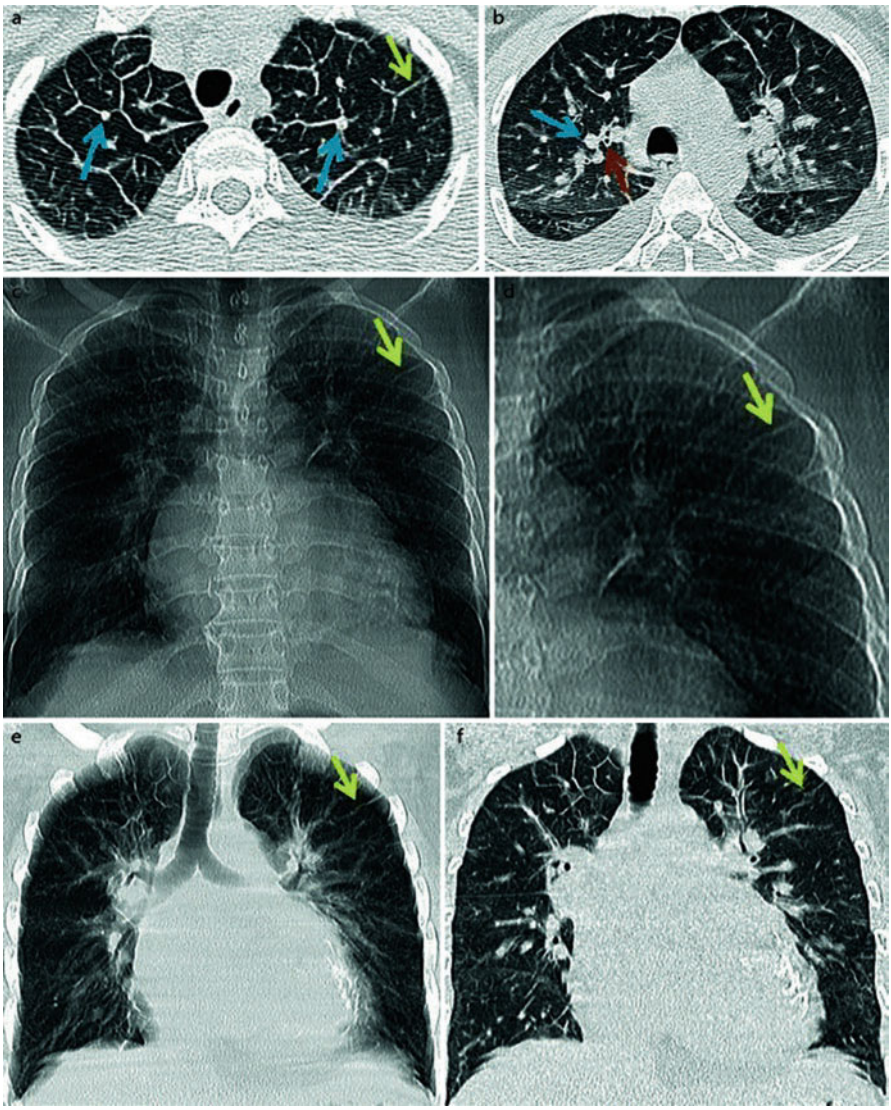
Imaging

- Chest x-ray should be obtained to look for cardiac enlargement, pleural effusion, signs of pulmonary edema, COPD, or pneumonia.



Cardiomegaly on chest X-ray. [Yıldırım SV, Durmaz C, Pourbagher MA, Erkan AN. A case of achondroplasia with severe pulmonary hypertension due to

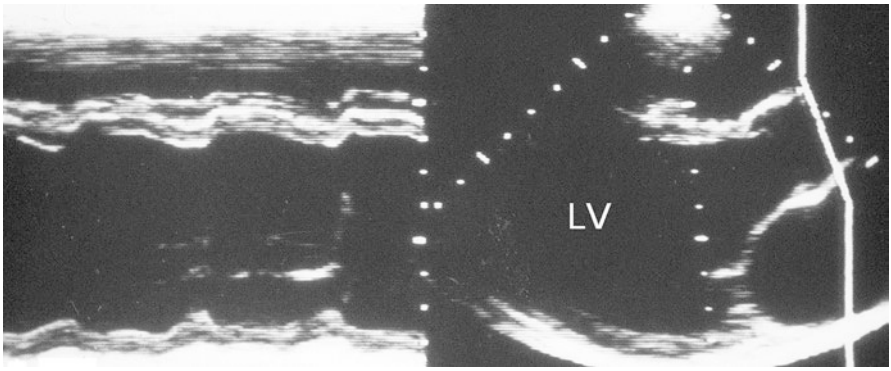
obstructive sleep apnea. European Archives of Oto-Rhino-Laryngology. 2006 Aug;263(8):775–7.] *Caption from original*



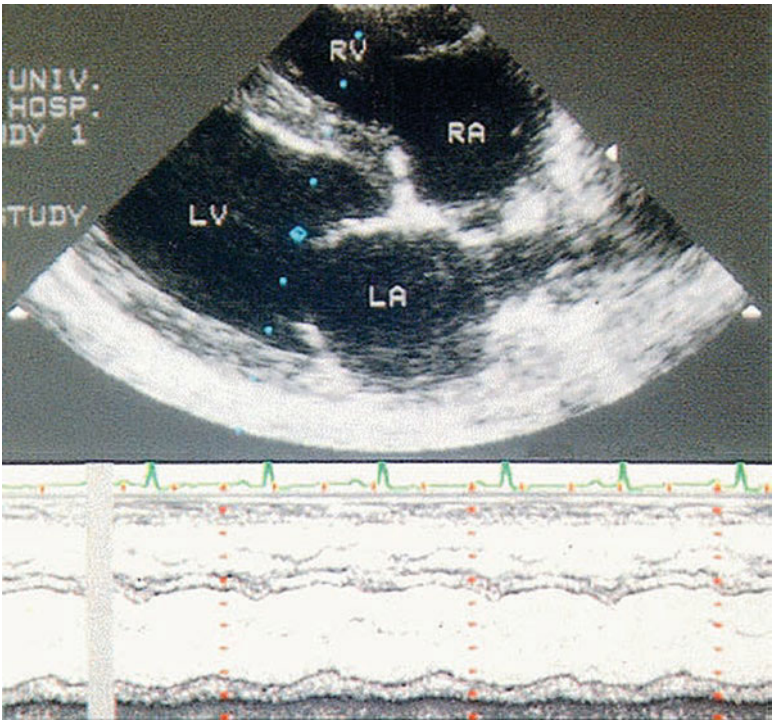
Hydrostatic pulmonary edema in a patient with congestive heart failure. Two successive axial computed tomography slices (a and b) demonstrate a nodular thickening of the interlobular septa reflecting the enlarged pulmonary veins (blue arrows) with bilateral pleural effusion. Note the peribronchial cuffing on (b; orange arrow). The chest radiograph equivalent (c) and the focused view on the left upper lobe (d) show a loss of definition of vascular markings throughout both lungs associated

with Kerley lines (yellow arrows), reminiscent of interstitial edema. Note the enlargement of the cardiac silhouette. By viewing average coronal slabs (c–f) of decreasing slice thickness, Kerley A lines seen on (f) corresponding to septal thickening are perfectly understood. [Ilsen B, Gosselin R, Delrue L, Duyck P, de Mey J, Beigelman-Aubry C. Interstitial Lung Disease. In: Coche EE, Ghaye B, de Mey J, Duyck P, editors. Comparative Interpretation of CT and Standard Radiography of the Chest [Internet]. Berlin, Heidelberg: Springer Berlin Heidelberg; 2011 [cited 2015 Jun 4]. p. 195–220. Available from: http://link.springer.com/10.1007/978-3-540-79942-9_8] *Caption from original*

- Echocardiography is helpful in diagnosing, staging, and following heart failure.



M-mode echocardiogram (left) and parasternal long-axis view from a patient with marked alcohol consumption and heart failure. The echocardiographic pattern is that of dilated cardiomyopathy with reduced contraction. [Nihoyannopoulos P. Cardiomyopathies. In: Nihoyannopoulos P, Kisslo J, editors. Echocardiography [Internet]. London: Springer London; 2009 [cited 2015 Jun 4]. p. 399–434. Available from: http://link.springer.com/10.1007/978-1-84882-293-1_20] *Caption from original*



Two-dimensional M-mode echocardiogram of a dog with congestive heart failure induced by rapid pacing. Note the generalized cardiac dilatation and decreased left ventricular shortening fraction. LA—left atrium; LV—left ventricle; RA—right atrium; RV—right ventricle. [Gwathmey J, Abelmann W. Chapter 11. In: Lee RT, Braunwald E, editors. Atlas of Cardiac Imaging, 1e. Philadelphia: Current Medicine; 1998. 248 p. ISBN: 0-443-07567-0] *Caption from original*

Other Studies

- None indicated in initial evaluation.

Special Populations

Age

- With rare exception, heart failure is a disease of older patients, with the incidence increasing with increasing age.

Co-morbidities

- Co-morbidities may include:
  - Hypertension
  - Renal disease
  - Cardio- and cerebrovascular disease
  - Drug and alcohol abuse

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Recognition of acute heart failure that may precipitate circulatory collapse or severe pulmonary

Mimics

- Potential mimics include:
  - Pneumonia
  - COPD
  - Acute coronary syndrome
  - Pulmonary embolism

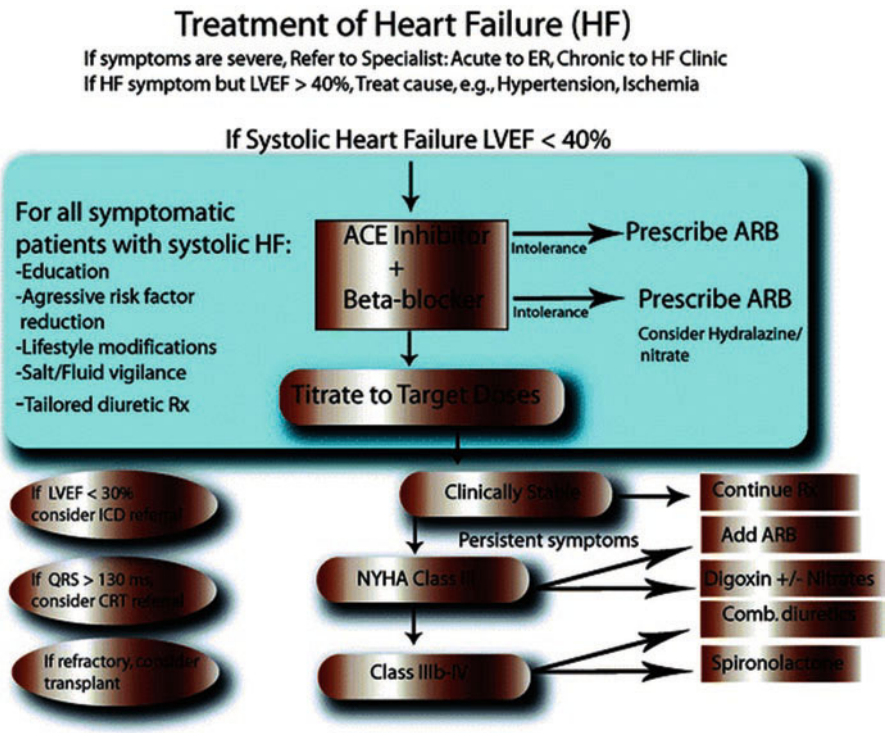
Time-Dependent Interventions

- Provide ventilatory and circulatory support as needed.
- Noninvasive ventilation should be attempted before intubation and mechanical ventilation unless the patient is already in ventilatory failure.
- Initiation of diuresis.

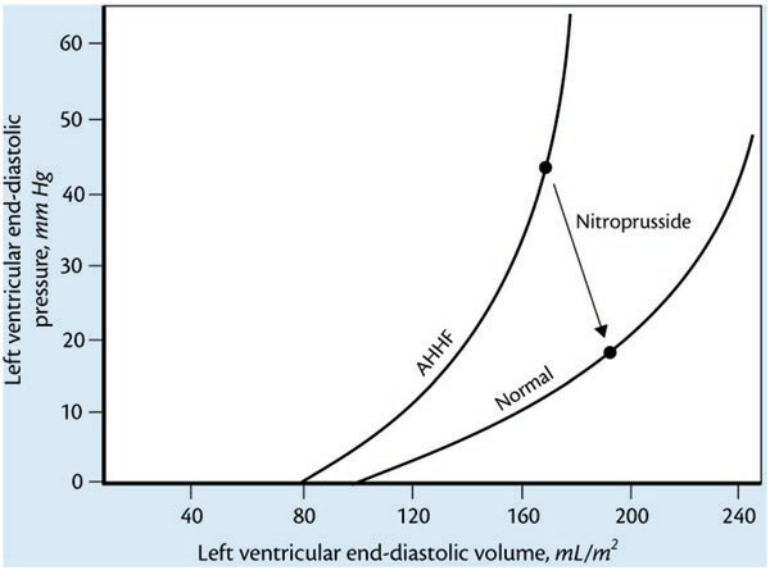
Overall Principles of Treatment

- Relief of fluid overload and improvement in ventilatory and circulatory status are paramount.
- Diuresis with attention to electrolyte levels will improve symptoms.

- ACE inhibitors and beta-blockers will improve long-term management.
- Diet and exercise counseling will help patients manage their symptoms better.



Treatment algorithm of patients with chronic heart failure. [Marín-García J. Treatment of Chronic Heart Failure. Heart Failure [Internet]. Totowa, NJ: Humana Press; 2010 [cited 2015 Jun 4]. p. 379–92. Available from: http://link.springer.com/10.1007/978-1-60761-147-9_20] *Caption from original*



Treatment of acute hypertensive heart failure. The left ventricular (LV) end-diastolic pressure-volume relationships (compliance curves) in acute hypertensive heart failure (AHHF) before and after treatment with sodium nitroprusside are represented schematically. In AHHF, the pressure-volume curve is shifted up and to the left, reflecting an acute decrease in LV compliance caused by severe systemic hypertension. In this setting, a higher than normal LV end-diastolic pressure (LVEDP) is required to achieve any given level of LV end-diastolic volume (LVEDV). Normal LV systolic function (ejection fraction and cardiac output) is maintained but at the expense of a very high wedge pressure that results in acute pulmonary edema. Treatment with sodium nitroprusside causes a reduction in the elevated systemic vascular resistance, with a concomitant decrease in impedance to LV ejection. As a result, LV compliance improves. Pulmonary edema resolves owing to a reduction in LVEDP, despite the fact that LVEDV actually increases during treatment. Sodium nitroprusside is the preferred drug for treatment of AHHF. There is no absolute blood pressure goal. The infusion should be titrated until signs and symptoms of pulmonary edema resolve or the blood pressure decreases to hypotensive levels. Rarely is it necessary to lower the blood pressure to this extent, however, because reduction to levels still within the hypertensive range is usually associated with dramatic clinical improvement. Although hemodynamic monitoring is not always required, it is essential in patients in whom concomitant myocardial ischemia or compromised cardiac output is suspected. After the hypertensive crisis has been controlled and pulmonary edema has resolved, oral antihypertensive therapy can be substituted as the patient is weaned from the nitroprusside

infusion. As in the treatment of hypertensive patients with chronic congestive heart failure symptoms owing to isolated diastolic dysfunction, agents such as β-blockers, angiotension-converting enzyme inhibitors, or calcium channel blockers may represent logical first-line therapy. These agents directly improve diastolic function in addition to reducing systemic blood pressure. In patients with malignant hypertension or resistant hypertension, however, adequate control of blood pressure may require therapy with more than one drug. Potent direct-acting vasodilators such as hydralazine or minoxidil may be used in conjunction with a β-blocker to control reflex tachycardia and a diuretic to prevent reflex salt and water retention. [Nolan CR. Hypertensive Crises. In: Schrier RW, Wilcox CS. Atlas of Diseases of the Kidney, Volume 3: Hypertension and the Kidney. Philadelphia: Current Medicine Group; 1999. 182 p.] *Caption from original*

Goals of Treatment in Decompensated Heart Failure

Clinical goals	Hemodynamic goals
Resolution of dyspnea and orthopnea	Systolic blood pressure ≥ 80 mm Hg
Resolution of ascites and peripheral edema	Right atrial pressure ≤ 8 mm Hg
Jugular venous pressure ≤ 8 cm H_20	Pulmonary capillary wedge pressure ≤ 16 mm Hg
Control of hypertension	Systemic vascular resistance ≤ 1200 dynes/s/cm-5
Minimize adverse effects of treatment, reduce duration and cost of stay	
Initiate treatments that improve long-term outcome	

Goals of treatment in decompensated heart failure. Goals of in-patient therapy. The early goal of treatment is to improve symptoms while maintaining or improving the hemodynamic status. Progress may be tracked by following body weights and fluid intake and output while monitoring vital signs, electrolytes, and renal function. Consideration also should be given to identifying precipitating factors and etiology, and patients who may benefit from coronary revascularization. [Givertz MM, Colucci WS. Heart Failure. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p.] Caption adapted from original

Drug	Dosing	Potential Advantage	Potential Disadvantages
Nitroglycerin	Sublingual: 1 tablet (or 1–2 sprays) three or four times at 5-minute intervals; IV: 0.4 μg/kg/min initially (increase as needed)	Favorable effect on coronary vasculature and in myocardial ischemia/infarction; preload reduction > afterload	Tolerance during prolonged infusion; inadequate afterload reduction in catastrophic cardiovascular disorders (*eg*, acute valvular insufficiency, ventricular rupture)
Nitroprusside	IV: 0.1 μg/kg/min initially; increase as needed	Relatively powerful preload and afterload reduction	Less favorable effects on coronary vasculature and myocardial ischemia; administration must be closely monitored to avoid marked hypotension; thiocyanate or cyanide toxicity during high-dose or prolonged infusions, particularly in patients with renal or hepatic dysfunction
Nesiritide	0.005–0.01 μg/kg/min initially, ± bolus; increase as needed	Preload and afterload reduction; possible facilitative effect on diuresis	Hypotension; meta-analysis of clinical trials suggests adverse effects on mortality and renal function

Principal preload- and afterload-reducing drugs for acute or severe heart failure. Nesiritide, nitroglycerin, and nitroprusside are the primary vasodilators used to reduce excessive preload and afterload in acute or severe heart failure. Nitroglycerin is used most often, particularly in conditions caused by occlusive atherosclerotic coronary artery disease. Nitroprusside is the drug of choice when more aggressive afterload and preload reduction are needed; examples include catastrophic cardiovascular events (eg, acute, severe mitral, or aortic regurgitation), hypertensive emergencies (eg, aortic dissection, pulmonary edema), and inadequate response to nesiritide or nitroglycerin. [Ooi H, Colucci WS. Management of the Hospitalized Patient. In: Colucci WS, editor. Atlas of heart failure, 5th ed. Philadelphia: Current Medicine Group; 2008. 344 p. ISBN: 1-57340-261-3] *Caption adapted from original*

Disease Course

- Prognosis depends on type and severity of failure.
- With aggressive medical therapy, ventricular assist devices, and even cardiac transplant, even severe heart disease is no longer a short-term mortality diagnosis.
- Patient compliance with management is an important predictor of both outcomes and quality of life.

Chapter 33
Hemoptysis

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Hemoptysis

Incidence/Epidemiology

- Hemoptysis is the expectoration of blood from the respiratory tract with cough. Because coughing sometimes leads to vomiting (tussive emesis), it is important to distinguish between hemoptysis and hematemesis.
- Hemoptysis may range in severity from scant blood-streaked mucous that is self-limited to life-threatening airway obstruction from blood clots or diminished gas exchange in blood-filled alveoli.
- Because there are so many varied causes of hemoptysis, epidemiologic data are not meaningful. Smokers and those with chronic lung or sinus disease are more likely to have hemoptysis.

New York: Springer; 2011 [cited 2015 May 28]. p. 485–96. Available from: http://link.springer.com/10.1007/978-1-4419-0184-2_34] *Caption from original*

Differential Diagnosis

- The important first differential issue to address is whether the bleeding is a result of a respiratory or gastrointestinal (GI) cause. The possibility of epistaxis as a cause should also be evaluated. Beyond that, the differential concerns regard the *cause* of hemoptysis, which generally may be divided into these categories:
  - Infectious
  - Vascular
  - Iatrogenic
  - Coagulopathic
  - Traumatic
  - Neoplastic
  - Pulmonary miscellaneous

Infections • Mycobacteria, particularly tuberculosis • Fungal infections (mycetoma) • Lung abscess • Necrotising pneumonia (Klebsiella, Staphylococcus, Legionella)	Vascular • Pulmonary embolism and infarction • Mitral stenosis • Arteriobronchial fistula • Arteriovenous malformations • Bronchial telangiectasia • Left ventricular failure
Iatrogenic • Bronchoscopy • Swan–Ganz catheterization • Transbronchial biopsy • Transtracheal aspirate	Coagulopathy • Von Willebrand's disease • Hemophilia • Anticoagulant therapy • Thrombocytopenia • Platelet dysfunction • Disseminated intravascular coagulation • Vasculitis • Behcet's disease • Wegener's granulomatosis
Parasitic • Hydatid cyst • Paragonimiasis	
Trauma • Blunt/penetrating injury • Suction ulcers • Tracheoarterial fistula	
Neoplasm • Bronchogenic carcinoma • Bronchial adenoma • Pulmonary metastases • Sarcoma	Pulmonary • Bronchiectasis (including cystic fibrosis) • Chronic bronchitis • Emphysematous bullae
Hemoptysis in children • Foreign body aspiration • Bronchial adenoma • Vascular anomalies	Miscellaneous • Lymphangioleiomyometosis • Catamenial (endometriosis) • Pneumoconiosis • Broncholith • Idiopathic
	Spurious • Epistaxis • Hematemesis

Causes of hemoptysis. [Subramanian S, Kate AH, Chhajed PN. Role of bronchoscopy in hemoptysis. In: Mehta A, Jain P, editors. Interventional bronchoscopy [Internet]. Totowa, NJ: Humana Press; 2013 [cited 2015 May 28]. p. 245–56. Available from: http://link.springer.com/10.1007/978-1-62703-395-4_14] *Caption from original*

Pathophysiology and Etiology

- Hemoptysis may result from several different processes.
- The two most common causes are bronchitis and other lung infections and endobronchial carcinoma with erosion into a bronchial vessel.
- Many patients may never have a definitive cause identified.
- Hemoptysis may result from inflammation/infection or from physical injury to a bronchial vessel.

- Hemoptysis may also result from the high pulmonary venous pressure that results from severe mitral valve stenosis
- The mnemonic "BATTLE CAMP" may be helpful in remembering common etiologies of hemoptysis:

B	Bronchitis, bronchiectasis
A	Aspergillosis, alveolar hemorrhage
T	Tumor, trauma
T	Tuberculosis
L	Lung abscess
E	Emboli
C	Coagulopathy
A	Autoimmune, AVM
M	Mitral stenosis
P	Pneumonia
Others	Tracheostomy related, foreign bodies, aortopulmonary collaterals

Causes of hemoptysis—"Battlecamp." [Hogan MJ. Bronchial artery interventions in children. In: Temple M, Marshalleck FE, editors. Pediatric interventional radiology [Internet]. New York: Springer; 2014 [cited 2015 May 28]. p. 71–83. Available from: http://link.springer.com/10.1007/978-1-4419-5856-3_6] Caption from original

Presentation

Typical/"Classic"

- Patients who present "coughing up blood" usually are hemodynamically stable (massive hemoptysis that causes shock is a medical emergency).
- Patients may not be able to distinguish among cough with expectoration of blood caused by pulmonary sources, posterior epistaxis, and GI bleeding with hematemesis.
- The amount of blood loss should be quickly assessed, and that will drive the pace of evaluation and management.

Atypical

- "Rusty"-colored sputum may not be recognized as hemoptysis.

Primary Differential Considerations

- Primary differential considerations for hemoptysis are limited to:
- Epistaxis
- Hematemesis
  - To help differentiate, remember that blood from the GI tract likely has been exposed to the acidic pH of the stomach and will be darker, whereas blood from the respiratory tract tends to be a brighter red, although chronic infection/tumor may result in expectoration of "older" blood that is darker in color.
- Airway foreign bodies

History and Physical Exam

- Expectoration of even small amounts of blood may provoke significant anxiety in patients, and their quantification of the amount of blood loss may be exaggerated.
- The first historical factors to be established include:
  - Timeframe—how long has hemoptysis been occurring?
  - Course—is it getting worse or better?
  - Character of hemoptysis—is it blood-streaked sputum or is it frank blood?
  - Associated issues—fever and chills? Night sweats? Weight loss? Using an anticoagulant or antiplatelet drug? Any chronic lung disease?
  - Is there pleuritic chest pain with or without dyspnea, suggesting a pulmonary embolism? Are there any signs of deep venous thrombosis?
  - Is the patient a smoker?
- On physical examination, the lungs should be auscultated for evidence of bronchospasm, consolidation, or pleural friction.
- Check the heart sounds for a murmur of mitral stenosis.

Mitral stenosis murmur. [Mitral stenosis (diastolic murmur); Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]
http://www.easyauscultation.com/cases?coursecaseorder=14&courseid=31

Bronchiectasis	Pulmonary tuberculosis
Fungal infections in cavities—aspergilloma	Bronchogenic carcinoma
Severe mitral stenosis	Coagulopathies
Foreign bodies	Trauma
Vasculitis	Pulmonary embolism

Causes of severe hemoptysis. [Bansal A, Kantroo V. Massive hemoptysis. In: Chawla R, Todi S, editors. ICU protocols [Internet]. India: Springer India; 2012 [cited 2015 May 28]. p. 65–70. Available from: http://www.springerlink.com/index/10.1007/978-81-322-0535-7_8] *Caption from original*

Findings That Confirm Diagnosis

- Witnessed expectoration of blood confirms the diagnosis; without firsthand evidence, it is difficult to know with certainty that there is a respiratory tract source.

Factors That Suggest Diagnosis

- A reported history of hemoptysis in a patient at risk for one or more common etiologies of hemoptysis (acute or chronic lung infection, chronic obstructive pulmonary disease [COPD], mitral stenosis, coagulopathy, or pulmonary embolism) should prompt diagnostic evaluation for one of these causes.

Factors That Exclude Diagnosis

- Clinically, hemoptysis cannot be excluded. The history of blood expectoration should be evaluated thoroughly on the supposition that the patient's history is accurate.

Ancillary Studies

Laboratory

- Patients with active hemoptysis and those with a history of repeated or chronic episodes should be evaluated with a complete blood count (CBC).
- Patients on warfarin anticoagulation should be checked for international normalized ratio (INR); patients on unfractionated heparin should be evalu-

ated for activated partial thromboplastin time (aPTT); patients taking an injectable low-molecular-weight heparin should be checked for renal function, and the time of last dose should be noted.
- D-dimer testing may be helpful in determining possible pulmonary embolism.
- Sputum evaluation may be helpful.

Electrocardiography

- In general, ECG should be performed in ill patients but is unlikely to be particularly helpful in the evaluation of hemoptysis.

Imaging

- Chest x-ray is an essential first step in evaluating hemoptysis. Look for mass lesions, infection, signs of chronic lung disease, or evidence of a foreign body.
- A computed tomographic pulmonary angiogram is indicated if pulmonary embolism is suspected.

Other Studies

- Bronchoscopy may be indicated.

Special Populations

Age

- Older patients have a higher risk of lung cancer, COPD, pulmonary embolism, and pneumonia.
- Hemoptysis in children is less common than in adults and has a different differential diagnosis. Infection of the lungs is less likely to manifest as hemoptysis in children. Instead, consider foreign body aspiration or
  - bronchial adenoma
  - congenital vascular anomalies

Co-morbidities

- COPD
- Lung cancer
- Bronchitis
- Pneumonia
- Therapeutic anticoagulation
- Tobacco abuse

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Evaluation for satisfactory oxygenation
- Evaluation for hemodynamic stability
- Evaluation for correctable coagulopathy
- Altered mental status may signal respiratory failure.
- Chest x-ray should be done early.

Mimics

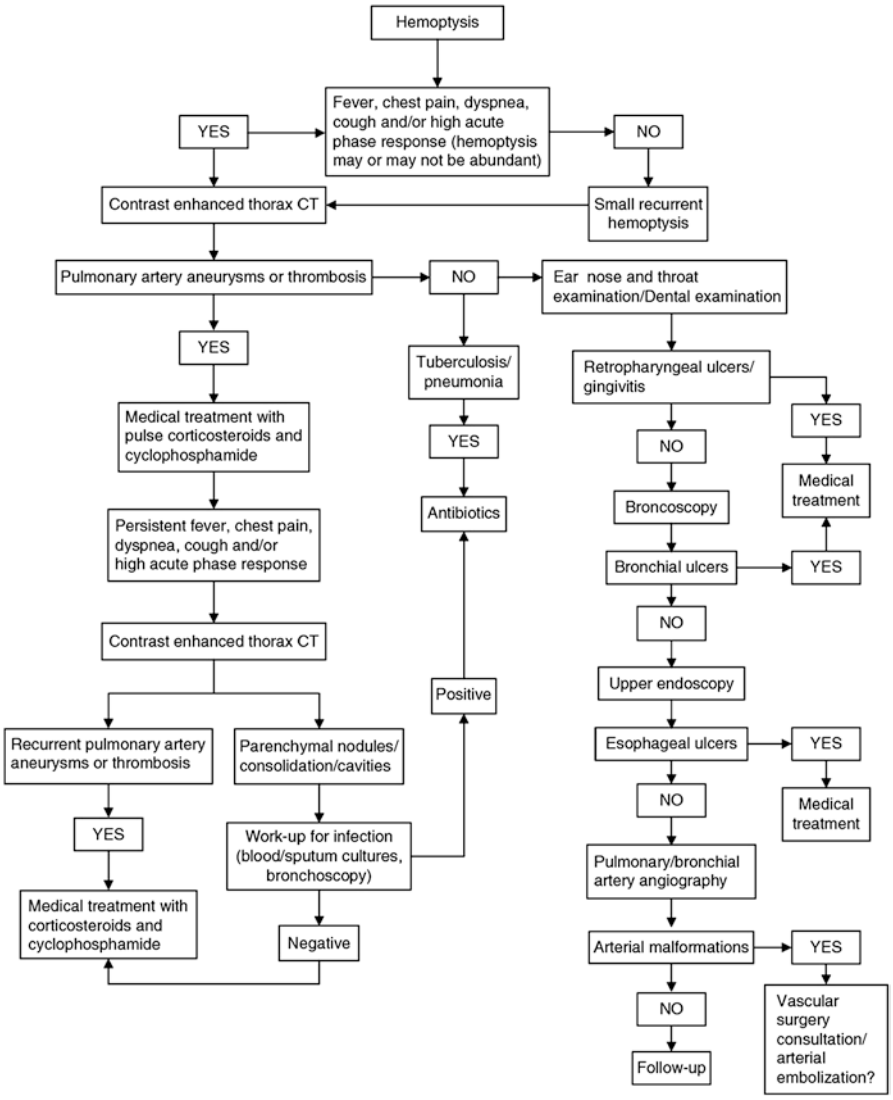
- Upper GI bleed
- Posterior epistaxis

Time-Dependent Interventions

- Immediate evaluation for adequate gas exchange and hemodynamic stability
- Chest x-ray early

Overall Principles of Treatment

- Stabilize hemodynamic and ventilatory status.
- Evaluate for etiology.
- Treat accordingly with antibiotics, bronchoscopic intervention, reversal of anticoagulation, etc.



Algorithm for diagnosis and management of hemoptysis due to Behçet's syndrome. [Seyahi E, Tascilar K, Yazici H. Behçet's syndrome: clinical presentations affecting prognosis and survival. In: Khamashta MA, Ramos-Casals M, editors. Autoimmune diseases [Internet]. London: Springer; 2011 [cited 2015 May 28]. p. 163–84. Available from: http://link.springer.com/10.1007/978-0-85729-358-9_11] *Caption from original*

Disease Course

- Course is determined by acuity of presentation and underlying etiology.
- The vast majority of hemoptysis cases are not life threatening, although the underlying etiology may be significant.

Chapter 34
Herpes Zoster

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Herpes Zoster; Shingles

Incidence/Epidemiology

- The Centers for Disease Control and Prevention (CDC) estimates that up to one-third of the adult population in the United States will be diagnosed with shingles at some point in their lives.
- There are about 1 million to 1.2 million cases annually in the United States.
- It may occur in all adult age groups, but the incidence increases dramatically after age 50.
- It is unusual in children.
- Shingles has a very low mortality and is rarely life threatening but has substantial morbidity, mostly as the result of postherpetic neuralgia (PHN).
- Most cases occur in healthy individuals, but the incidence increases among the immunocompromised.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_34

Differential Diagnosis

- Coxsackievirus and herpes simplex virus also may cause a vesicular rash in a dermatomal distribution.

Pathophysiology and Etiology

- The varicella-zoster virus (VZV) causes shingles.
- Primary infection with VZV causes chickenpox.
- After primary infection, the virus may become dormant in the dorsal root ganglia of the spinal cord. It may lie dormant for decades, but in response to immunosuppression, or the waning of innate immunity due to aging, the virus may reactivate. The virus travels down the corresponding sensory nerve of the involved dorsal root ganglion to cause the rash along those sensory dermatomes. Reactivation usually involves just one dermatome, but may involve several or many dermatomes, especially if there is an underlying immunosuppression.
- The exact mechanisms and causes of reactivation are unknown.

Presentation

Typical/"Classic"

- Symptoms usually start with pain in one sensory dermatome. Patients also often note paresthesias or itching in the area of pain. The dermatomal distribution of the pain sometimes is not recognized by either the patient or the physician.
- In retrospect, most patients also describe a prodrome of malaise with a mild headache.
- The rash classically erupts within 1-10 days (most typically 3) of symptom onset.
- The skin lesions often start as an erythematous maculopapular rash. Vesicles then erupt. The vesicles are generally small and closely grouped into clusters of lesions. The grouped vesicles remain on an erythematous base. The vesicles initially contain clear fluid, but the fluid becomes cloudy and appears more purulent over the next several days. Ultimately the lesions dry, ulcerate, and crust over. It may be 2 weeks until the lesions crust, and then another 2 weeks for the scabs to fall off.
- The lesions do not cross the midline.
- The vesicles may be of differing sizes, and they may be of differing stages in the same areasimialr to primary chicken pox.
- The thorax and face are the most commonly affected areas, but shingles may occur anywhere on the body.

Vesicles in a dermatomal distribution represent herpes zoster. [Allen HB. Vesiculobullous Disorders (Including Dermatitis/Eczema). In: Dermatology Terminology [Internet]. London: Springer London; 2010 [cited 2016 Aug 22]. p. 15–32. Available from: http://link.springer.com/10.1007/978-1-84882-840-7_2] *Caption from original*

Early stage of shingles with clear vesicles on an erythematous base. [Gilsdorf J, Shope T. Viral exanthems of childhood. In: Fekety R, editor. External manifestations

of systemic infections. Philadelphia: Current Medicine; 1996. 237 p. (Mandell GL, editor. Atlas of infectious diseases; vol. 6.) ISBN: 0-443-07760-6]

More developed stage of shingles with crusting. [Gilsdorf J, Shope T. Viral exanthems of childhood. In: Fekety R, editor. External manifestations of systemic infections. Philadelphia: Current Medicine; 1996. 237 p. (Mandell GL, editor. Atlas of infectious diseases; vol. 6.) ISBN: 0-443-07760-6]

Atypical

- Shingles may occur less commonly in more than one dermatome, or be generalized.
- There is some thought and evidence that zoster may cause a syndrome of dermatomal pain without a rash: zoster sine herpetica.

Primary Differential Considerations

- Pain from shingles may precede the appearance of the rash, making early diagnosis more challenging. Differential diagnoses that should be considered include:
  - Acute coronary syndrome
  - Pulmonary embolism
  - Pleurisy

History and Physical Exam

Findings That Confirm Diagnosis

- Shingles is a clinical diagnosis. A full classic presentation of prodromal pain with development of the classic rash confirms the diagnosis.

Factors That Suggest Diagnosis

- Any rash or pain in a dermatomal distribution should suggest the diagnosis.

Factors That Exclude Diagnosis

- There are no historical or physical exam findings that can exclude the diagnosis.

Ancillary Studies

Laboratory

- Laboratory studies often are not required to make the diagnosis.
- Confirmatory testing may include antigen testing, viral culture, and polymerase chain reaction (PCR) on vesicular fluid. Culture and PCR generally are not available clinically; they usually are research techniques.
- The diagnosis may be suggested by performing a Tzanck smear. A fresh vesicle is unroofed, the bottom of the lesion is superficially scraped, and a slide is made of the scraped material. The presence of multinucleated giant cells may confirm the diagnosis; however, the false negative rate is high.

Imaging

- There are no diagnostic imaging findings that are helpful in the diagnosis of shingles.

Special Populations

Age

- It may occur in all adult age groups, but the incidence increases dramatically after age 50.
- It is unusual in children.

Co-morbidities

- Co-morbidities of importance are any type of immune compromise, including:
  - iatrogenic, from immune suppressive therapy for organ transplants, and long-term glucocorticoid therapy
  - lymphoproliferative disorders (especially leukemia and Hodgkin's lymphoma) and HIV
- The incidence of shingles increases with immune suppression, as does the risk for complications.
- Patients who have undergone hematopoietic stem cell transplantation are at particularly increased risk for shingles and its complications.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Always consider this diagnosis.

Mimics

- Coxsackievirus and herpes simplex virus also may cause a vesicular rash in a dermatomal distribution.
- Shingles may cause severe pain and can mimic many other causes of acute, severe pain if the patient presents before the rash develops.

Time-Dependent Interventions

- The only time-dependent intervention in shingles is to start treatment with antivirals within 3 days of the eruption of the rash.
- Treatment within this timeframe has been shown to reduce the incidence of developing PHN, especially in those over 50.

Overall Principles of Treatment

- The primary goal of treatment is to reduce the incidence and severity of PHN.
- This is accomplished by starting antivirals (typically valacyclovir) within 72 hours of the onset of the rash.
- Immunocompromised patients should be treated regardless of the timing from the onset of rash.
- Adjunctive corticosteroids may be considered for severe pain or for older patients with no contraindications to their use.
- Administering the shingles vaccine in those over 65 may help reduce the incidence and severity of shingles, and also reduces the incidence of PHN by up to two-thirds.
- Admission for intravenous antivirals is often indicated for disseminated shingles, central nervous system (CNS) shingles, and severely immunocompromised patients.

Disease Course

- The rash usually dries and crusts within 2 weeks. Crusts fall off over the next 2 weeks.
- Recurrence occurs in only 1–4 %. Recurrence should make one consider underlying immunocompromise.
- Complications may be serious and debilitating, and they account for most of the morbidity associated with shingles.
- PHN is the continuation of pain (often severe) for more than 30 days after the rash resolves. PHN is the most common complication of shingles. It is more common in older and immunocompromised patients. The incidence rises from 5 % in those under 60 to greater than 20 % in those over 80. The pain from PHN may be debilitating and may last for months to years. At least 50 % of affected patients over age 50 report some pain in the involved dermatome even months after resolution of rash. Many patients with PHN also describe sensory changes over the affected dermatome. The incidence may be reduced by the appropriate use of the shingles vaccine.
- Multidermatomal (disseminated zoster) is much more common in the immunocompromised. If shingles disseminates, the risk for other complications rises by 5–10 %. If an otherwise young, healthy person presents with shingles in three or more dermatomes, it is important to consider underlying immunosuppression (such as HIV).
- Shingles occurring along the ophthalmic division of the trigeminal nerve may cause zoster ophthalmicus. Shingles involving the eye may lead to severe retinitis and blindness. Patients with zoster in this distribution should be evaluated and followed up by an ophthalmologist. Vesicles present on the tip of the nose should increase suspicion of zoster ophthalmicus.

Zoster ophthalmicus. Note lesions on tip of nose. [Wassilew SW, Wutzler P. Schutz vor zoster: impfung blockiert virusreaktivierung. Präv Gesundheitsf. 2010 Jun;5(S1):23–7.]

- Ramsay-Hunt syndrome (zoster oticus) may occur when shingles involves the sensory branch of the facial nerve. The classic triad of Ramsay-Hunt is pain and vesicles in the external auditory canal, loss of taste on the anterior two-thirds of the tongue, and ipsilateral facial palsy. The facial palsy may be prolonged and severe. The presence of Ramsay-Hunt is a risk factor for CNS zoster.

Zoster oticus. Note lesions in the external auditory canal. [Weisshaar E, Kallen U, Klintworth N, Zenk J. Pruritus, erytheme & co: das ohr aus dermatologischer sicht. HNO. 2011 Mar;59(3):301–10.]

- Shingles rarely may involve the CNS. CNS involvement can manifest as meningoencephalitis, transverse myelitis (with or without motor involvement), or, very rarely, granulomatous angiitis.

Chapter 35
Hiatal Hernia

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Hiatal Hernia

- Hiatus Hernia

Incidence/Epidemiology

- Hiatal hernias commonly are found incidentally when patients undergo imaging for other reasons, or during endoscopy.
- Most hiatal hernias are asymptomatic.
- The true incidence is unknown, as they often are asymptomatic and only incidentally found.
- The incidence increases with age, obesity, and pregnancy.
- Hiatal hernias (especially type 1) significantly increase the risk for gastroesophageal reflux disease (GERD).

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_35

Differential Diagnosis

- Because hiatal hernias usually are found incidentally during either chest or abdominal imaging to evaluate another issue, there is no specific differential diagnosis. However, it is important to determine the type of hiatal hernia that exists.
- If the patient has symptoms, they usually are the symptoms of GERD; therefore, the differential is that of GERD, including:
    - Esophagitis
    - Gastritis
    - Peptic ulcer disease
    - Esophageal motility disorders
    - Functional dyspepsia

Pathophysiology and Etiology

- A hiatal hernia is a structural disorder of the esophagus marked by the herniation of intra-abdominal contents (most often the cardia of the stomach) through the esophageal hiatus of the diaphragm.
- The esophagus is anchored to the diaphragm by the phrenoesophageal membrane (PEM) or ligament. The PEM is composed mostly of elastic connective tissue and inserts circumferentially into the esophageal musculature at the diaphragmatic hiatus. A defect or laxity of the PEM allows for the herniation of abdominal contents.
- It most commonly is thought to be caused by age-related degeneration of the PEM.
- Longstanding acid reflux also may lead to tonic contracture of the longitudinal muscle layer of the esophagus, resulting in increased stress on and degeneration of the PEM.
- Types II through IV are recognized complications of surgery involving the hiatus.
- There are four distinct anatomic types of hiatal hernia.
- Type I, or sliding hiatal hernia:
    - These account for about 95 % of all hiatal hernias.
    - Laxity of the PEM allows the gastric cardia to “slide” through the diaphragmatic hiatus. It is not a true hernia; there is no defect in the PEM and no true hernia sac.
    - The likelihood of symptomatic GERD increases with the size of the hernia.
    - It is felt that a hiatal hernia impairs the function of the gastroesophageal (GE) junction and prolongs clearance of esophageal contents, leading to symptoms of GERD.

- However, many asymptomatic patients are found to have a type I hiatal hernia.

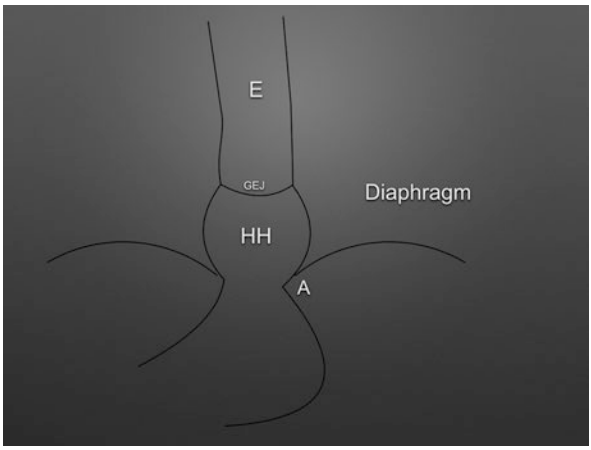

Diagram of a type I (sliding) hiatal hernia (HH). The gastroesophageal junction (GEJ) has migrated above the diaphragm into the chest. The Angle of HIS (A) is blunted, reducing its ability to protect against gastroesophageal reflux [Belafsky PC, Kuhn MA. The clinician's guide to swallowing fluoroscopy [Internet]. New York: Springer; 2014. Chapter 11, Abnormal esophageal fluoroscopy; [cited 2015 Aug 14]; p. 95–123. Available from: http://link.springer.com/10.1007/978-1-4939-1109-7_11] *Caption from original*

- Type II through IV:
  - Types II through IV are all paraesophageal hernias. They are true hernias with defects in the PEM and true hernia sacs, and include viscera other than the gastric cardia.
  - In a type II hernia, the gastric fundus also herniates, but the GE junction remains fixed at the hiatus.
  - Type III hernia is a combination of types I and II: it is both a sliding and a paraesophageal hernia.
  - Types II and III may lead to gastric volvulus and ischemia. As the defect enlarges, more of the stomach may herniate through. Because the stomach remains fixed at the GE junction, it may invert, leading to an upside down, intrathoracic stomach. This may interrupt the blood supply and cause ischemia, resulting in a mechanical gastric volvulus.
  - Type IV hiatal hernias are associated with the largest defects in the PEM, and they involve herniation of abdominal contents other than the stomach, most commonly the colon.
  - Type III is the most common type of paraesophageal hiatal hernia, accounting for about 90 % of paraesophageal hernias. Type II is the least common.

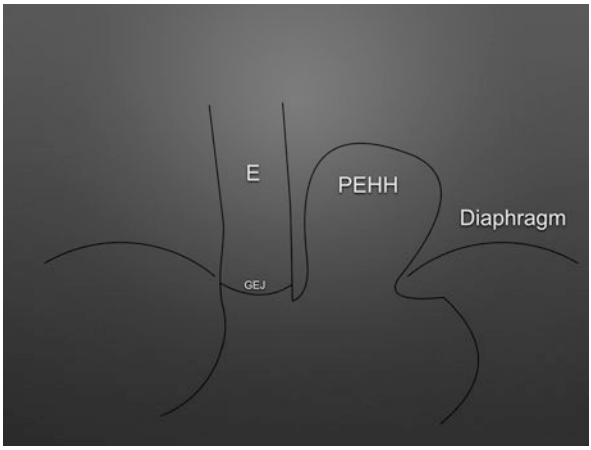

Diagram of a type II hiatal hernia. A type II hernia is a pure paraesophageal hiatal hernia (PEHH) and the gastroesophageal junction (GEJ) remains at or below the level of the diaphragm [Belafsky PC, Kuhn MA. The clinician's guide to swallowing fluoroscopy [Internet]. New York: Springer; 2014. Chapter 11, Abnormal esophageal fluoroscopy; [cited 2015 Aug 14]; p. 95–123. Available from: http://link.springer.com/10.1007/978-1-4939-1109-7_11] *Caption from original*

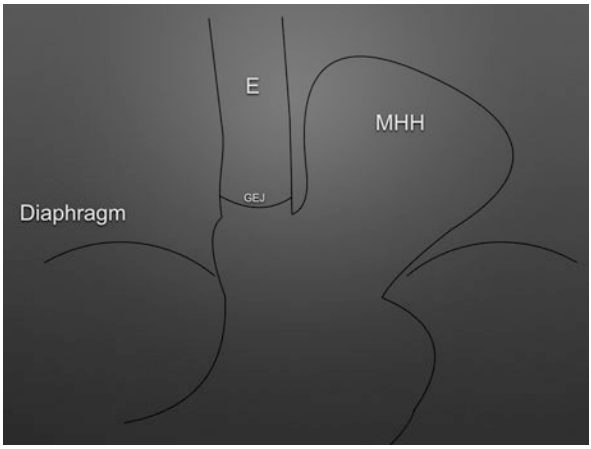

Diagram of a type III (mixed) hiatal hernia (MHH). A type III hiatal hernia is a mixed hernia in which the fundus and gastroesophageal junction (GEJ) have herniated alongside each other above the diaphragm into the chest. The majority of paraesophageal hiatal hernias are type III [Belafsky PC, Kuhn MA. The clinician's guide to swallowing fluoroscopy [Internet]. New York: Springer; 2014. Chapter 11, Abnormal esophageal fluoroscopy; [cited 2015 Aug 14]; p. 95–123. Available from: http://link.springer.com/10.1007/978-1-4939-1109-7_11] *Caption from original*

Sagittal CT scan images of a patient with a large Type IV hiatal hernia; note the retrocardiac herniation of small bowel [Sarpel U. Surgery: an introductory guide [Internet]. New York: Springer; 2014. Chapter 4, Fundoplication; [cited 2015 Aug 14]; p. 27–35. Available from: http://link.springer.com/10.1007/978-1-4939-0903-2_4] *Caption from original*

Presentation

Typical/"Classic"

- Most are asymptomatic.
- Type I (sliding) hiatal hernias often are associated with symptomatic GERD.
- Type II through IV (paraesophageal) hernias often have ambiguous symptoms. They may be asymptomatic, or patients may describe epigastric or chest pain, early satiety, excessive fullness after eating, nausea, or retching. GERD is a less common complaint for these types.

Atypical

- Because most hiatal hernias are asymptomatic, there are no typical or atypical features.

Primary Differential Considerations

- Chest pain resulting from hiatal hernia often is nonspecific. Other diagnoses that should be considered early in the evaluation of patients with similar symptoms include:
  - Acute coronary syndrome
  - GERD
  - Peptic ulcer disease
  - Pneumonia
  - Gastric outlet obstruction
  - Esophageal food bolus impaction or other foreign body

History and Physical Exam

Findings That Confirm Diagnosis

- The diagnosis can be confirmed only by imaging, most likely by CT scan but also by barium study of the upper gastrointestinal tract.
- There are no confirmatory historical or physical examination findings.

Factors That Suggest Diagnosis

- Sliding hiatal hernias are suggested in patients with symptoms of GERD and increasing age.
- Paraesophageal hernias are suggested in patients who have vagus upper abdominal symptoms have had a previous surgical procedure involving the diaphragmatic hiatus.

Factors That Exclude Diagnosis

- Paraesophageal hernias can be excluded by a normal CT scan.
- Small sliding hiatal hernias may be missed on endoscopy and imaging and therefore cannot be excluded, but their clinical significance remains in question.

Ancillary Studies

Laboratory

- Laboratory studies are not helpful in the diagnosis of hiatal hernia.

Imaging

- Sliding hiatal hernias often are diagnosed incidentally on imaging studies (chest x-ray, chest and abdominal CT). They also may be found on other imaging studies, such as endoscopy, barium swallow or upper gastrointestinal series, or esophageal manometry. However, sliding hiatal hernias less than 2 cm long may be missed by all the aforementioned studies.
- Paraesophageal hernias usually are diagnosed by CT of the chest and abdomen. Although barium swallow is performed less frequently, it is more sensitive in detecting paraesophageal hernias.

Special Populations

Age

- The incidence of sliding hiatal hernias increases with age.

Co-morbidities

- Sliding hiatal hernia may coexist with any other diagnosis.
- Paraesophageal hernias are found mostly in patients who have had prior thoracic or abdominal surgery involving manipulation of the diaphragmatic hiatus.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- A critical mistake would be attributing a patient's symptoms (especially chest pain, epigastric pain, nausea and/or vomiting, and shortness of breath) to a sliding hiatal hernia and not continuing diagnostic evaluation for other causes.

Mimics

- Because hiatal hernias usually are asymptomatic, no significant mimics exist, and they typically do not mimic any other diseases.
- The appearance on imaging studies, especially plain radiographs, may sometimes mimic that of an elevated hemidiaphragm or a cavitary lung lesion.

Time-Dependent Interventions

- There are no time-dependent interventions.

Overall Principles of Treatment

- There is no specific treatment for a sliding hiatal hernia; treatment often is aimed at symptomatic treatment of GERD.
- It is important to stress that atypical symptoms, such as chest pain, abdominal pain, and shortness of breath, should not be attributed to a sliding hiatal hernia.
- Asymptomatic paraesophageal hernias often are treated conservatively with only follow-up.
- Symptomatic or very large paraesophageal hernias may need to be repaired surgically.

Disease Course

- Sliding hiatal hernias often grow and worsen in radiologic appearance as the patient ages, which may increase the likelihood of symptomatic GERD, although the true clinical significance is unknown.

Chapter 36
Hypertension

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Hypertension

- High blood pressure, "high blood"

Incidence/Epidemiology

- Hypertension is the most prevalent disease state in the world.
- There are many definitions and staging systems for hypertension, but in general, a diastolic blood pressure greater than 90 mm Hg and/or a systolic blood pressure greater than 150 mm Hg are associated with the incidence of cardiovascular and cerebrovascular disease, and with benefit from chronic pressure-lowering therapy.
- Most cases of hypertension are "primary" (also called "essential"), but there are secondary causes, such as renal disease, pheochromocytoma, hyperaldosteronism, and Cushing's syndrome. Pregnancy is also often associated with hypertension.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_36

- Many adjectives frequently are associated with hypertension, such as *controlled* or *uncontrolled*, *resistant* for hard-to-treat hypertension, and *accelerated* or *malignant* for hypertension that is severe and acute.
- Prevalence is higher among African American populations than white populations.

Hypertension is highly prevalent
Hypertension is associated with an increased risk of heart disease, stroke, renal failure, and death
The treatment of moderate and severe hypertension reduces the risk of hypertensive complications
The treatment of mild hypertension decreases the incidence of strokes and probably reduces the incidence of CHD
The treatment of hypertension is widespread, and approximately $10 billion/y is spent on therapy

Differential Diagnosis

- Hypertension is a quantitatively defined disease. Consideration of differentials is more limited to possible causes of secondary disease. Hypertension may also be a cardinal aspect of the presentation of acute coronary syndrome, acute heart failure, acute renal failure, and acute stroke. Acute presentations also may be prompted by anxiety, stimulant use, or steroid use.

Primary care	Cause of resistant hypertension	Tertiary center
Problems with BP measurement		
20–30%	White-coat hypertension	10–20%
Medication-related causes		
~5%	Suboptimal medication regimen	30–60%
~10%	Drug-drug interaction	<5
<2%	Objective medication intolerance[a]	<2%
Interfering substances		
1–5%	Excessive dietary sodium	1–10%
1–7%	Ethanol or illicit substances	1–12%
Secondary hypertension		
<5%	Sleep apnea/aldosterone excess	1–83%
<5%	Traditional secondary causes[b]	5–28%
Psychological causes		
1–2%	Anxiety/panic disorder/depression	1–2%
1–2%	Subjective medication intolerance[a]	1–5%

[a] Objective and subjective medication intolerance are distinguished based on whether or not, respectively, the patient's reported adverse effect is mentioned in the prescribing information approved by the US Food and Drug Administration.

[b] Traditional secondary causes include renovascular hypertension, primary hyperaldosteronism, pheochromocytoma, Cushing's syndrome, etc.

BP blood pressure.

Differential diagnosis of resistant hypertension, with relative proportion of each, depending on the population studied. [Elliott WJ. Management of resistant hypertension. Curr Cardiovasc Risk Rep. 2011 Oct;5(5):373–82.] *Caption from original*

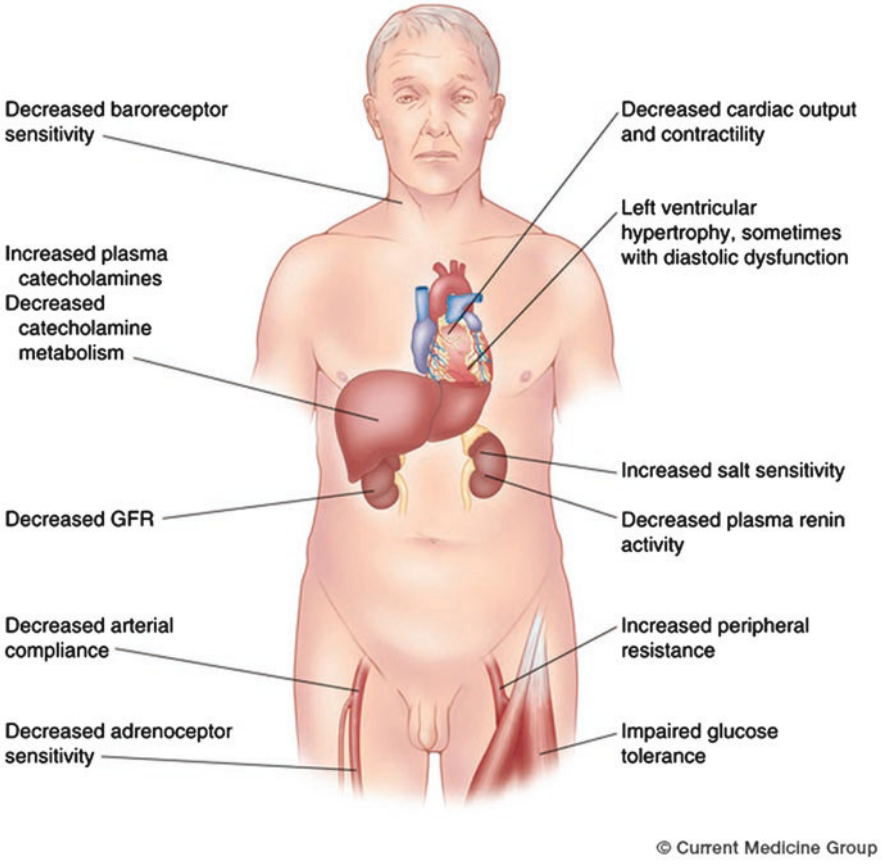
Pathophysiology and Etiology

- Hypertension is a pleomorphic disease, the etiology of which may be inapparent (although even in these cases, a genetic contribution is likely)
- Other defined causes include
  - Renal (renal artery stenosis, chronic pyelonephritis, polycystic kidney disease)
  - Endocrine (adrenocortical hyperfunction, pheochromocytoma)
  - Neurogenic (dysautonomia)
  - Vascular (such as coarctation of the aorta or polyarteritis nodosa)
- Factors contributing to hypertension are varied and include
  - Obesity
  - Salt intake
  - Alcohol intake
  - Medication use
  - Drug abuse
  - Tobacco use

Age Group	Etiology
Newborn	Renal artery or venous thrombosis
	Renal artery stenosis
	Congenital renal abnormalities
	Coarctation of the aorta
	Bronchopulmonary dysplasia
	History of Prematurity
First Year	Renovascular disease
	Renal parenchymal disease
	Coarctation of the aorta
	Iatrogenic (medication, volume)
	Tumor
	History of Prematurity
1 to 6 years	Renal parenchymal disease
	Renovascular disease
	Coarctation of the aorta
	Tumor
	History of Prematurity
	Endocrine causes*
	Iatrogenic
	Essential hypertension
Age 6 to 10 years	Renal parenchymal disease
	Essential hypertension
	Renovascular disease
	Coarctation of the aorta
	Endocrine causes
	Tumor
	Iatrogenic
Adolescence, Age 12 to 18 years	Essential hypertension
	Iatrogenic
	Renal parenchymal disease
	Endocrine causes
	Coarctation of the aorta

Shaded areas are uncommon for category

Most Common Causes of Secondary Hypertension: By Age. [Samuel JP, Swinford RD, Portman RJ. Evaluation of hypertension in pediatric patients. In: Flynn JT, Ingelfinger JR, Portman RJ, editors. Pediatric hypertension [Internet]. Totowa, NJ: Humana Press; 2013 [cited 2015 Jun 22]. p. 491–504. Available from: http://link.springer.com/10.1007/978-1-62703-490-6_32] *Caption from original*



Some of the pathophysiologic features of hypertension in the elderly. Although some features are common in many elderly patients with elevated blood pressure, it is unusual for all of these features to be present in any one patient. GFR—glomerular filtration rate. [Elliott WJ, Black HR. Special situations in the management of hypertension. In: Hollenberg NK, editor. Atlas of hypertension. 6th ed. Philadelphia, PA: Springer; 2009. 334 p. ISBN: 978-1-57340-308-5] *Caption from original*

Presentation

Typical/"Classic"

- Most patients with hypertension are asymptomatic, and their elevated blood pressure is discovered incidentally.
- Moderate to severe hypertension may prompt presentation with headache, dizziness, epistaxis, or hematuria. Anxiety also is common.

- Severe hypertension may present as headache, dizziness, epistaxis, chest pain, dyspnea and heart failure, syncope, or stroke.
- There may be a history of stimulant use/abuse.

Atypical

- Health care providers often are surprised that patients with (chronically) very high blood pressures are asymptomatic.

Primary Differential Considerations

- As above, differential considerations usually apply to the symptoms that manifest with hypertension, not the elevated blood pressure itself.

History and Physical Exam

- In the history, focus on family history, age of onset, medication use (especially steroids and oral contraceptives), alcohol and drug abuse, history of renal disease, and signs and symptoms of other cardiovascular disease.
- On physical examination, note the patient's general appearance and overall health. Blood pressure should be checked in both upper extremities. Note height and weight. A thorough funduscopic exam should be performed to look for hypertensive changes. Check for neck and abdominal bruits. Listen for a fourth heart sound.

Fourth heart sound. [Fourth Heart Sound; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]
http://www.easyauscultation.com/cases-listing-details?caseID=42

Findings that Confirm Diagnosis

- Elevated blood pressure in both upper extremities should be documented in confirmation of the diagnosis. To make a new diagnosis of hypertension, the blood pressure should be elevated on at least two separate evaluations.

Factors that Suggest Diagnosis

- A history of elevated blood pressure and suggestive symptoms as above.

Factors that Exclude Diagnosis

- Repeatedly normal blood pressure excludes acute hypertension but may not fully exclude chronic disease.

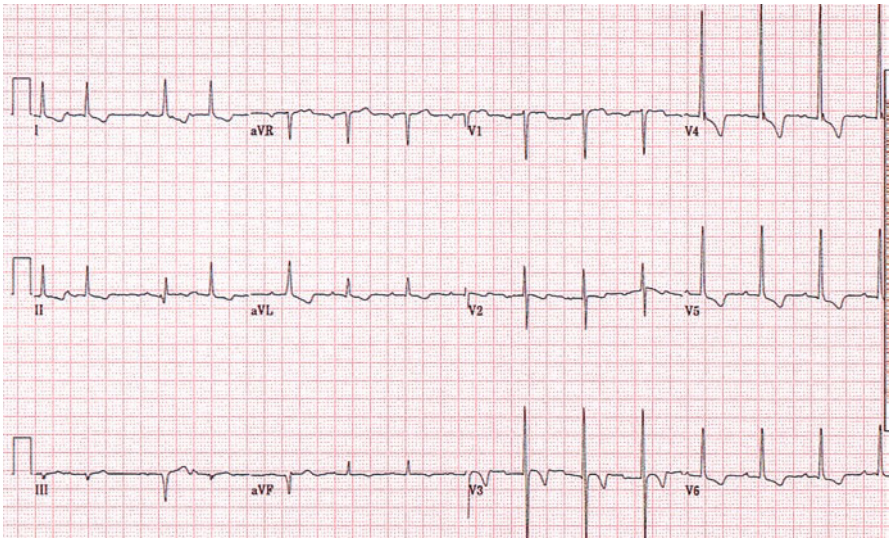
Ancillary Studies

Laboratory

- Baseline CBC (to exclude anemia) and renal function should be evaluated.
- Urine should be checked for protein, blood, and glucose.
- Serum electrolytes (especially potassium) should be checked.
- Lipid profile may be helpful.
- Serum calcium, phosphate, and uric acid should be checked.

Electrocardiography

- Should be obtained to evaluate rhythm and to look for left ventricular hypertrophy or Q waves.

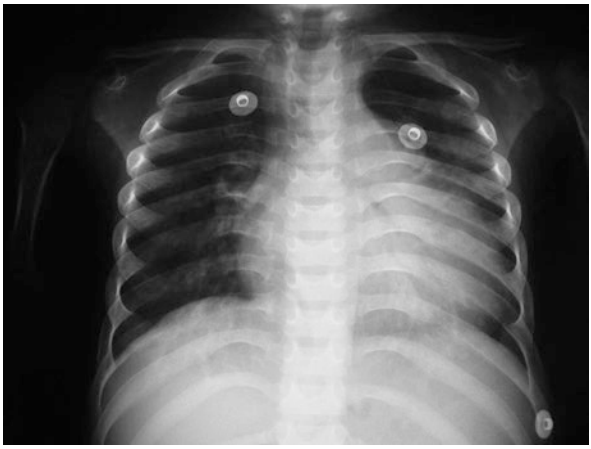


A 12-lead electrocardiogram demonstrating left ventricular hypertrophy with a "strain" pattern. [Fleisher L. Chapter 3. In: Lichtor JL, editor. Preoperative preparation and intraoperative monitoring. Philadelphia: Current Medicine; 1997. 251 p.

(Miller RD, editor. Atlas of anesthesia; vol. 3.) ISBN: 0-443-07902-1] *Caption adapted from original*

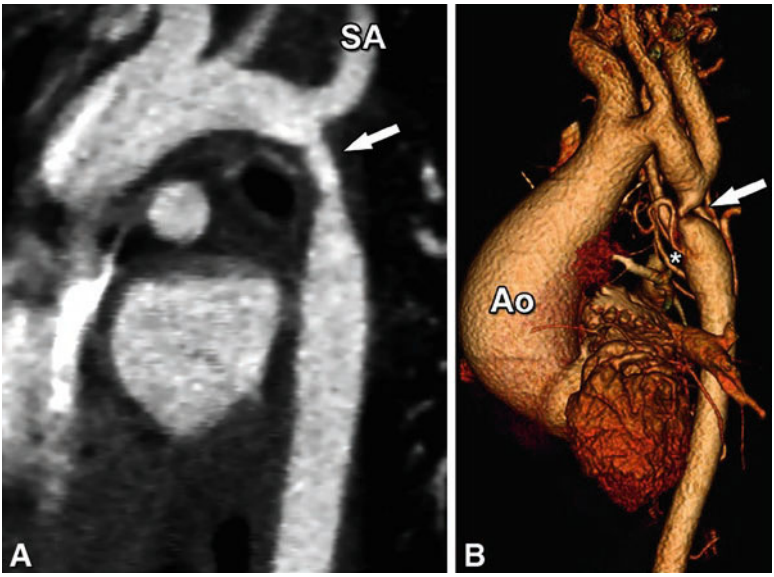
Imaging

- Chest x-ray should be obtained to look for cardiac enlargement, aortic dilation, rib notching from aortic coarctation, or signs of pulmonary edema.



Cardiomegaly on chest X-ray. [Yıldırım SV, Durmaz C, Pourbagher MA, Erkan AN. A case of achondroplasia with severe pulmonary hypertension due to obstructive sleep apnea. Eur Arch Otorhinolaryngol. 2006 Aug;263(8):775–7.] *Caption from original*

- Concern for aortic disease should prompt more sophisticated imaging.



Aortic coarctation in two patients. Panel A is a double-oblique image from a prospectively ECG-triggered CT scan showing coarctation in a 2-year-old patient (arrow) just distal to the takeoff of the left subclavian artery (SA). The high-pitch CT scan was performed during free breathing with an acquisition time of 0.25 s and a dose-length product of 6 Gy.cm. The patient underwent subsequent repair of coarctation with an end-to-end anastomosis. Panel B shows a three-dimensional reconstruction of a CT scan performed for evaluation of severe aortic coarctation (arrow) in an 11-year-old patient who presented for evaluation of a murmur. His ascending aorta (Ao) was dilated and the murmur was secondary to aortic insufficiency. He was noted to be hypertensive with a blood pressure gradient of 30 mmHg between the right arm and leg. Note the collateral vessels supplying the descending aorta (asterisk). He underwent surgical repair of aortic coarctation and has since been followed clinically for aortic insufficiency and aortic root dilation [Ley S, Han BK, Arnold R, Lesser JR. Congenital and acquired heart disease. In: Dewey M, editor. Cardiac CT [Internet]. Berlin, Heidelberg: Springer; 2014 [cited 2015 Jun 22]. p. 393–414. Available from: http://link.springer.com/10.1007/978-3-642-41883-9_26] *Caption from original*

Other Studies

- Echocardiography or renal ultrasound imaging may be indicated

Special Populations

Age

- Essential hypertension rarely occurs in children. Younger patients with hypertension should be evaluated for secondary causes.
- The most common causes of hypertensive emergencies by age are listed in the table below:

Infancy	Childhood	Adolescence
Renal vascular disease	Renal disease	Primary hypertension
Congenital renal anomaly	Renal vascular disease	Nonadherence to meds
Coarctation	Pheochromocytoma	Renal disease
Volume overload	Increased intracranial pressure	Toxemia
Renal disease	Drug induced	Pheochromocytoma
Renal vein thrombosis		Illicit drug use
Congenital adrenal hyperplasia		

Co-morbidities

- May include:
  - Renal disease
  - Cardio- and cerebrovascular disease
  - Drug and alcohol abuse
  - Endocrine disorders such as diabetes, metabolic syndrome, Cushing's syndrome, or primary hyperaldosteronism

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Recognition of "hypertensive emergency," as this requires parenteral treatment. Hypertensive emergency is defined as acute hypertension plus end-organ damage, such as acute heart failure, acute coronary syndrome, acute aortic dissection, or acute stroke.

Definitions of Hypertensive Emergencies and Urgencies

Hypertensive emergency
Severe elevation in blood pressure with signs or symptoms of acute, severe target organ damage, which must be reduced within minutes (typically using parenteral therapy)
Hypertensive urgency
Severe elevation in blood pressure with mild or no acute target organ damage, which must be reduced within hours (typically with oral therapy)

Definitions of hypertensive emergencies and hypertensive urgencies (Chobanian AV, Bakris GL, Black HR, et al. The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: The JNC 7 Report. JAMA. 2003;289:2560–72; Chobanian AV, Bakris GL, Black HR, et al. Seventh report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure. National High Blood Pressure Education Program Coordinating Committee. Hypertension. 2003;42:1206–52). Note that the older terms *accelerated hypertension* and *malignant hypertension* have been eliminated (with the exception of the terminology used by hospital administrators, as mandated by the Federal Diagnosis-Related Groups Handbook). Severe hypertension without acute target organ damage is never an emergency and does not require parenteral therapy. [Elliott WJ, Black HR. Special situations in the management of hypertension. In: Hollenberg NK, editor. Atlas of hypertension. 6th ed. Philadelphia, PA: Current Medicine Group; 2009. 334 p. ISBN: 978-1-57340-308-5] *Caption from original*

Essential or accelerated hypertension
Acute aortic dissection
Preeclampsia and eclampsia
Acute myocardial infarction or ischemia
Endocrine disorders
  Pheochromocytoma (excess catecholamines)
  Aldosteronism
  Renin-secreting tumors
  Glucocorticoid excess
Renal diseases
  Chronic pylonephritis
  Renal parenchymal disease (glomerulonephritis)
  Renovascular disease
Drugs
  Cocaine
  Amphetamines
  Clonidine and methyldopa withdrawal
  Monoamine oxidase inhibitor interactions
Central nervous system injury/trauma

Causes of hypertensive emergencies. [Brennan KJ, Goldman J, D'Alonzo GE. Hypertensive crisis. In: Criner GJ, Barnette RE, D'Alonzo GE, editors. Critical care study guide 2e [Internet]. New York, NY: Springer; 2010 [cited 2015 Jun 22].

p. 1060–75. Available from: http://link.springer.com/10.1007/978-0-387-77452-7_53] *Caption from original*

Mimics

- Anxiety
- Intoxication

Time-Dependent Interventions

- In true hypertensive emergency, rapid reduction of the blood pressure (by no more than 20 %), with accompanying treatment as needed for reflex tachycardia, is required

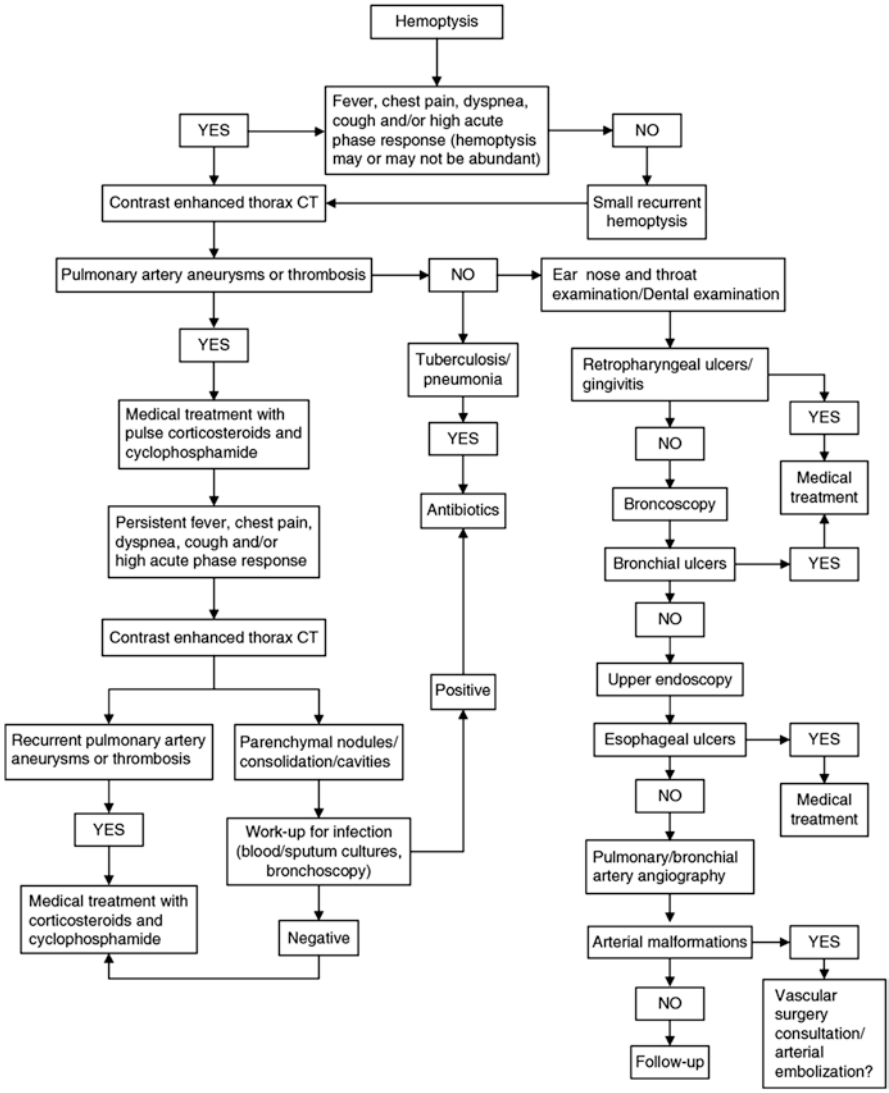
*These doses may vary from those in the Physicians Desk Reference, 51st edition.†Hypotension may occur with all agents.‡Requires special delivery system.

DRUG	DOSE	ONSET OF ACTION	DURATION OF ACTION	ADVERSE EFFECTS†	SPECIAL INDICATIONS
Vasodilators					
Sodium nitroprusside	0.25–10 μg/kg/min as IV infusion‡	Immediate	1–2 min	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; caution with high intracranial pressure or azotemia
Nicardipine hydrochloride	5–15 mg/h IV	5–10 min	15–30 min, may exceed 4 h	Tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies, except acute heart failure; caution with coronary ischemia
Fenoldopam mesylate	0.1–0.3 μg/kg/min IV infusion	< 5 min	30 min	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Nitroglycerin	5–100μg/min as IV infusion	2–5 min	5–10 min	Headache, vomiting, methemoglobinemia, tolerance with prolonged use	Coronary ischemia
Enalaprilat	1.25–5 mg every 6 h IV	15–30 min	6–12 h	Precipitous fall in pressure in high-renin states; variable response	Acute left ventricular failure; avoid in acute myocardial infarction
Hydralazine hydrochloride	10–20 mg IV	10–20 min IV	1–4 h IV	Tachycardia, flushing, headache, vomiting, aggravation of angina	Eclampsia
	10–40 mg IM	20–30 min IM	4–6 h IM		
Adrenergic inhibitors					
Labetalol hydrochloride	20–80 mg IV bolus every 10 min	5–10 min	3–6 h	Vomiting, scalp tingling, bronchoconstriction, dizziness, nausea, heart block, orthostatic hypotension	Most hypertensive emergencies, except acute heart failure
	0.5–2.0 mg/min IV infusion				
Esmolol hydrochloride	250–500μg/kg/min IV bolus	1–2 min	10–30 min	Hypotension, nausea, asthma, first-degree heart block, heart failure	Aortic dissection, perioperative
Phentolamine	5–15 mg IV bolus	1–2 min	10–30 min	Tachycardia, flushing, headache	Catecholamine excess

Parenteral drugs for treatment of hypertensive emergencies. IM—intramuscular; IV—intravenous. [Hollenberg NK. Recommendations of the JNC 7 report. In: Hollenberg NK, editor. Atlas of hypertension. 5th ed. Philadelphia, PA: Current Medicine Group; 2005. 383 p. ISBN: 1-57340-220-6] *Caption from original*

Overall Principles of Treatment

- Do not treat chronic hypertension aggressively; it may have taken years for the patient to develop hypertension; there is no physiologic reason to try to correct it in days, much less hours.
- Be alert for signs of end-organ damage in patients with acute hypertension.



Algorithm for diagnosis and management of hemoptysis due to Behçet's syndrome [Seyahi E, Tascilar K, Yazici H. Behçet's syndrome: clinical presentations affecting prognosis and survival. In: Khamashta MA, Ramos-Casals M, editors. Autoimmune

diseases [Internet]. London: Springer; 2011 [cited 2015 Jun 22]. p. 163–84. Available from: http://link.springer.com/10.1007/978-0-85729-358-9_11] *Caption from original*

Situations	Systolic blood pressure (mm Hg)	Diastolic blood pressure (mm Hg)
Uncomplicated hypertension	140	90
Elderly	140–150	90
Diabetes mellitus	140	85
Stroke	140	90
Coronary artery disease	140	90
Chronic kidney disease		
Without albuminuria[a]	140	90
With albuminuria	130	80

[a]Microalbuminuria or macroalbuminuria.

Target blood pressures in hypertension treatment. [From article: 2013 Korean Society of Hypertension guidelines for the management of hypertension. Part II—treatments of hypertension. Disease Course

- Patients with hypertension die prematurely, most often of heart disease, stroke, or renal failure
- Treatment is positively correlated with outcomes.

Chapter 37
Hypertrophic Cardiomyopathy

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Hypertrophic cardiomyopathy (HCM)

- Obstructive cardiomyopathy, idiopathic hypertrophic subaortic stenosis (IHSS)

Incidence/Epidemiology

- HCM is defined by hypertrophy of the left ventricle, usually in the absence of dilation of the chamber itself.
- At least half the cases of HCM are hereditary.
- It occurs in well under 1 % of the US population.

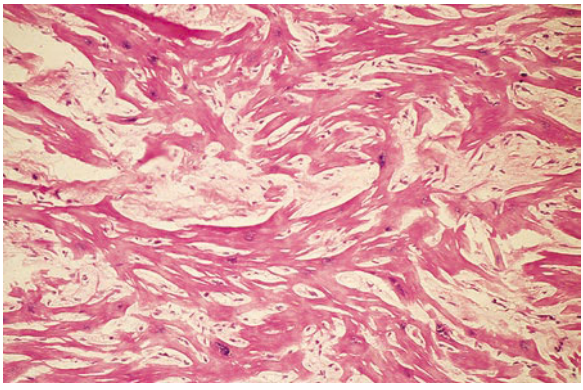
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_37

Differential Diagnosis

- The primary differential considerations for chest pain due to HCM include valvular aortic stenosis and other types of obstructive or restrictive cardiomyopathy.
- Simple left ventricular hypertrophy (LVH) may be identified on electrocardiogram or chest radiography, and is much more common than HCM. LVH is usually the result of systemic hypertension.
- The entire constellation of differential considerations for unstable angina, aortic dissection, and pulmonary embolism should be considered, and may coexist with HCM.
- HCM may also present as syncope or near-syncope, which has broad differentials, including cardiac, neurologic, metabolic, psychiatric, and toxicologic etiologies.

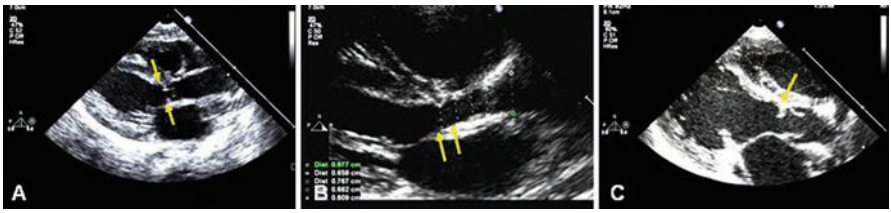
Pathophysiology and Etiology

- The hallmark of HCM is that it occurs in the absence of typical inciting factors for LVH.



Hypertrophic cardiomyopathy. Typical histologic appearance in hypertrophic cardiomyopathy. Histologically, the left ventricle in hypertrophic cardiomyopathy exhibits disarray of myofibers and often extensive interstitial fibrosis. [Saffitz J, Zimmerman F, Lindsay B. Pathology of cardiac arrhythmias. In: McManus B, Braunwald E, editors. Atlas of cardiovascular pathology for the clinician. Philadelphia: Current Medicine; 2000. Chapter 16. ISBN: 1-57340-160-9; 2002-01-21] *Caption adapted from original*

- It is often hereditary.
- Abnormal calcium metabolism in the myocardium may lie at the root of HCM. As intracellular calcium concentrations rise, the muscle hypertrophies.
- The hypertrophy is often asymmetric. As the interventricular septum hypertrophies, there is often narrowing of the LV outflow tract, resulting in "stenosis" below the aortic valve itself (hence the term *hypertrophic subaortic stenosis*). Reduction in flow may result in anginal chest pain.



Subaortic stenosis diagnosed by echocardiography. (**a)** Parasternal left ventricular long-axis sectional view showing circumferential membranous subaortic stenosis. (**b)** Parasternal left ventricular long-axis sectional view showing tunnel-type subaortic narrowing. (**c)** Parasternal left ventricular long-axis sectional view showing an asymmetric obstructive fibrous ridge at the interventricular septum side of the left ventricular outflow tract below the aortic valve. [Ma X, Huang G, Liang X, Liu X, Jia B. Atypical Shone's complex diagnosed by echocardiography. Pediatr Cardiol. 2011 Apr;32(4):442-8. https://doi.org/10.1007/s00246-011-9886-y; 2011-03-19] *Caption from original*

Presentation

Typical/"Classic"

- Many patients with HCM are asymptomatic, and the diagnosis is discovered incidentally on imaging studies.
- Symptomatic patients may present with:
  - Dyspnea, the most common presentation of symptomatic HCM, probably occurs because stiffness of the LV walls limits LV filling.
  - Anginal chest pain, thought to be due to inadequate cardiac output for the level of the patient's exertion.
  - Sudden cardiac death, usually due to ventricular fibrillation.
  - Syncope ("black-outs") and near-syncope ("gray-outs"), due to inadequate cardiac output for the level of the patient's exertion.
  - Palpitations, due to both ventricular and atrial ectopic beats.

Atypical

- Anginal chest pain (especially with dyspnea) and sudden cardiac death often present without known antecedent. These presentations may distract the clinician from the potential diagnosis of HCM.
- Syncope and near-syncope, especially in younger patients, have a broad differential and may often have a component of anxiety. This should not distract the clinician from completing a thorough cardiovascular examination.

Primary Differential Considerations

- In the patient presenting with signs and symptoms of HCM, early consideration should also be given to the following differential diagnoses:
  - Valvular aortic stenosis
  - Restrictive cardiomyopathy

History and Physical Exam

Findings That Confirm Diagnosis

- History and physical examination are not diagnostic for HCM.

Factors That Suggest Diagnosis

- A family history of known HCM is helpful.
- Confirming that symptoms are related to exertion (especially chest pain, palpitations, dyspnea, and syncope/near-syncope) is helpful.
- A fourth heart sound (S4) is often present.

https://www.youtube.com/watch?v=r-HqK7NRL8I
Video about the fourth heart sound

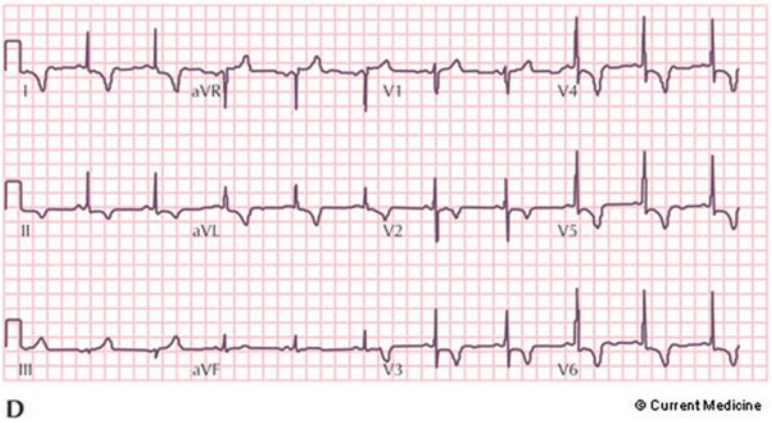
- A harsh, crescendo-decrescendo systolic murmur, heard best at the apex and lower left sternal border.

https://www.youtube.com/watch?v=2OK4-vWRlWo
Systolic Murmur video with color flow Doppler

- Mitral regurgitation is common in HCM, so the murmur may sound more blowing in nature.

https://www.youtube.com/watch?v=k3ubxo-JATU
Mitral regurgitation video providing sound and depiction of anatomy

- A double carotid pulse (pulsus bisferiens) is common.
- The 12-lead ECG shows LVH.



Echocardiogram of apical hypertrophic cardiomyopathy. Apical HCM is often associated with giant negative T waves on ECG, present in the lateral precordial leads (D). [Ho C, Maron B. Hypertrophic cardiomyopathy. In: Solomon SD, Braunwald E, editors. Atlas of echocardiography. Philadelphia: Current Medicine; 2008. Chapter 13. ISBN: 1-57340-217-6; 2008-10-22;] *Caption adapted from original*

Factors That Exclude Diagnosis

- There are no history or physical findings that conclusively exclude HCM.

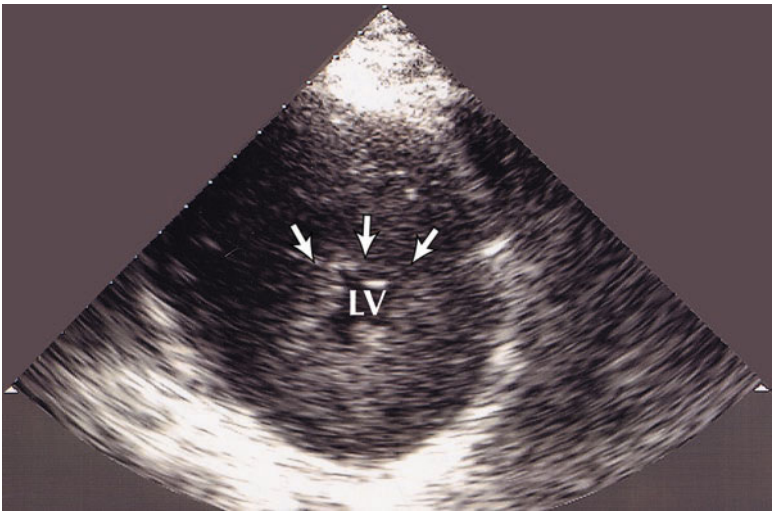
Ancillary Studies

Laboratory

- There are no diagnostic laboratory studies for HCM.

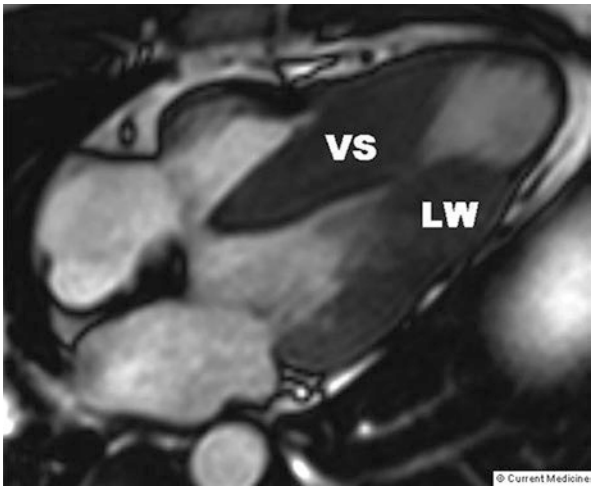
Imaging

- The diagnosis of HCM is confirmed on 2D echocardiography.



Hypertrophic cardiomyopathy. [Reimold S, Lee R. Echocardiography in acquired heart disease. In: Lee R, Braunwald E, editors. Atlas of cardiac imaging. Philadelphia: Current Medicine; 1998. Chapter 1. ISBN: 0-443-07567-0; 2002-01-23; Braunwald, Eugene]

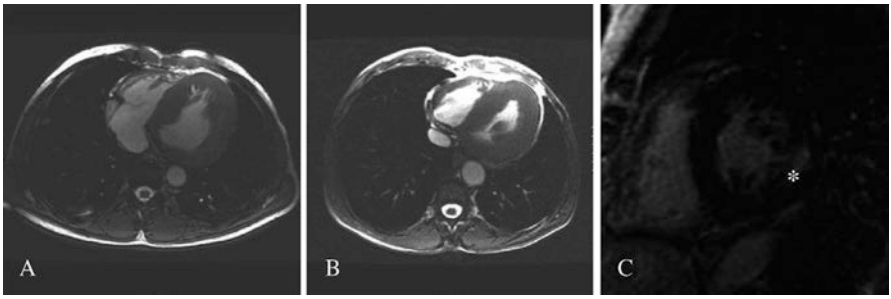
- Cardiac MRI also demonstrates HCM.



Cardiac MRI: hypertrophic cardiomyopathy with left ventricular aneurysm. Hypertrophic cardiomyopathy (HCM) patients with left ventricular (LV) apical

aneurysm represent an important but fairly uncommon subgroup of the HCM disease spectrum. HCM patients with apical aneurysms also commonly demonstrate midventricular obstruction because of midsystolic apposition of the hypertrophied ventricular septum (VS) and LV free wall. It was proposed that long-standing increased LV systolic pressures created by midventricular obstruction may contribute to apical aneurysmal formation in select susceptible HCM patients in the absence of coronary artery disease. A, HCM patient with an LV apical aneurysm and characteristic midventricular hypertrophy with apposition to the septum and LV free wall in midsystole, creating midventricular obstruction. [Maron M. Dilated cardiomyopathy. In: Manning WJ, Braunwald E, editors. Atlas of cardiovascular magnetic resonance. Philadelphia: Current Medicine; 2009. Chapter 13. ISBN: 978-1-57340-299-6; 2009-01-16] *Caption from original*

- If cardiac catheterization is performed (perhaps in the evaluation of anginal chest pain), HCM may be detected as an elevated LV diastolic pressure.



Cardiac MRI for the assessment of left ventricular hypertrophy and fibrosis: A: Left ventricular hypertrophy in a 51-year-old male patient with cerebrovascular involvement and end stage renal disease (dialysis). B: Hypertrophic cardiomyopathy in a 56-year-old male patient with arrythmya, leukoareiosis and kidney transplant. C: Late enhancement after gadolinium in a 63-year-old female patient with end stage renal disease (dialysis). [From article: Fabry disease. Orphanet J Rare Dis. 2010 Nov;5(1):30. https://doi.org/10.1186/1750-1172-5-30, at http://link.springer.com/article/10.1186/1750-1172-5-30; by Dominique P Germain, © Germain; licensee BioMed Central Ltd. 2010; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

Special Populations

Age and Gender

- HCM occurs slightly more often in males than in females.
- In females, HCM often presents at a younger age and tends to be more symptomatic.

- HCM is most commonly diagnosed in either the first or the third decade of life.
- HCM may present in infancy, but most pediatric cases present during the growth spurt associated with the onset of puberty.
- When it occurs in younger patients, it is most common for LVH to develop during the pubertal growth spurt.
- Wall thickness measurements generally do not change once adulthood is reached.

Co-morbidities

- A hereditary pattern is seen in about half the cases of HCM, but there are no typical co-morbidities.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step. Echocardiography is required to confirm the diagnosis.

Mimics

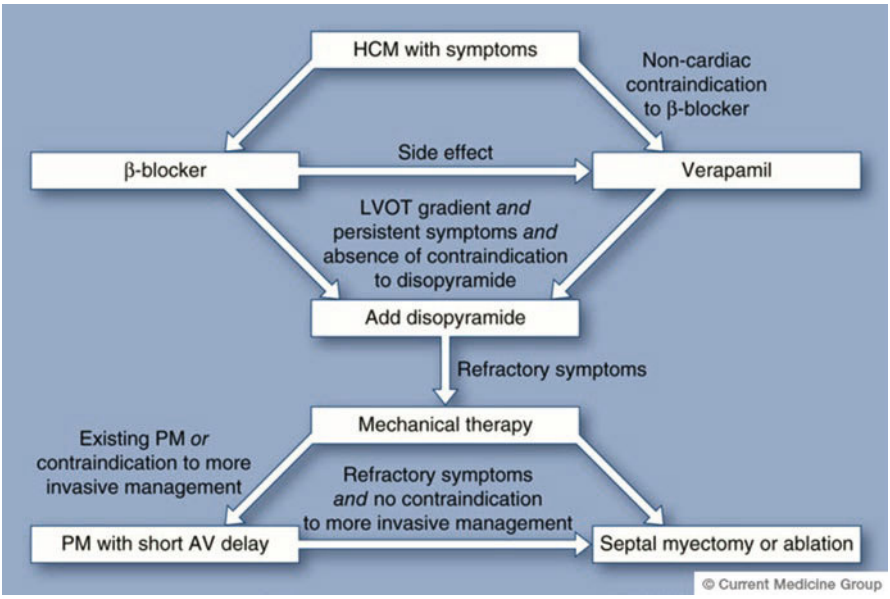
- The entire constellation of diagnoses that underlies chest pain syndrome, especially those often accompanied by dyspnea, can mimic the pain and overall presentation of HCM.
- Sudden cardiac death may mimic or be a presentation of HCM.
- Syncope or near-syncope may mimic or be a presentation of HCM.

Time-Dependent Interventions

- There are usually no time-dependent interventions in the management of HCM, unless the presentation is dramatic (angina, heart failure, arrhythmia/sudden death).

Overall Principles of Treatment

- Treatment of HCM is multimodal, with abstention from strenuous activities, beta-blockers, and calcium blockers often being used in maintenance care.



Treatment algorithm for hypertrophic cardiomyopathy. Proposed algorithm for the medical, mechanical, and surgical/interventional ablative treatment of patients with hypertrophic cardiomyopathy. Only 20% to 30% of patients with hypertrophic cardiomyopathy have outflow obstruction and would be candidates for the addition of disopyramide pacemaker therapy, or septal ablation [15]. AV—atrial ventricular; HCM—hypertrophic cardiomyopathy; LVOT—left ventricular outflow tract; PM—pacemaker. [Baughman K. Cardiomyopathy, myocarditis, and pericardial disease. In Libby P, editor. Essential atlas of cardiovascular disease. Philadelphia: Current Medicine; 2009. Chapter 6. ISBN: 978-1-57340-309-2; 2009-05-21;] *Caption from original*

Disease Course

- HCM may improve or stabilize over time.
- The risk of sudden cardiac death is always present and, even in less symptomatic patients, is justification for limited strenuous/athletic activities.
- There are limited surgical options for severe cases.

Chapter 38
Idiopathic Pulmonary Fibrosis

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Idiopathic Pulmonary Fibrosis (IPF)

- Cryptogenic Fibrosing Alveolitis

Incidence/Epidemiology

- IPF is the most common interstitial lung disease (ILD). It accounts for 25–35 % of all diagnoses of ILD.
- The diagnosis usually is not considered in those under 40.
- It is typically seen in those over 55 years of age.

Differential Diagnosis

- The differential diagnosis of IPF is broad and includes all the diagnoses encompassing the ILDs, of which there are more than 200.

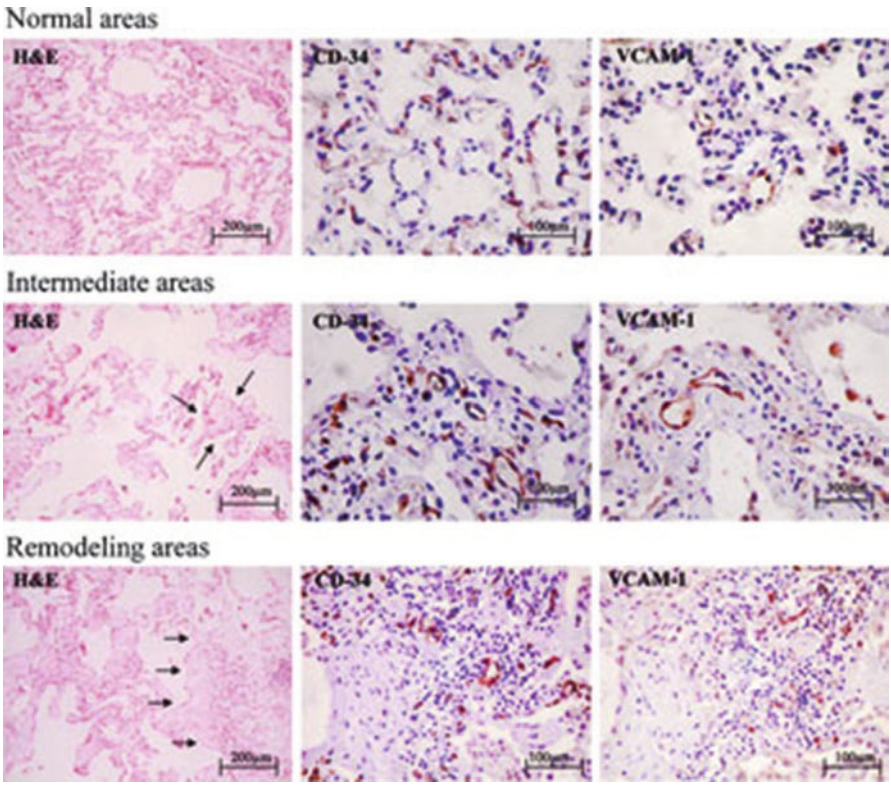
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_38

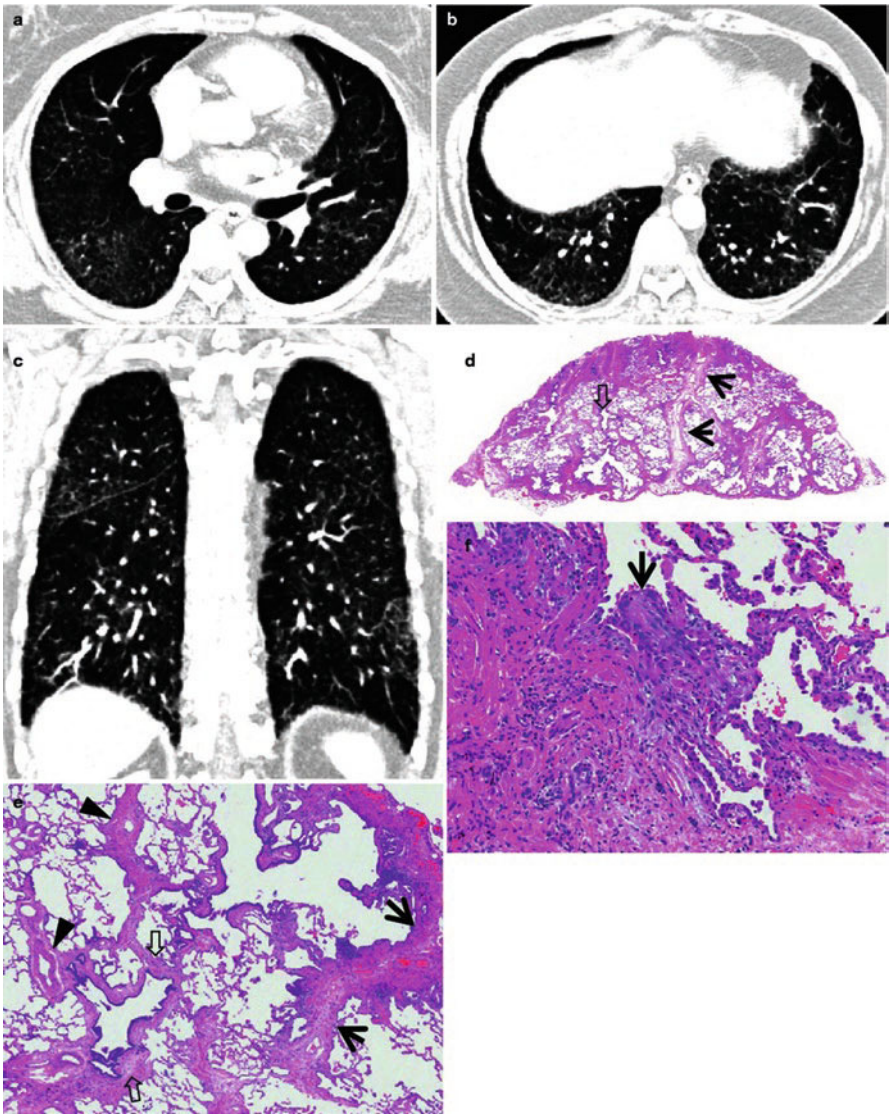
- The differential also includes all the causes of chronic dyspnea and cough, especially chronic obstructive pulmonary disease (COPD) and congestive heart failure (CHF).

Pathophysiology and Etiology

- IPF is a chronic, progressive disease of the lower respiratory tract; so far, no precipitating cause has been identified.
- It is predominately a fibrotic disease, with abnormal fibroblast proliferation and abnormal collagen metabolism.
- Chronic inflammation, once thought to play a role in the pathogenesis, is now known to be less important than fibrosis in the pathophysiology of IPF. When biopsies are performed for diagnosis, there often is little inflammation present.
- The classic histologic pattern is termed *usual interstitial pneumonia* (UIP). Although UIP is not pathognomonic to IPF, it may be seen in other lung diseases marked by fibrosis, such as diseases associated with connective tissue disorders, chronic hypersensitivity pneumonitis, and asbestosis.
- UIP is characterized by the presence of "honeycomb cysts." These are subpleural, cystic airspaces in which there are an abnormal proliferation of mesenchymal cells, varying degrees of fibrosis, and overproduction and disorganized deposition of collagen and extracellular matrix.
- Another characteristic feature of UIP is the presence of fibroblast foci, clusters of fibroblasts and myofibroblasts found next to areas of established fibrosis. The presence and number of fibroblastic foci correlate with disease severity and mortality.



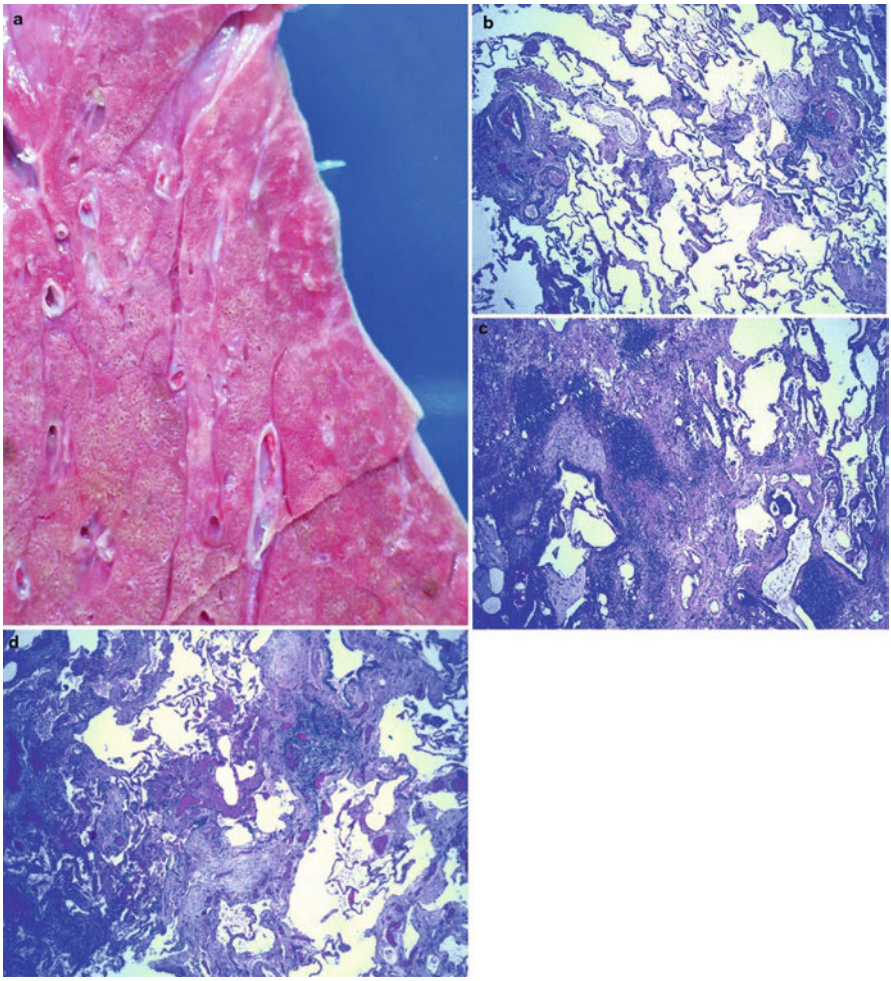
UIP (usual interstitial pneumonia) lungs showing nonhomogeneous CD34-positive and VCAM-1-positive immunostaining in alveolar capillaries. In normal parenchyma areas (H&E) (×100), a diffuse decrease of CD34 immunolocalization and endothelial cells of increased capillaries strongly immunoreactive with VCAM-1 can be appreciated (×200). Collapsed and mural organizing fibrosis areas present in UIP are shown at H&E staining (×100). In a high magnification of the area with arrows, CD34 decreases gradually toward more severe mural fibrosis. In contrast, increased VCAM-1 is shown in inflammatory septal thickening (nonorganizing fibrosis) and mural organizing fibrosis areas (200). [Parra ER, da Costa LRS, Ab'Saber A, de Carvalho CRR, Kairalla RA, Fernezlian SM, Teixeira LR, Capelozzi VL. Nonhomogeneous density of CD34 and VCAM-1 alveolar capillaries in major types of idiopathic interstitial pneumonia. Lung. 2005 Oct;183(5):363–73.] *Caption from original*

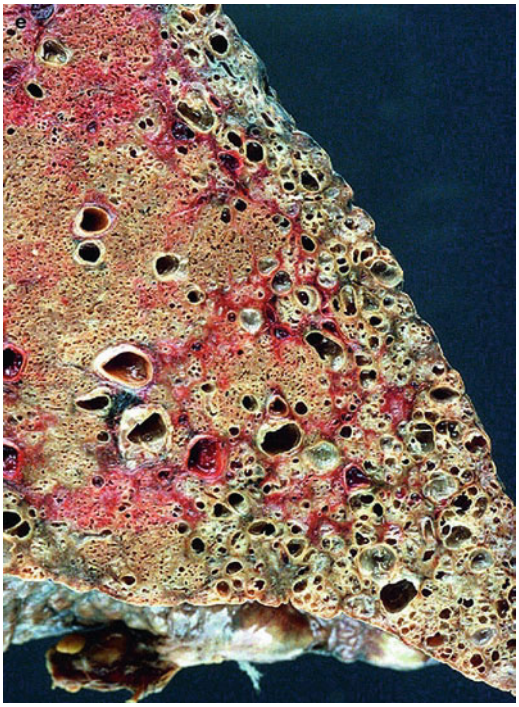


Interstitial fibrosis of usual interstitial pneumonia pattern in a 59-year-old woman with progressive systemic sclerosis. (a, b) Lung window of CT scans (3.0-mm section thickness) obtained at levels of bronchus intermedius (a) and liver dome (b), respectively, show patchy and extensive areas of reticulation and ground-glass opacity in both lungs. (c) Coronal reformatted image (3.0-mm section thickness) demonstrate similar pattern of reticulation and ground-glass opacity extensively in both lungs. (d) Low-magnification (×4) photomicrograph of surgical lung biopsy specimen obtained from right lower lobe exhibits dense fibrosis along interlobular septum

(arrows) and around bronchiole (open arrow). (e) High-magnification (×100) photomicrograph depicts dense fibrosis in interlobular septum (arrows) and around bronchiole (open arrows). Also note thick fibrotic vessel wall (arrowheads). (f) High-magnification (×200) photomicrograph discloses area of focal active fibrosis (arrow) [Lee KS, Han J, Chung MP, Jeong YJ. *Radiology illustrated: chest radiology [Internet]. Berlin, Heidelberg: Springer; 2014. Chapter 28,* Interstitial *lung disease in collagen vascular disease;* [cited 2015 Aug 21]*;* p. 275–83. Available from: http://link.springer.com/10.1007/978-3-642-37096-0_28] *Caption from original*

- The end result is an abnormal fibrotic response within the lung that distorts and destroys lung tissue from the pleura into the lung parenchyma.





Idiopathic pulmonary fibrosis (interstitial lung disease, idiopathic interstitial pneumonias) with varying alveolar and interstitial inflammatory infiltrates, progressive interstitial fibrosis, secondary hypertensive vascular disease, and a final stage with honeycombing of the lungs. Note the fleshy gross appearance of the lungs in earlier stages (a), with various microscopic interstitial infiltrates (b–d) and gross honeycombing at the end stage (e). [Krueger GRF, Wagner M, Oldham SAA. Pathology of the respiratory tract. In: Krueger GRF, Buja LM, Chandrasekhar C, editors. Atlas of anatomic pathology with imaging [Internet]. London: Springer; 2013 [cited 2015 May 28]. p. 105–89. Available from: http://link.springer.com/10.1007/978-1-4471-2846-5_3] *Caption adapted from original*

- Causative factors currently are unknown.
- There are, however, some known risk factors, including:
    - Cigarette smoking
    - Viral infection
    - Environmental pollutants
    - Chronic aspiration
    - Genetic predisposition
    - Drugs
- None of these risk factors can explain the pathogenesis of IPF. It is felt that these risks precipitate the process in those who are susceptible.

- Several mutations have been found that may increase the risk. These mutations have been identified in both sporadic cases and in familial clusters. They include mutations of surfactant proteins, gel-forming mucin, and telomerase.

Presentation

Typical/"Classic"

- The typical presentation is chronic cough with progressive dyspnea associated with decreased lung function, as measured by a decrease in the forced vital capacity in one second (FVC1) and a decrease in the diffusing capacity to carbon monoxide (DLCO).
- High-resolution CT scan (HRCT) of the lungs will reveal typical findings of UIP, including:
  - Reticular opacities in a peripheral and basal lung distribution
  - Traction bronchiectasis
  - Honeycombing (clustered, abnormal, enlarged airspaces 3 to 10 mm in diameter) in subpleural distribution
  - Ground-glass opacities may be present but usually are less extensive than reticular opacities.
- A thorough search must be undertaken for other contributing factors that may lead to an alternative diagnosis. This includes a search for asbestos exposure, hypersensitivity pneumonitis, systemic sclerosis, and rheumatoid arthritis.

Atypical

- Some patients may present with a typical clinical syndrome of chronic cough, dyspnea, and decreased lung function but have atypical findings on HRCT. In this situation, it may be necessary to proceed to lung biopsy for a confirmation of the diagnosis.
- Patients may present with more focus on either the cough or dyspnea, but both usually are present.

Primary Differential Considerations

- In patients presenting with signs and symptoms suggesting IPF, other diagnoses warranting early consideration include:

- Acute and chronic pneumonias
- "Exposure" lung disease such as asbestosis, farmer's lung, coal worker's lung, and tobacco worker's lung
- Fungal disease such as histoplasmosis

History and Physical Exam

Findings That Confirm Diagnosis

- A full classic presentation with chronic cough, chronic progressive dyspnea, and decreased lung function, with the usual findings of UIP on HRCT, usually confirms the diagnosis.
- However, no historical or physical exam findings are pathognomonic for IPF. For example, digital clubbing is present in only 30 % of patients with IPF.

An example of digital clubbing. [Siddiqui M, Melia MT. Clinical image: clubbed with a reminder to test for HIV. J Gen Intern Med. 2014 Sep;29(9):1308–1308.] *Caption adapted from original.*

Factors That Suggest Diagnosis

- The diagnosis should be considered in any person with chronic cough and dyspnea, especially if he or she is over 55 years of age and no other causes for the cough and dyspnea are easily identified.
- On lung exam, patients often have bilateral basilar (sometimes diffuse) "dry" crackles, although this finding is not specific to IPF.

  http://en.wikipedia.org/wiki/File:IPF_Lung_Sound.ogg

Dry or "Velcro" crackles in a patient with IPF. [File:IPF Lung Sound.ogg [Internet]. Wikipedia, the free encyclopedia. [cited 2015 Jun 11]. Available from: http://en.wikipedia.org/wiki/File:IPF_Lung_Sound.ogg; licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license.]

Factors That Exclude Diagnosis

- It is difficult to completely exclude the diagnosis with either historical or physical exam findings. However, if another easily identified cause for the symptoms is found, the diagnosis becomes less likely.

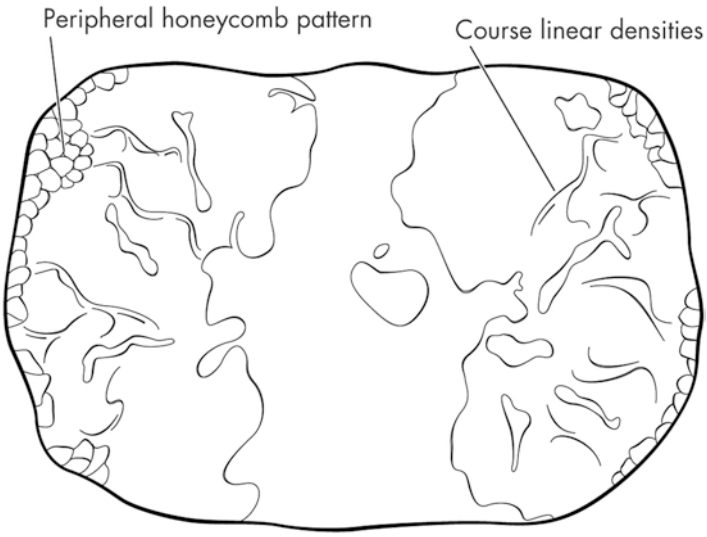
Ancillary Studies

Laboratory

- Laboratory studies are not useful in the diagnosis and confirmation of IPF, but they are helpful in seeking alternative and complicating diagnoses.
- It is useful to check laboratory studies to evaluate for abnormalities such as significant anemia, infectious issues (leukocytosis, eosinophilia, etc.), rheumatologic disorders (rheumatoid arthritis, systemic sclerosis), cardiac issues (such as brain natriuretic peptide for CHF), and other alternative and complicating diagnoses.

Imaging

- Imaging is a necessary part of the evaluation of patients with suspected IPF, indeed for any suspected ILD.
- Nearly all patients with unexplained chronic cough and dyspnea will require HRCT of the lungs as part of their diagnostic evaluation.
- HRCT showing the typical changes of UIP (peripheral and basal reticular opacities, traction bronchiectasis, honeycombing) in a patient with chronic cough and dyspnea associated with decreased lung function is nearly diagnostic of IPF, as long as alternative diagnoses (e.g., asbestos exposure, hypersensitivity pneumonitis, systemic sclerosis, and rheumatoid arthritis) have been considered and excluded.



Schematic representation of chest computed tomography in IPF, showing coarse linear densities and a peripheral honeycomb pattern. [Smith M, Grichnik K. Anesthetic considerations for lung transplant and thoracic aortic surgery. In: Reves JG, editor. Cardiothoracic anesthesia. Philadelphia: Current Medicine; 1999. (Miller RD, editor. Idiopathic pulmonary fibrosis. HRCT at the level of the lower lobes shows a subpleural "reticular pattern" characterized by thickened interlobular septae, thickened intralobular interstitium, traction bronchiolectasis and bronchiectasis and

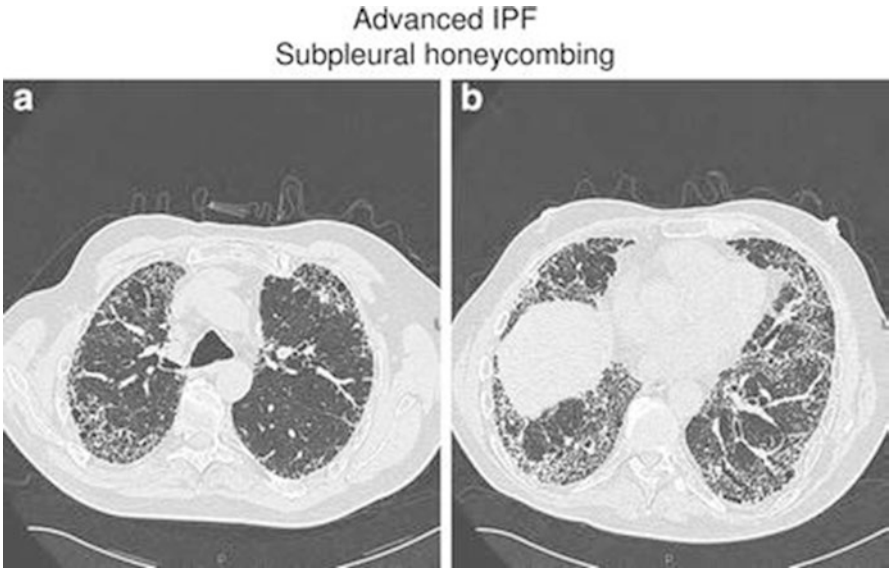
minimal honeycombing. [From article: Mimics in chest disease: interstitial opacities. Insights into Imaging. 2013 Feb;4(1):9–27; https://doi.org/10.1007/s13244-012-0207-7, at http://link.springer.com/article/10.1007%2Fs13244-012-0207-7/fulltext.html; by Anastasia Oikonomou, Panos Prassopoulos, © The Author(s) 2012; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

- HRCT also is helpful in staging the severity of the disease.
- HRCT and chest x-ray also are helpful during periods of acute exacerbation to help identify and exclude complicating and alternative diagnoses and causes for the worsening dyspnea, as well as to evaluate new and advancing changes of UIP.



Patient with idiopathic pulmonary fibrosis. Subpleural honeycombing is identified. Disease is more extensive at the base of the lung (b) than in mid lung (a). [Baughman R, Pirozynski M. Health effects of nanoparticles (inhalation) from medical point of view/type of diseases. In: Marijnissen JC, Gradon L, editors. Nanoparticles in medicine and environment [Internet]. Dordrecht: Springer; 2010 [cited 2015 Jun 11]. p. 187–202. Available from: http://www.springerlink.com/index/10.1007/978-90-481-2632-3_10] *Caption from original*

Lung Biopsy

- Lung biopsy may be necessary when the findings on HRCT are equivocal. Transbronchial biopsy is not recommended, as the specimen usually is too small for examination. The usual approach is video-assisted thoracoscopic or open surgical biopsy.

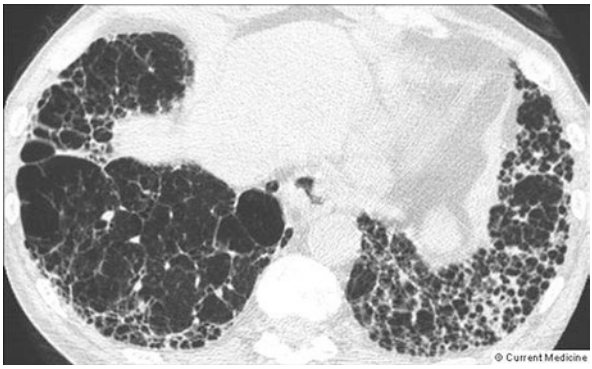
Special Populations

Age

- IPF is a disease of middle-aged and older adults. It is typically diagnosed after age 55 and usually is not even considered a diagnostic possibility before age 40.

Co-morbidities

- Important co-morbid conditions to consider include all diseases and conditions that may worsen dyspnea and accelerate the course of IPF. Most importantly, given the population most at risk for IPF (older than 50), both COPD and CHF are important diseases to consider. However, any condition that may worsen dyspnea (e.g., anemia, coronary vascular disease, pneumonia, lung cancer, pulmonary embolism (PE), pneumothorax) must be considered in the evaluation of both newly diagnosed IPF and IPF exacerbations.
- Gastroesophageal reflux disease (GERD) is an important co-morbid condition to consider in patients diagnosed with IPF. Up to 90 % of patients with IPF also have GERD. Treatment of GERD in those with IPF has been associated with a decrease in the radiographic findings of IPF and may even be associated with improved survival.
- Pulmonary hypertension. Development of pulmonary hypertension is relatively common in patients with IPF, especially as the disease advances, and is a poor prognostic sign.



Emphysema associated with idiopathic pulmonary fibrosis in a heavy smoker. Axial thin slices of the chest, showing advanced emphysema predominantly distributed in the upper lobes. Honeycombing, as typically present in usual interstitial pneumonia-idiopathic pulmonary fibrosis, involves the subpleural regions of the lung bases. It is identified as clustered, cystic airspaces usually measuring 2 mm to 10 mm in diameter and having well-defined walls. The cysts appear to share walls and occur in several layers. [Grenier P, Beigelman-Aubry C. Radiologic phenotypes of COPD. In: Crapo JD, editor. Atlas of chronic obstructive pulmonary disease. Philadelphia: Current Medicine; 2009. ISBN: 978-1-57340-294-1] *Caption adapted from original*

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step, next is establishing the diagnosis.
- More than 200 diseases encompass the diagnosis of ILD. Many of them have more and better treatment options than currently exist for IPF, so an accurate diagnosis is important for the patient to obtain the best available information about treatment and prognosis.

Mimics

- The diagnosis category of ILD includes more than 200 different diseases, many of which present similarly to IPF, with chronic cough, dyspnea, and decreased lung function.

- In addition, several other diseases may have a similar clinical syndrome and show signs of UIP on HRCT, including asbestosis, hypersensitivity pneumonitis, and lung disease associated with systemic sclerosis and rheumatoid arthritis.

Time-Dependent Interventions

- There are no time-dependent interventions in most cases of IPF. The disease is chronic and progressive.
- As with all diseases that cause dyspnea, hypoxemia must be promptly and aggressively treated and avoided.
- In the setting of an acute exacerbation of IPF, it is important and somewhat time sensitive to evaluate and rule out the presence of an emergent complication such as acute coronary syndrome, CHF, PE, pneumothorax, or infection.

Overall Principles of Treatment

- The treatment of IPF has been changing dramatically during the past several years. In 2014, the US Food and Drug Administration approved two new agents: pirfenidone and nintedanib. In clinical trials, both drugs slowed the progression of disease, and they may even confer a mortality benefit.
- In the past, many different anti-inflammatory treatments were attempted, most without success. This is not surprising considering the pathophysiology of IPF, in which biopsy samples show progressive fibrosis with little to no inflammation.
- Treatment has been mostly supportive, including:
  - Patient education
  - Oxygen therapy if hypoxemia is present
  - Pulmonary rehabilitation
  - Appropriate vaccination
  - Identification and treatment of all co-morbidities
  - Prevention and treatment of GERD
  - Lung transplantation as the disease progresses
- Pirfenidone is an antifibrotic agent that inhibits transforming growth factor-β (TGF-β). TGF-β stimulates collagen synthesis as well as fibroblast proliferation; therefore, blocking this protein decreases the extracellular matrix and fibroblast proliferation, two of the major pathophysiologic mechanisms of IPF. Side effects may include rash, photosensitivity, nausea, diarrhea, abdominal discomfort, anorexia, fatigue, and elevation in liver function tests (LFTs). It is recommended that LFTs be checked before and during treatment.

- Nintedanib is a monoclonal antibody that blocks multiple tyrosine kinase receptors. Tyrosine kinases are known to stimulate production of multiple fibrogenic growth factors. As with pirfenidone, this agent may cause LFT elevations; therefore, liver tests should be performed before and during treatment. Nintedanib also may increase the risk of bleeding from anticoagulation. Other common adverse effects include diarrhea, nausea, and vomiting.
- In severe cases complicated by pulmonary hypertension, some authorities add phosphodiesterase inhibitors (or other vasodilators) to the treatment regimen. These agents, however, are used primarily to treat pulmonary hypertension; their use in IPF is under study.
- Currently, IPF is the second most frequent diagnosis for which lung transplantation is performed. Because IPF is a chronically progressive disease associated with numerous co-morbidities, it generally is believed that lung transplantation is better and more safely performed earlier in the course of the illness.

Disease Course

- IPF is a relentlessly progressive disease. All patients have progression; no spontaneous remissions have been reported.
- The overall prognosis is poor, with a 5-year mortality rate of about 75 %.
- Multiple factors are associated with more rapidly progressive disease and shortened survival:
    - Older age at diagnosis
    - History of prolonged tobacco use
    - Lower weight
    - More severe disease at diagnosis
    - The presence of a co-morbid condition that may worsen and complicate the clinical course of IPF, such as COPD, CHF, pulmonary hypertension, coronary artery disease, or lung cancer.
- At the time of diagnosis, it is important to try to pinpoint the severity of the disease.
- Currently no validated staging system exists for IPF; its classification is based mainly on clinical grounds, including symptoms, pulmonary function test (PFT) findings, and results of HRCT.
- A typical assessment of severity is based on the following guidelines:
    - Mild or early disease
        - Patient may be asymptomatic or have only a mild cough.
        - Patient may have dyspnea on exertion (DOE), but it may be mild and unnoticed or thought to be related to some other cause.
        - Radiographic changes (reticular opacities and honeycombing) typically involve less than 10 % of the lungs.

    - PFTs may be normal or demonstrate only mild decreases in FVC1 and DLCO.
  - Moderate disease
    - Cough and DOE are more pronounced and noticeable.
    - Radiographic changes involve 20–30 % of the lungs.
    - On PFTs, the FVC1 is 50–70 % predicted and DLCO is about 50 % predicted.
  - Severe/advanced disease
    - DOE is severe; patient cannot climb one flight of stairs without stopping to rest.
    - Patient usually requires supplemental oxygen.
    - Extensive honeycombing is seen on HRCT.
    - FVC1 and DLCO are less than 50 % predicted.
- Acute exacerbations of IPF. The clinical course of IPF may be complicated by acute exacerbations in up to 60 % of patients. The term *exacerbation* is somewhat misleading, as patients often do not return to their "pre-exacerbation" level of functioning. These acute exacerbations also are known as *accelerated phases of rapid clinical deterioration*. They are associated with a poor prognosis, with in-hospital mortality approaching 80 %. Recurrences are common.
  - Accepted definition of an acute exacerbation of IPF includes:
    - Known diagnosis of IPF
    - An unexplained worsening of dyspnea within the past 30 days
    - HRCT demonstrating new bilateral ground-glass opacities and/or consolidation on a background of UIP (honeycombing and reticular opacities)
    - No evidence of pulmonary infection by endotracheal aspirate or bronchoalveolar lavage
    - The exclusion of alternative causes of worsened dyspnea, especially pneumonia, heart failure, PE, and pneumothorax
  - Treatment usually involves the administration of antibiotics for presumed superinfection and glucocorticoids for acute inflammation; however, there is no evidence that either of these agents is helpful.

Chapter 39
Infective Endocarditis

Christopher J. Rees, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Infective Endocarditis

Incidence/Epidemiology

- Infective endocarditis (IE) has an estimated annual incidence of between 3 to 9 cases per 100,000 people per year in developed nations. Incidence rates can vary widely based upon predisposing conditions, risk factors, and geographic area.
- Predisposing conditions include the presence of a prosthetic heart valve, the presence of an intracardiac device, unrepaired cyanotic congenital heart disease, a prior history of infective endocarditis, chronic rheumatic heart disease, age-related degenerative valvular lesions, hemodialysis, diabetes, HIV infections, and intravenous drug use, dental infections, and poor dental hygiene. Age greater than 65 and male sex are also risk factors for IE.
- Rheumatic heart disease is now an uncommon cause of IE in developed nations, but remains a significant cause of IE in developing nations.
- Incidence has been increasing among and shifting toward those greater than 65 years old.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_39

- Increasing proportions (up to one-third) of cases of IE are now health-care associated.
- The male-to-female ratio is about 2:1.
- About 10,000–15,000 cases per year are diagnosed in the United States.

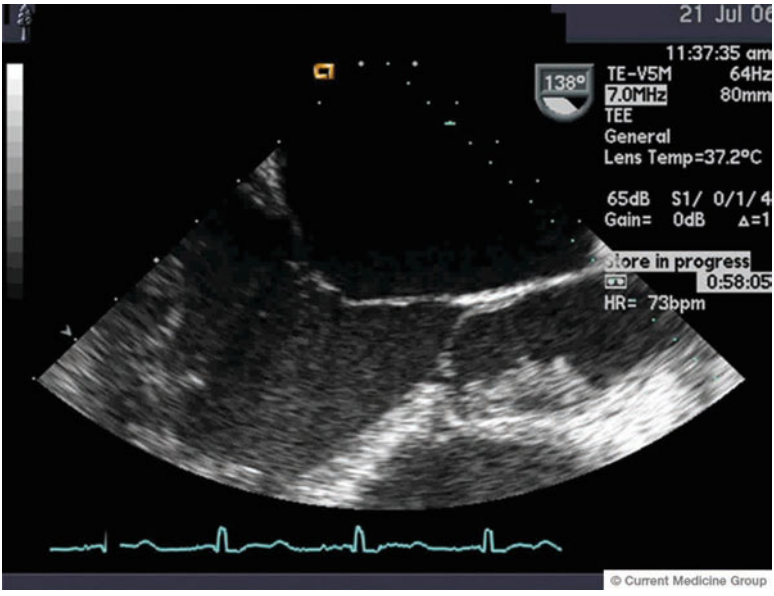
Differential Diagnosis

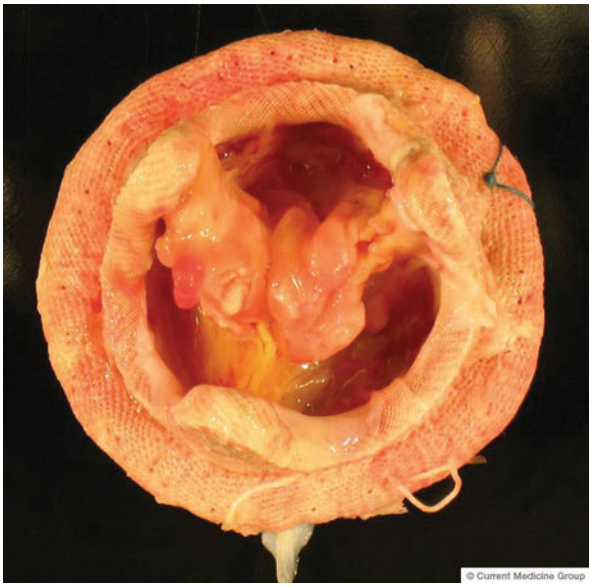
- The differential diagnosis for IE is exceptionally broad, and a high index of suspicion needs to be maintained.
  - Many diseases can present with fever and diffuse/multi-organ symptoms, including many infections, vasculitides, connective tissue diseases, and malignant diseases.
  - Many diseases can be associated with bacteremia, such as skin and soft tissue infections, osteomyelitis, pneumonia, meningitis, and others. All patients with bacteremia, even if there is an associated cause as above, should have an evaluation for valvular vegetations with echocardiography, as all causes of bacteremia can coexist with IE, and many are known predisposing factors for IE or complications of IE.

Pathophysiology and Etiology

- The majority of cases of endocarditis (80 %) are caused by Streptococci and Staphylococci.
- Staphylococci are the most frequent cause of health-care associated IE.
- Ten percent of cases of IE are blood culture negative. This generally results from either exposure to antibiotics prior to the diagnosis of IE, or when IE is due to slow-growing, fastidious organisms.
  - These slow-growing, fastidious organisms include bartonella species, brucella species, Coxiella burnetii, Tropheryma whippelii, and bacteria in the HACEK group. The HACEK group of organisms includes haemophilus species, Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, and Kingella kingae.
- The classic model of the pathogenesis of native-valve infectious endocarditis involves valvular endothelial damage that allows colonization by bacteria.
  - Endothelial damage may result from turbulent blood flow around the valve, direct trauma from the repeated injection of particulate contaminants in those who inject intravenous drugs, or by direct trauma from electrodes or catheters used during cardiac procedures.

- The bacteria that are most likely to cause IE often have specific adherence factors that facilitate their adherence and formation of vegetations.
- Vegetations are the characteristic pathologic lesions of IE. They are a mass of platelets, fibrin, organisms, and inflammatory cells that adhere to damaged endothelium or myocardium. Vegetations are most commonly found on heart valves, but can also attach to any area of myocardial damage or scarring, such as an atrial septal defect, ventricular septal defect, or endocardium damaged by foreign bodies (pacemakers, automatic implantable cardiac defibrillators [AICD]).





Infective endocarditis. **A**, Large, multilobulated vegetation on the anterior leaflet of the mitral valve from a patient with *Staphylococcus lugdunensis* endocarditis who died of a rupture mycotic cerebral aneurysm. **B**, Transesophageal echocardiographic image showing a cluster of vegetative material adherent to and above the anterior leaflet of the aortic valve. TEE is more sensitive than transthoracic echocardiogram (TTE) for the detection and characterization of vegetation and abscess in patients with suspected infective endocarditis. **C**, Gross operative specimen from a patient with prosthetic valve endocarditis affecting the valve leaflets, but sparing the sewing ring. [O'Gara P. Chapter 9. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009. 432 p.] *Caption adapted from original*

- Chronic inflammation of valvular tissue can also lead to endothelial damage and bacterial colonization. This is the case in rheumatic heart disease and degenerative valve disease.
- Several microorganisms are felt to cause endocarditis from a maladaptive host immune response. C. burnetii, bartonella species, and T. Whippelii are all intracellular pathogens, and when they infect valvular tissue they can cause a host immune response that can damage valvular tissue.

Presentation

Typical/"Classic"

- The classic presentation is a patient with a known predisposing factor with a fever and a new or worsened murmur.
- Fever is the most common symptom. It is present in up to 80 % of patients.
- The majority of patients will have one of the predisposing conditions noted in the etiology section.
- About half of all patients will have new murmur; about a quarter will have worsening of a known prior murmur.
- There is usually no other obvious source for the fever.

Atypical

- Infective endocarditis frequently presents atypically, especially early in the course of the disease.
- Symptoms may be non-specific, and the diagnosis may not be considered until there is fever or a complication secondary to IE.
- Patients may initially present with a complication of IE, especially from embolic infected vegetations. These complications include:
  - Pulmonary embolism, pneumonia, or pulmonary abscess from septic pulmonary emboli.
  - Stroke (both ischemic and hemorrhagic), TIA, brain abscess, and meningitis.
  - Renal failure.
  - Peripheral arterial occlusion.
  - Sepsis.
- IE caused by S. aureus, especially involving the mitral valve, is the most common cause of systemic embolic complications.
- It is important to know that embolic complications (for example, septic pulmonary emboli, cerebrovascular emboli) can occur before the diagnosis of IE is made, and may be a clue to the diagnosis.
- IE associated with injection drug use is limited to the tricuspid valve about half the time, and as such usually has no murmur that can be appreciated by auscultation, and will have no peripheral manifestations of IE. There is a higher incidence of septic pulmonary emboli in IE among injection drug users, so the diagnosis of pulmonary abscess should lead one to suspect and evaluate for the diagnosis of IE.

Primary Differential Considerations

Other diagnoses to consider in patients with signs and symptoms suggestive of IE include:

- Fever of unknown origin
- Septic pulmonary emboli
- Vasculitis
- Connective tissue diseases

History and Physical Exam

Findings That Confirm Diagnosis

- There are no completely confirmatory historical or physical examination findings for IE.
- The Duke Criteria is the current reference standard for the diagnosis of IE. They are a series of clinical, microbiologic, and echocardiographic findings that together have a sensitivity and specificity of greater than 80% for the diagnosis of IE.

Definite IE any of (1) or (2)	(1) Pathologic criteria: Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen, or pathologic lesions – vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
	(2) Clinical criteria: Any of two major criteria, or one major criterion and three minor criteria, or five minor criteria
Possible IE	One major criterion and one minor criterion or three minor criteria
Rejected	Firm alternative diagnosis explaining evidence of IE, or resolution of IE syndrome with antibiotic treatment for 4 or less days, or no pathologic evidence of IE at surgery or autopsy with antibiotic therapy for 4 or less days, or does not meet criteria for possible IE
Major criteria:	(1) Positive blood culture for IE: (a) Typical microorganisms consistent with IE from two separate blood cultures: Viridans streptococci, *Streptococcus bovis*, HACEK group; *Staphylococcus aureus* or community-acquired enterococci in the absence of a primary focus (b) Microorganisms consistent with IE from persistently positive blood cultures defined as: At least two positive blood cultures drawn more than 12 h apart, or all of three, or a majority of four or more blood cultures with first and last sample drawn at least 1 h apart (c) Single positive blood culture for *Coxiella burnetii* or antiphase I IgG antibody titer >1:800
	(2) Evidence of endocardial involvement: (a) Positive echocardiogram for IE: Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation, or abscess, or new partial dehiscence of prosthetic valve, or new valvular regurgitation (worsening or changing of preexisting murmur not sufficient)
Minor criteria:	(1) Predisposition – predisposing heart condition or injection drug use
	(2) Fever – temperature of 38 °C or more
	(3) Vascular phenomena – major arterial embolism, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
	(4) Immunological phenomena – glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
	(5) Microbiological evidence – positive blood culture but does not meet a major criterion as noted above or serological evidence of active infection with organism consistent with IE

Modified Duke Criteria for the Diagnosis of Infective Endocarditis (IE) [Rodriguez ER, Tan CD. Cardiovascular Pathology. In: Cheng L, Bostwick DG, editors. Essentials of Anatomic Pathology [Internet]. Cham: Springer International Publishing; 2016 [cited 2016 Aug 8]. p. 1295–351. Available from: http://link.springer.com/10.1007/978-3-319-23380-2_27]

- The Duke criteria require microbiologic and echocardiographic results and as such are not particularly helpful early in the course of evaluation. A high index of suspicion is necessary for the early diagnosis of IE.

Factors That Suggest Diagnosis

- The presence of a fever with no obvious source, with any of the predisposing factors discussed in the etiology section, or with a new or worsened murmur suggests the diagnosis.
- The classic physical examination findings associated with IE have become uncommon, but their presence should suggest the diagnosis.
  - Splinter hemorrhages (linear petechiae in the center of the nail bed, as opposed to traumatic petechiae which are usually in the distal nail bed) are found in only about 5 –8% of patients.

Splinter hemorrhages in a fingernail. Splinter hemorrhages may be due to simple trauma, but when multiple nails are involved in a patient with infective endocarditis, they represent a vasculitic component of the infection. [Miró J, Wilson W, Chapter 01. In: Korzeniowski O, editor. Cardiovascular Infections, 1e. Philadelphia: Current Medicine; 1998. (Mandell GL, editor. Atlas of infectious diseases; vol. 10). ISBN: 0-443-07750-9] *Caption adapted from original*

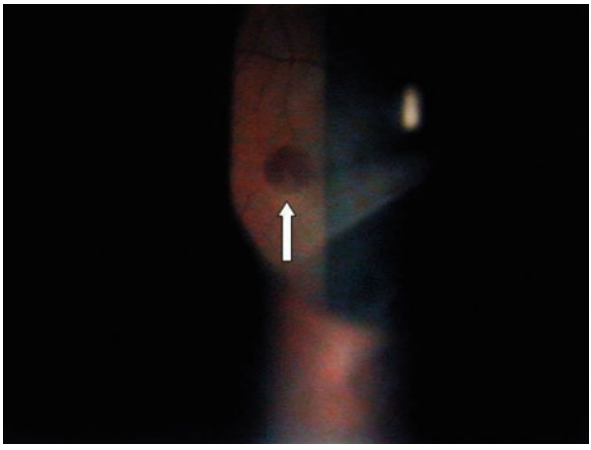
- Janeway lesions (non-tender, palpable hemorrhages on the palms and soles) in about 5%.

Janeway lesions in *Staphylococcus aureus* left-sided endocarditis [Miró J, Wilson W, Chapter 01. In: Korzeniowski O, editor. Cardiovascular Infections, 1e. Philadelphia: Current Medicine; 1998. (Mandell GL, editor. Atlas of infectious diseases; vol. 10). ISBN: 0-443-07750-9] *Caption from original*

- Osler's nodes are painful, purple nodules found on fingerpads and toepads, and are very rarely seen.

A and **B**, Osler's nodes in patients with infective endocarditis. These lesions usually occur in the tufts of the fingers or toes and are painful and evanescent. They likely are mediated by immunopathologic factors. [Scheld MW. Chapter 02. In: Fekety R, editor. External manifestations of systemic infections. Philadelphia: Current Medicine; 1997. 237 p. (Mandell GL, editor. Atlas of infectious diseases; vol. 8.) ISBN: 0-443-07760-6] *Caption from original*

- Roth's spots (white centered retinal hemorrhages) in 5%.



Roth's spot on the retina of the left eye. [From article: Case report: Infective endocarditis caused by *Brevundimonas vesicularis*. BMC Infectious Diseases. 2006 Dec;6(1). https://doi.org/10.1186/1471-2334-6-179, at http://link.springer.com/article/10.1186%2F1471-2334-6-179/fulltext.html; by Mei-Li Yang, Yen-Hsu Chen, Tun-Chieh Chen, Wei-Ru Lin, Chun-Yu Lin, Po-Liang Lu, © Yang et al; licensee BioMed Central Ltd. 2006; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

- Conjunctival hemorrhages in 5%.

Conjunctival hemorrhages in a patient with *Staphylococcus aureus*endocarditis. [Scheld MW. Chapter 02. In: Fekety R, editor. External manifestations of systemic infections. Philadelphia: Current Medicine; 1997. 237 p. (Mandell GL, editor. Atlas of infectious diseases; vol. 8.) ISBN: 0-443-07760-6] *Caption from original*

- Patients with prosthetic heart valves are at increased risk for IE, and the diagnosis should always be considered when these patients have unexplained fever or other constitutional symptoms (such as unexplained weight loss, night sweats, loss of appetite).
- Hospitalization, especially prolonged hospitalization with indwelling venous access or recent intravascular procedures, also increases the risk for IE.

Factors That Exclude Diagnosis

- There are historical or physical examination findings that can reliably exclude the diagnosis.
- Negative blood cultures also do not reliably exclude the diagnosis, as 10% of cases of IE will have negative blood cultures (see pathophysiology and etiology section).
- The diagnosis can be rejected as per the Duke Criteria.

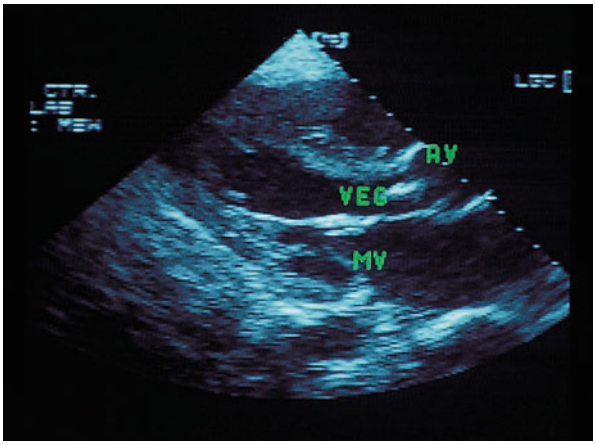
Ancillary Studies

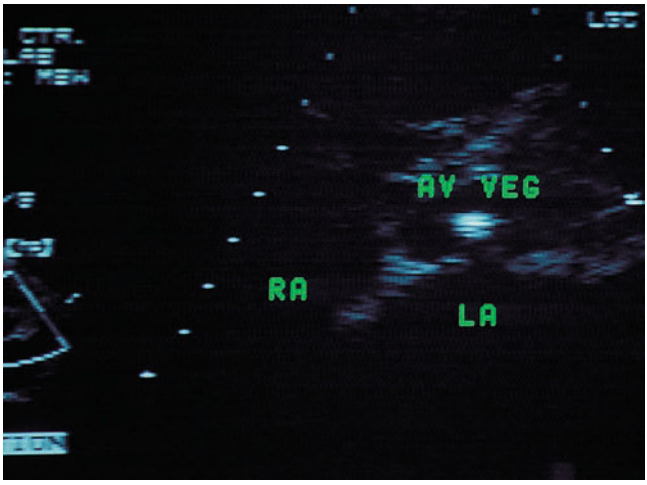
Laboratory

- Blood cultures are imperative for the diagnosis of IE. All patients with suspected IE should have three sets of blood cultures drawn. Each individual blood culture should be from a separate venipuncture site (not from a vascular catheter), and include at least 10 ml of blood for adults (5 ml for each bottle), 0.5 ml for infants, and 5 ml for children. If the patient is acutely ill, the cultures should be obtained over a one-hour period. All cultures should be obtained prior to the initiation of antibiotic therapy.
    - When three sets of appropriately drawn blood cultures are performed, the causative microorganism is identified in about 90 % of cases of IE.
- Multiple other laboratory studies are often abnormal in the setting of IE, but they are also very nonspecific.
- Patients with either acute Streptococcal or Staphylococcal IE often have elevated white blood cell counts and a thrombocytopenia.
    - In sub-acute presentations, the WBC count may be normal.
- Other laboratory markers of inflammation and infection may be elevated, such as the erythrocyte sedimentation rate (ESR), and the c-reactive protein (CRP).
- IE can cause interference with and abnormal results on multiple serologic and immune tests. In fact, an elevated rheumatoid factor in a patient without a known prior history of a rheumatologic disorder is a minor criterion for the diagnosis of IE in the Duke criteria.
- The majority of patients with IE will have an abnormal urinalysis. There may be proteinuria, pyuria, and either microscopic or gross hematuria. All of these findings are nonspecific. However, glomerulonephritis, often manifested with red blood cell casts on a microscopic urinalysis, is a minor criterion for the diagnosis of IE in the Duke criteria.

Echocardiography

- Echocardiography is indispensible in the diagnosis of IE, and should be performed as soon as reasonably possible when the diagnosis of IE is considered. Echocardiography can show valvular vegetations, valve dysfunction, and para-valvular abscesses.
- In general, trans-thoracic echocardiography (TTE) should be performed first. It is less sensitive and less specific than trans-esophageal echocardiography (TEE), but it is also less invasive and doesn't require sedation to perform.

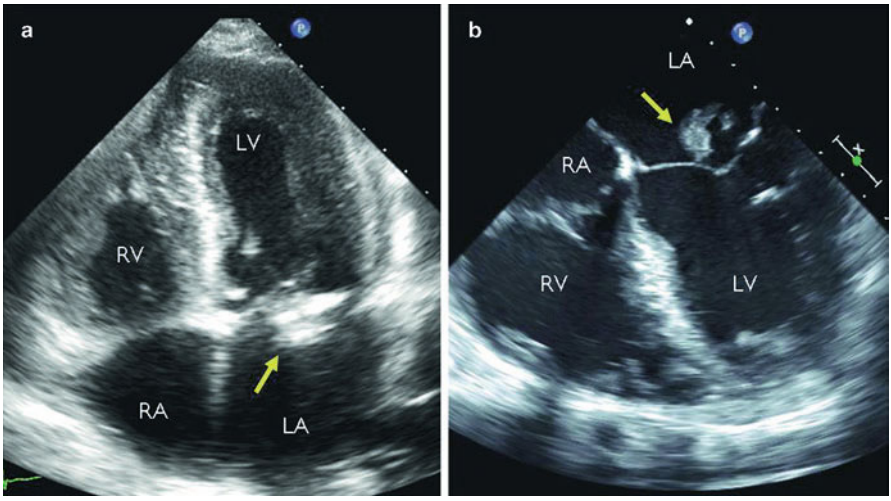




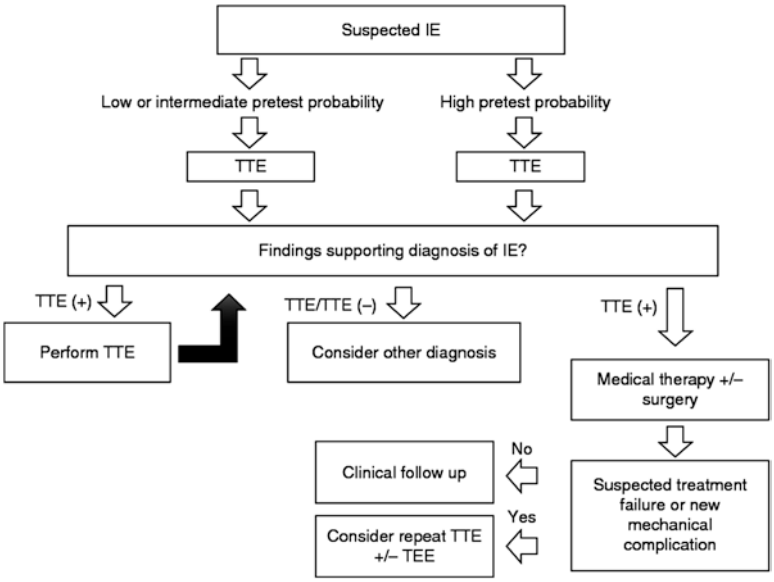
Transthoracic echocardiographic views of aortic valve endocarditis. **A**, Parasternal long-axis view shows an aortic valve vegetation prolapsing into the left ventricular outflow tract. **B**, Short axis view of the aortic valve shows a prominent vegetation in the same patient.[Scheld MW. Chapter 02. In: Fekety R, editor. External manifestations of systemic infections. Philadelphia: Current Medicine; 1997. 237 p. (Mandell GL, editor. Atlas of infectious diseases; vol. 8.) ISBN: 0-443-07760-6] *Caption from original*

- TEE is more sensitive and specific for the diagnosis of IE and should be performed in multiple situations:

- After a negative or technically difficult TTE when the clinical concern for IE is moderate-to-high.
- After a positive TTE (demonstrating a valvular vegetation) when there is also a concern for an intracardiac complication such as para-valvular abscess, significant valvular regurgitation, and in the assessment for the need for surgery.
- In patients with a prosthetic valve.
- In patients with a known history of valvular disorder (including a prior history of IE).



Representative images acquired by transthoracic echocardiography (TTE,**a**) and transesophageal echocardiography (TEE, **b**) in the same patient with mitral valve endocarditis (arrowhead points to bacterial vegetation adherent to the anterior leaflet). The proximity of the mitral valve to the esophagus and superior acoustic window results in improved spatial resolution of TEE over TTE. RA right atrium, RV right ventricle, LA left atrium, LV left ventricle [Michelis KC, Choi BG. Cardiovascular Imaging in Global Health Radiology. In: Mollura DJ, Lungren MP, editors. Radiology in Global Health [Internet]. New York, NY: Springer New York; 2014 [cited 2016 Aug 8]. p. 189–203. Available from: http://link.springer.com/10.1007/978-1-4614-0604-4_18] *Caption from original*



Algorithm for the use of echocardiography in the diagnosis and management of infective endocarditis [Kiefer TL, Wang A. Infective Endocarditis. In: Stergiopoulos K, Brown DL, editors. Evidence-Based Cardiology Consult [Internet]. London: Springer London; 2014 [cited 2016 Aug 8]. p. 71–8. Available from: http://link.springer.com/10.1007/978-1-4471-4441-0_6] *Caption from original*

- The combination of TTE and TEE demonstrates valvular vegetations in 90% of cases of IE.
- Echocardiography may need to be repeated if the initial study was unrevealing but the clinical suspicion remains high (for example, known risk factor in setting of positive blood cultures.)
- Echocardiography also may need to be repeated if there is a new or suspected complication of IE, clinical worsening, and at the end of therapy.

Imaging

- Chest X-ray. There are no specific findings of IE on CXR. CXR may, however, reveal complications of OE such as infiltrates or pulmonary abscess from septic pulmonary emboli.
- Other imaging studies, such as CT scan or MRI, have no specific findings for IE, but may also demonstrate, or be used to search for, complications of IE such as vertebral osteomyelitis with MRI of the spine, solid organ or other intraperitoneal collection with CT scan of the abdomen and pelvis, and any intracranial complication with either CT scan or MRI of the brain.

Special Populations

Age

- Greater than 50% of cases of IE occur in patients above the age of 65.
- IE is uncommon in children, but the incidence has been reported to be increasing over the last several decades due to the increased rate of successful surgery for congenital heart disease, and the increased use of central venous catheters. Correspondingly, these are the two biggest risk factors for IE in children.
    - As in adults, Streptococci and Staphylococci are the most common causative organisms.
    - The presentation, diagnosis, and treatment are similar in children and adults.
    - Duke's criteria are applicable to the pediatric population.
    - There is about a 5% mortality rate for children with IE.

Co-morbidities

- Important pre-disposing and co-morbid conditions that increase the incidence and complications are detailed as per the incidence and epidemiology section, and include the presence of a prosthetic heart valve, the presence of an intracardiac device, unrepaired cyanotic congenital heart disease, a prior history of infective endocarditis, chronic rheumatic heart disease, age-related degenerative valvular lesions, hemodialysis, diabetes, HIV infections, intravenous drug use, age greater than 65, poor dental hygiene, and dental infection.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- All patients in whom IE is being considered need three sets of correctly drawn blood cultures prior to the administration of antibiotics.
- All patients in whom IE is being considered need to have echocardiography as soon as possible.
- It is important to know that embolic complications (for example, septic pulmonary emboli, cerebrovascular emboli) can occur before the diagnosis of IE is made, and may be a clue to the diagnosis.
- IE associated with injection drug use is limited to the tricuspid valve about half the time, and as such usually has no murmur that can be appreciated by auscultation, and will have no peripheral manifestations of IE. There is a

higher incidence of septic pulmonary emboli in IE among injection drug users, so the diagnosis of pulmonary abscess should lead one to suspect and evaluate for the diagnosis of IE.

Mimics

- Many diseases can present with fever and diffuse/multi-organ symptoms, including many infections, vasculitides, connective tissue diseases, and malignant diseases.
- Many diseases can be associated with bacteremia, such as skin and soft tissue infections, osteomyelitis, pneumonia, meningitis, and others.

Time-Dependent Interventions

- It is important to obtain three sets of appropriately drawn blood cultures prior to the initiation of antibiotics.
- An echocardiogram needs to be performed as soon as possible in any patient in whom the diagnosis of IE is being seriously considered.
- Patients that present acutely with fever and other constitutional symptoms should have empiric antibiotics initiated only after blood cultures are drawn.
- Patients may present with acute complications of IE, such as brain abscess, cerebrovascular accident from emboli/infarct, pulmonary embolism, pulmonary abscess, splenic abscess/infarct, renal abscess/infarct, and vertebral osteomyelitis. These patients need to have the complication treated.
- Patients who develop acute heart failure, or who have significant embolic complications, may require urgent surgical valve replacement or repair.

Overall Principles of Treatment

- The goal of treatment is the eradication of the causative agent of IE, with sterilization of the valve, blood, and all involved organs.
- This usually requires prolonged courses of bactericidal antibiotics.
- Multiple professional societies and organizations have published guidelines for the administration of antibiotics in IE. All are available both in printed and online formats.
- Surgery may be required to aid in removing infected material and draining associated abscesses.
- Patients who present acutely with fever and have a high clinical concern for endocarditis (i.e., a known risk factor or predisposing factor) should have

empiric therapy initiated after three sets of blood cultures are obtained. Empiric therapy should generally cover the most likely etiologic organisms. In developed countries that would be staphylococci, streptococci, and enterococci. For this reason, most empiric regimens should include vancomycin (15-20 mg/kg/dose, every 12 hours, not to exceed 2 grams per dose.).
- Subsequent therapy should be guided by culture results and sensitivity results.
- Therapy usually continues for at least 6-weeks.
- Surgical therapy, either valve repair or replacement, will be necessary in up to 50% of cases. The need for early valve surgery (surgery occurring during the initial course of antibiotics) is indicated by: acutely decompensated heart failure; inability to control infection marked by persistent bacteremia; and the prevention of embolic events.

Disease Course

- In-hospital mortality can range from 10–20%, based upon the predisposing factors (10% for native valve lesions to 40% for prosthetic valve lesions).
- The six-month mortality ranges from 25–30%, and the 5-year mortality approaches 40%.
- Complications of IE can include multiple organ systems (such as cardiovascular, central nervous system, renal, and musculoskeletal), and can occur from multiple pathologic mechanisms (direct extension (abscess), embolization of infected and thrombotic material, and damage and scarring of infected structures (mycotic aneurysm).
- Multiple complications can occur in the same patient.
- Cardiovascular complications include:
    - Heart failure (can be acute or chronic). Heart failure is the most common indication for valve surgery. Heart failure is also the leading cause of death among patients with IE.
    - Abscess around the affected valve.
    - Pericarditis.
    - Intracardiac fistula.
    - Mycotic aneurysm. These can develop in any vessel, including intracerebral vessels, and are most common at areas of weakness such as bifurcations.
- Central Nervous system complications include:
    - Stroke
    - Brain abscess
    - Meningitis

- Renal complications include:
  - Kidney abscess
  - Kidney infarction
  - Immune-mediated glomerulonephritis
- Musculoskeletal complications include:
  - Vertebral osteomyelitis
  - Septic arthritis
- Prolonged antibiotic therapy can also be associated with complications (especially allergic and renal complications).

Chapter 40
Interstitial Lung Disease

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Interstitial Lung Disease (ILD); Diffuse Parenchymal Lung Disease (DPLD); Diffuse Infiltrative Lung Disease (DILD)

Incidence/Epidemiology

- The interstitial lung diseases encompass more than 200 individual diseases, all with unique incidences and epidemiology.
- The incidence of specific disorders depends upon many factors, including age, sex, smoking status, environmental and occupational exposures, medications used, exposure to radiation, and medical history.
- Most are rare diseases.
- The most common of these disorders, idiopathic pulmonary fibrosis (IPF), accounts for about 55 % of all ILD diagnoses. It has an incidence that ranges from 10–25/100,000 in the population between 40 and 50 years old, to >175/100,000 in those over age 75.
- All of these disorders are associated with considerable morbidity and mortality.

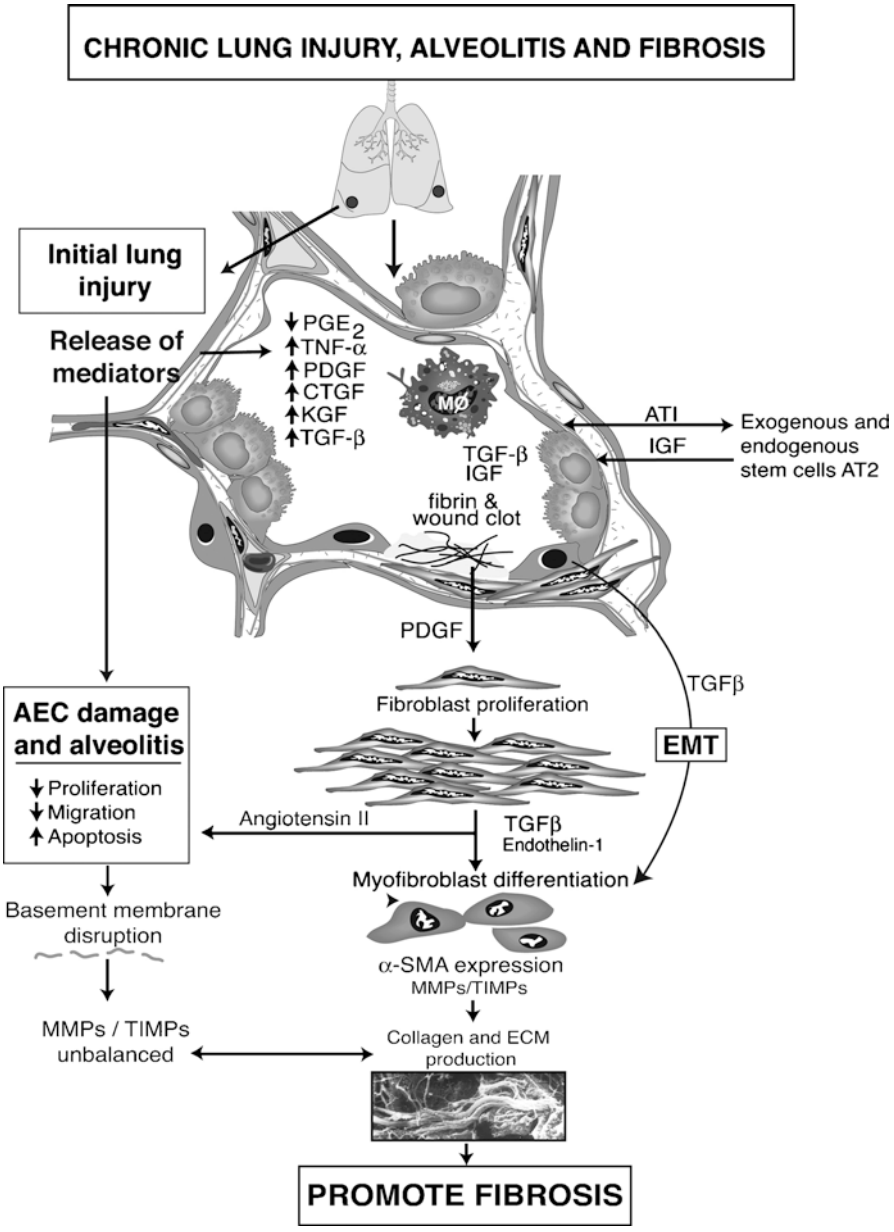
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_40

Differential Diagnosis

- The differential diagnosis is broad and encompasses all diseases that can present primarily with dyspnea and cough, such as asthma, COPD, CHF, and bronchiectasis, among others.
- The differential diagnosis within this class of disorders is also very broad, with over 200 individual diseases to consider.

Pathophysiology and Etiology

- ILD is a broad category of diseases that share pathologic involvement of the lung parenchyma and common clinical, radiologic, and physiologic manifestations.
- These are all non-malignant and non-infectious diseases.
- There are several different classification schemes for these diseases. Some schemes classify based upon whether there is a known cause. Some classify based upon primary underlying histopathology (inflammation with fibrosis versus granulomatous.) Some systems classify based upon a combination of both known cause and underlying histopathology.
- Inflammation and fibrosis. This pathophysiologic process starts with some injury or insult to the epithelial surface of the lung that leads to a diffuse inflammatory response in the air spaces and alveoli. This may remit or become chronic. If the inflammatory becomes chronic, the inflammation spreads to the lung interstitium and vasculature, which can lead to permanent interstitial fibrosis and scarring. This then leads to progressive and permanent impairment in physiologic parameters such as gas exchange and ventilation. Most of these disorders are difficult to treat and resistant to treatment.



A schematic drawing of pathogenetic mechanism of alveolar epithelial cells (AEC) in lung injury alveolitis and fibrosis. An initial injury of known or unknown etiology provokes an unresolved inflammation or AEC damage and alveolitis. Alveolitis is an initial event in the pathogenesis of lung fibrosis. A fibrin clot forms early and serves as a provisional matrix for the migration and proliferation of endogenous

AEC stem cells. Bone marrow-derived stem cells, HSCs, can also contribute to the populations of AECs. Activated epithelial cells secrete numerous mediators that create a strong profibrotic microenvironment in lung fibrosis inducing AEC injury, alveolitis and apoptosis. Also injured AEC exhibit a defect in the release of some antifibrotic mediators such as prostaglandinE-2 (PGE2). Epithelial cell damage and cell death during alveolitis induce the formation of gaps in the epithelial basement membrane. Progression from the acute phase of lung injury is accompanied by abnormal alveolar reepitalization, tissue repair and remodeling, which may result in progressive fibrosis. AEC produce MMPs that increase basement membrane disruption and allow fibroblast migration, proliferation and differentiation to myofibroblasts. Myofibroblasts secrete extracellular matrix proteins, mainly collagens. An imbalance between MMPs and TIMPs provokes the progressive deposit of the extracellular matrix (ECM) and abnormal collagen accumulation and promotes fibrosis. Alveolar macrophages and AEC secrete TGF-β1, which induces epithelial mesenchymal transition (EMT), and this may contribute to fibroblast/myoflbroblast accumulation in the processes of fibrosis. [Gharaee-Kermani M, Gyetko MR, Hu B, Phan SH. New Insights into the Pathogenesis and Treatment of Idiopathic Pulmonary Fibrosis: A Potential Role for Stem Cells in the Lung Parenchyma and Implications for Therapy. Pharmaceutical Research. 2007 Apr 12;24(5):819–41.] *Caption from original*

Idiopathic pulmonary fibrosis (interstitial lung disease, idiopathic interstitial pneumonias) with varying alveolar and interstitial inflammatory infiltrates, progressive interstitial fibrosis, secondary hypertensive vascular disease, and a final stage with honeycombing of the lungs. Note the fleshy gross appearance of the lungs in earlier stages (a), with various microscopic interstitial infiltrates (b–d) and gross honeycombing at the end stage (e). The etiology of these diseases is inhomogeneous, as demonstrated by the large variety of terms in use. In many cases, these diseases appear to be autoimmune, either primary or secondary in the course of other systemic autoimmune disorders, but frequently the etiology remains obscure. These disorders are grouped together because of similar clinical manifestations, including severe shortness of breath, diffuse abnormalities of lung mechanics and gas exchange, and diffuse abnormalities in chest radiographs and CT scans, as well as similar clinical outcomes [Krueger GRF, Wagner M, Oldham SAA. Pathology of the Respiratory Tract. In: Krueger GRF, Buja LM, editors. Atlas of Anatomic Pathology with Imaging [Internet]. London: Springer London; 2013 [cited 2015 May 28]. p. 105–89. Available from: http://link.springer.com/10.1007/978-1-4471-2846-5_3] *Caption adapted from original*

- The granulomatous disorders are marked by the pathologic accumulation of inflammatory cells and epithelial cells into granulomas within lung tissue. Many of these patients can remain with mild-to-moderate symptoms, and many may improve with treatment.

- A helpful schema clinically is to group these disorders as to whether the cause is known or unknown.
- Known causes: Inflammatory pathology unless otherwise labeled.
  - Associated with connective-tissue diseases (most commonly rheumatoid arthritis, scleroderma, and polymyositis).
  - Hypersensitivity pneumonitis (e.g., farmer's lung and bird fancier's lung). Granulomatous.
  - Pneumonoconioses (asbestosis, silicosis, coal miner's lung).
  - Drug-induced (chemotherapeutic agents, amiodarone, methotrexate).
  - Smoking-related.
  - Pulmonary Langerhans cell histiocytosis.
  - Respiratory bronchiolitis ILD.
  - Desquamative interstitial pneumonia.
  - Acute eosinophilic pneumonia.
  - Radiation-induced.
  - Toxic-inhalation induced (e.g., cocaine, ammonia, etc.).
- Unknown Causes: Inflammatory pathology unless labeled otherwise.
  - Idiopathic pulmonary fibrosis.
  - Sarcoidosis. Granulomatous.
  - Other idiopathic interstitial pneumonias.
  - Cryptogenic organizing pneumonia (bronchiolitis obliterans organizing pneumonia).
  - Nonspecific interstitial pneumonia.
  - Lymphocytic interstitial pneumonia.
  - Acute interstitial pneumonia.
  - Eosinophilic pneumonias.
  - Pulmonary vasculitides. Mostly granulomatous.
  - Pulmonary lymphangioleiomyomatosis.
  - Pulmonary alveolar proteinosis.
  - Many other rare disorders.

Presentation

Typical/"Classic"

- Dyspnea is the most common and prominent complaint in ILD.
- Classically, patients will have dyspnea with a persistent, non-productive cough associated with diffuse, interstitial infiltrates on chest x-ray.
- Often, patients will have been treated with one or several courses of antibiotics for typical and atypical pneumonia. This non-response to antibiotics should raise suspicion for an ILD.

- The most common time course of presentation is chronic, with symptoms ongoing over months-to-years. A sub-acute presentation over weeks-to-months is also common.
- A detailed history is very important in the evaluation of a patient with a suspected ILD. It can help to narrow the differential to a manageable number of conditions. The history should include detailed questioning as to the pattern and timing of symptoms, smoking history, a detailed environmental and occupational history, and a family history.
- Patients with inflammatory/fibrotic disorders will often have bibasilar "dry" crackles on physical exam. These are often also called "Velcro" crackles as they sound like Velcro being pulled apart.
- Cyanosis and clubbing can occur with advanced disease, and are noted in up to 30% of patients with advanced idiopathic pulmonary fibrosis.

Clubbing of the fingers [Karkucak M, Erturk E, Capkin E, Akyazi H, Ozden G, Tosun M. Primary hypertrophic osteoarthropathy (pachydermoperiostosis): a case report. Rheumatology International. 2007 Jan 11;27(4):403–5.] *Caption from original*

https://www.youtube.com/watch?v=9C5RFb1qWT8
Audio recording of crackles, including late inspiratory crackles.

Atypical

- An acute presentation is unusual, happening mostly in disorders with an allergic basis.
- Some disorders will present in an episodic fashion with acute exacerbations that improve with treatment (sarcoidosis).
- Wheezing and chest pain are not common presenting complaints/findings, except in sarcoidosis.
- Hemoptysis is uncommon, but may be seen in the alveolar hemorrhage syndromes.

Primary Differential Considerations

- Early consideration should be given to
  - ARDS
  - Sarcoidosis
  - Pneumoconiosis
  - Hypersensitivity or drug-induced pneumonitis
  - Pulmonary edema
  - Pneumonia

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical exam findings that can confirm the diagnosis.
- The diagnosis is confirmed with appropriate findings on high-resolution CT of the lungs, or by specific pathologic findings on lung biopsy.

Factors That Suggest Diagnosis

- A classic presentation as described, with slowly progressive dyspnea, a chronic non-productive cough, and diffuse infiltrates on chest x-ray, with symptoms that don't improve with antibiotic treatment, should clearly raise suspicion for an ILD.
- A careful physical examination can help to identify related systemic processes such as any evidence of a connective-tissue disease.

Factors That Exclude Diagnosis

- There are no historical or physical exam findings that can exclude the diagnosis.
- A normal high-resolution CT scan of the lungs would essentially rule out the diagnosis.

Ancillary Studies

Laboratory

- Most patients will have had routine laboratory studies (CBC, basic chemistries) checked, but they are unlikely to be helpful.
- Specific laboratory evaluation for specific disorders being considered should be performed.
- A raised lactate dehydrogenase (LDH) level is a common, non-specific finding in many ILDs.
- The serum level of angiotensin-converting enzyme (ACE) is commonly elevated in sarcoidosis.
- Anti-nuclear Ab and anti-immunoglobulin Ab (rheumatoid factor) can be found even in patients without an obvious connective-tissue disease.
- If a vasculitis is suspected, it may be helpful to check for the presence of anti-neutrophil cytoplasmic Ab's and anti-basement membrane Ab.

Imaging

- Most evaluations for ILD are initiated and suspected based upon an abnormal chest x-ray But plain CXRs are neither sensitive nor specific for a diagnosis of ILD. In fact, up to 20% of patients with ILD can have a CXR that is read as normal. CXR findings correlate poorly with clinical findings, and also with the histopathologic stage of the disease.
- High-resolution CT (HRCT) of the chest is the imaging study of choice for the diagnosis of any diffuse interstitial process. The classic "honeycombing" of lung tissue is an end-stage finding.
- HRCT can narrow the differential diagnosis, and in some cases can confirm the diagnosis.
- The pattern of abnormalities, distribution of abnormalities, and associated findings (pleural effusions, lymphadenopathy) found on HRCT, used in conjunction with the clinical context, can sometimes confirm the diagnosis. This can obviate the need for a lung biopsy.

Pulmonary Function Tests

- Spirometry is helpful in evaluating the extent of disease.
- Most forms of ILD will produce a restrictive pattern of PFTs (COPD gives an obstructive pattern). This includes a reduced total lung capacity (TLC), functional residual capacity (FRC), and residual volume (RV).
- Forced expiratory volume in one second (FEV1) and functional vital capacity (FVC) are often reduced, but their ratio is usually normal or increased, as opposed to COPD, where there is a reduced ratio.
- Lung volumes continue to decrease as the disease progresses and lung compliance worsens (the lungs become "stiff").
- The rate of decline of PFTs can have prognostic significance.
- The diffusing capacity to carbon monoxide (DLCO) is reduced in most ILDs, but this is a nonspecific finding and does not correlate with disease stage.
- Arterial blood gases can be normal, but may also show hypoxia from ventilation perfusion mismatch. Ventilation perfusion mismatch occurs because as the fibrosis worsens, lung compliance reduces (the lungs become more stiff). This reduces ventilation in these areas of the lung, but perfusion in these areas remains the same. This leads to blood that has not been adequately oxygenated returning to the heart, which allows this "venous" blood to mix with oxygenated blood in the left heart.
- Carbon dioxide retention is uncommon in ILD (it is more common in COPD), but if present it indicates severe, end-stage disease.
- Exercise pulmonary testing can be used to follow disease progression.

Lung Biopsy

- Lung biopsy may be necessary if the diagnosis is in question after work-up, including HRCT.
- Lung biopsy is the most effective method for diagnosis and assessment of disease severity.
- If possible, a biopsy should be performed prior to the initiation of treatment.
- Bronchoscopy with transbronchial biopsy is usually the first approach to obtaining lung tissue for biopsy. However, this approach gives small tissue samples, and often cannot lead to a definitive diagnosis.
- In these cases it may be necessary to perform a surgical lung biopsy. Surgical lung biopsy has a diagnostic yield of nearly 90%.
- Surgical lung biopsy is usually performed under video-assisted thorascopic surgery (VATS). However, this approach can have a mortality of 2% and a complication rate of 5–10%.

- Bronchoalveolar lavage during bronchoscopy is not useful in the diagnosis of ILD, but may help offer alternative diagnoses (cancer or infections), or assess for complications of ILD (also cancer and infections).

Special Populations

Age

Infants and Children

- Interstitial lung disease does occur in infants and children. It is marked by pulmonary symptoms with diffuse pulmonary infiltrates on lung imaging.
- It is very rare in this age group, with a reported incidence between 1.5–3.6 cases per 1 million in those under the age of 16.
- Many of the causes of ILD in children are similar to the causes in adults, but there are syndromes unique to infants and neonates. These include:
  - Diffuse developmental disorders. This includes alveolar capillary dysplasia with misalignment of the pulmonary veins (ACD-MPV), and acinar dysplasia.
  - Disorders of lung growth and development. This group includes pulmonary hypoplasia and chronic neonatal lung disease with bronchopulmonary dysplasia.
  - Neuroendocrine cell hyperplasia of infancy (NEHI). This is a very rare disorder with an unknown etiology.
  - Pulmonary interstitial glycogenolysis (PIG).
  - Genetic disorders of surfactant production and metabolism.
- In neonates and infants, ILD often presents with unexplained respiratory failure.
- In older infants and children the presentation can be non-specific and includes persistent and unexplained tachypnea, chronic cough, hypoxemia, exercise intolerance, and clubbing of the digits. ILD can also present as failure to thrive and unexplained feeding difficulties. Children above age 2 are more likely to present with exercise intolerance and clubbing.
- The work-up should begin with a complete history and physical examination. The evaluation should initially focus on assessing and excluding the more common causes of respiratory symptoms with diffuse infiltrates. These include: infectious causes, congenital heart disease, and cystic fibrosis. Other rare causes can include immunodeficiencies and structural lung and airway abnormalities.
- The evaluation can then follow as described above for adults.
- An important addition to the evaluation of ILD in children, especially in neonates with respiratory failure and children with suspected ILD and another

affected sibling, is genetic testing for mutations of surfactant production and metabolism. Finding one of these mutations can be diagnostic and obviate the need for lung biopsy.
- Treatment is often supportive (avoiding respiratory irritants, nutritional support, oxygen for hypoxemia, appropriate vaccinations, and appropriate treatment of intercurrent infections), and should be guided by the specific syndrome.
- The prognosis greatly depends upon the specific disorder. Some will spontaneously remit.
- The prognosis is generally poor with ACD-MPV, surfactant mutations, and if pulmonary hypertension complicates ILD.
- Lung transplantation can be considered for end-stage disease not responding to therapy.

Adults

- ILD can present across the spectrum of age groups. The age at presentation can be a significant help in narrowing the differential.

Co-morbidities

- The presence of other or multiple co-morbidities can make the diagnosis and management of ILD more challenging. Of particular concern would be the presence of cancer, heart disease, congestive heart failure, diabetes mellitus, and renal failure.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step. Strong consideration of the diagnosis should be given when a patient has not responded to several courses of antibiotics for presumed infectious pneumonia when there are diffuse infiltrates on the CXR.
- When considering the diagnosis, it is critical to take an exhaustive history that should include a complete occupational, travel, and hobby/leisure activity history.
- HRCT is a critical test in the evaluation of suspected ILD.

Mimics

- With several hundred different forms of ILD, any of these may mimic another.
- Other diseases that can present with a cough, dyspnea, and diffuse infiltrates include: primary or metastatic cancer, atypical pneumonias, congestive heart failure, and bronchiectasis.

Time-Dependent Interventions

- Most ILDs are insidious and progress slowly.
- Diagnosis often requires months, and symptoms may have been ongoing and worsening for months to years.
- Some of these diseases may present in an acute fashion, developing over days to weeks. These can include allergy, vasculitides, acute interstitial pneumonia, eosinophilic pneumonia, and hypersensitivity pneumonitis.
- In patients with known ILD, acute respiratory worsening, especially if over 4 weeks or less, is usually due to either acute infection or pulmonary edema.

Overall Principles of Treatment

- Treatment should be tailored to the specific disorder if possible.
- The course can be highly variable, but most ILDs are chronic and progressive.
- There is no therapy to reverse fibrosis once present, so the goal of therapy is usually to reduce inflammation to limit any further damage.
- Oxygen should be used if the patient is hypoxemic (resting PaO2 <55 mmHg)
- Pulmonary rehabilitation has been shown to improve quality of life.
- Glucocorticoids are the most commonly used pharmacologic agents in the majority of ILDs. They are commonly started at high doses, up to 1 mg/kg/day, and continued for 1–3 months. If there has been a response, they are slowly tapered over 3–12 months. Too rapid tapering can lead to recurrence. Many patients will require a maintenance dose of steroids. However, the overall response rate is low.
- If patients on glucocorticoids don't improve, or if their condition worsens, second-line agents include cyclophosphamide and azathioprine. These agents can be used alone or in combination with glucocorticoids.

Disease Course

- Most cases are chronic, slowly progressive, and resistant to most treatments.
- Lung transplant can be considered for end-stage disease.

Chapter 41
Ischemic Cardiomyopathy

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Jaime Friel Blanck

Name and Synonyms

Ischemic cardiomyopathy

- Heart failure; there is some overlap with Dilated Cardiomyopathy (the term *ischemic cardiomyopathy* refers to severe coronary artery disease PLUS global left ventricular dysfunction)

Incidence/Epidemiology

- It is the most common cause of heart failure in developed countries.
- It effects approximately one out of 100 people.
  - Occurs most often middle-aged-to-elderly men.

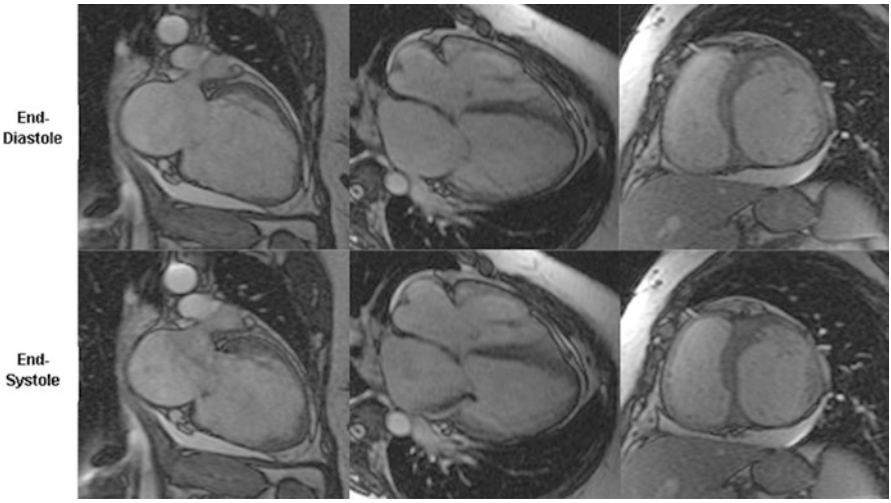
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_41

Differential Diagnosis

- Nonischemic cardiomyopathy
- Dilated cardiomyopathy
- Restrictive cardiomyopathy
- Hypertrophic cardiomyopathy
- Peripartum cardiomyopathy
- Infectious cardiomyopathy

Pathophysiology and Etiology

- Impaired left ventricular function (less than 35–40 %) that results from coronary artery disease
  - may result from irreversible loss of myocardial cells from infarction.
  - may result from contractility deficit that is variable in the setting of ischemic but not frankly infarcted myocardial cells.
  - Ejection fraction less than 35–40 %.



Ischemic cardiomyopathy demonstrating inferior wall thinning and akinesis in the two chamber image (far left). In the four chamber image (middle) there is lateral wall akinesis with RV dilatation and markedly reduced RV free wall shortening and minimal tricuspid annular movement from end-diastole to end-systole. In the short axis images there is RV dilatation with reduced free wall thickening and severe LV systolic dysfunction. The LV inferior wall akinesis is also present in the inferior portion of the interventricular septum [Dell'Italia LJ. The Right Ventricle in Left Heart Failure. In: Voelkel NF, Schranz D, editors. The Right Ventricle in Health and Disease [Internet]. New York, NY: Springer New York; 2015 [cited 2015 Oct 22]. p. 361–90. Available from: http://link.springer.com/10.1007/978-1-4939-1065-6_17] *Caption from original*

Presentation

Typical/"Classic"

- Patients usually have a clear clinical history of coronary heart disease.
- Shortness of breath, with or without chest pain.
- Edema which may cause weight gain.
- Easy fatigability.
- Palpitations.
- Dizziness, lightheadedness, or syncope.

Atypical

- An atypical presentation would manifest as unexplained easy fatigability without the other symptoms noted above.

Primary Differential Considerations

- Consider acute heart failure of other etiologies, acute coronary syndrome, pulmonary embolism, and primary ventricular arrhythmia.

History and Physical Exam

Findings That Confirm Diagnosis

- There are no clinical findings that irrefutably confirm the diagnosis of ischemic cardiomyopathy.

Factors that Suggest Diagnosis

- Fatigue.
- Dyspnea on exertion, shortness of breath.
- Orthopnea, paroxysmal nocturnal dyspnea.
- Increasing edema, weight, or abdominal girth.
- Physical exam may note:
  - Tachypnea
  - Tachycardia
  - Hypertension
  - Hypoxia
  - Jugular venous distension (JVD)
  - Pulmonary crackles and/or wheezes
  - S_3 gallop
  - Peripheral edema
- The level of cardiac compensation determines which signs are present.

Factors That Exclude Diagnosis

- While there are no clinical factors that can exclude ischemic cardiomyopathy in the patient with heart failure symptoms, the finding (on imaging) of no significant coronary artery disease essentially removes the diagnosis from consideration.

Ancillary Studies

Laboratory

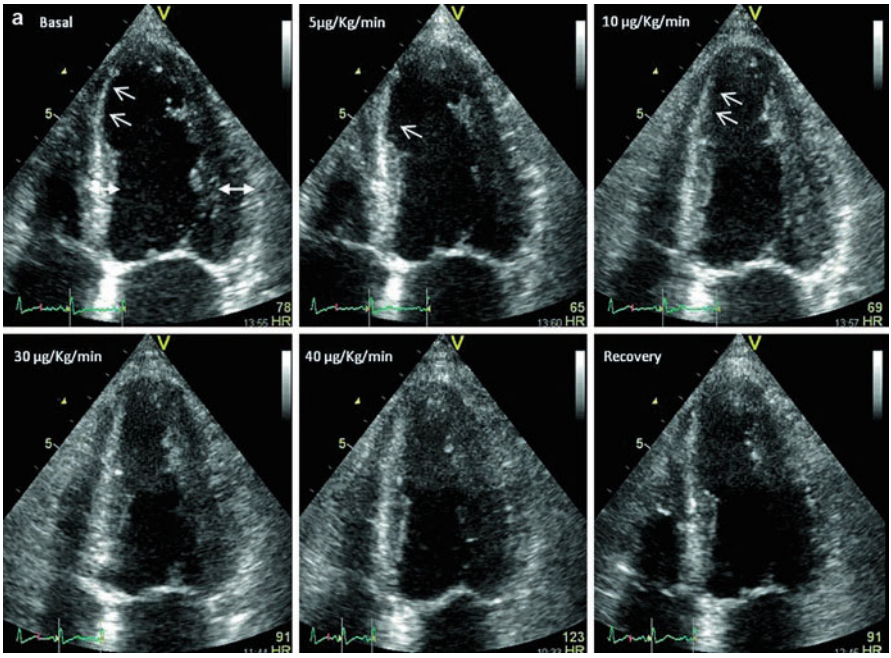
- Cardiac biochemical markers
- Brain-type natriuretic peptide (BNP) or NT-pro-BNP
- Coronary risk profile including lipid profile

Electrocardiography

- Left ventricular hypertrophy.
- Left bundle branch block is not uncommon.
- Nonspecific ST-T wave changes and Q waves are common and may reflect past infarction or current ischemia as much as the cardiomyopathy.

Imaging

- Chest x-ray:
  - Cardiomegaly is uniformly present.
  - There may be signs of heart failure, with pulmonary vascular congestion and Kerley B lines.
- Echocardiography is commonly performed to assess pump function.
- Needs evaluation for coronary artery disease, usually including exercise stress testing with myocardial imaging.



Example of a patient with ischemic cardiomyopathy (left ventricular ejection fraction 35%). At baseline, the resting echocardiography shows areas of thinning (<1 cm markers) in the mid and apical segments of the septal wall (arrows) whereas the lateral wall and the basal segment of the septum show preserved thickness (double arrows). During low-dose and peak-dose dobutamine stress echocardiography, the mid and apical segments of the septal wall show improved thickening (arrows) consistent with myocardial viability. [Delgado V, Schinkel AFL, Yiu K-H, Bax JJ. Nuclear Imaging to Assess Infarction, Reperfusion, No-Reflow, and Viability. In: Kaski JC, Hausenloy DJ, Gersh BJ, Yellon DM, editors. Management of Myocardial Reperfusion Injury [Internet]. London: Springer London; 2012 [cited 2015 Sep 15]. p. 161–89. Available from: http://link.springer.com/10.1007/978-1-84996-019-9_8] *Caption adapted from original*

- Cardiac catheterization with coronary angiography is reasonable for a patient with new-onset heart failure of uncertain cause, who would be eligible for revascularization.
- Noninvasive coronary arteriography including CT or cardiovascular magnetic resonance imaging is also available if the patient does not have angina or is not a candidate for revascularization.

Special Populations

Age

- Most patients with ischemic cardiomyopathy have experienced a transmural myocardial infarction. That means most of these patients are at least 50 years of age.

Co-morbidities

- Coronary artery disease with risk factor:
  - A family history of heart disease
  - Hypertension
  - Smoking
  - Hypercholesterolemia
  - Obesity
  - Diabetes
  - End-stage kidney disease

Pediatric Considerations

- Ischemic cardiomyopathy is generally not a pediatric disease.

Pitfalls in Diagnosis

Critical Steps not to Miss

- Diagnosis consists of 2 steps:
  - 1) The detection of significant coronary artery disease
  - 2) The detection of potentially reversible myocardial function

Mimics

- Chest pain alone is insufficient to make the diagnosis.
  - Nonischemic cardiomyopathy may have chest pain that resembles angina.

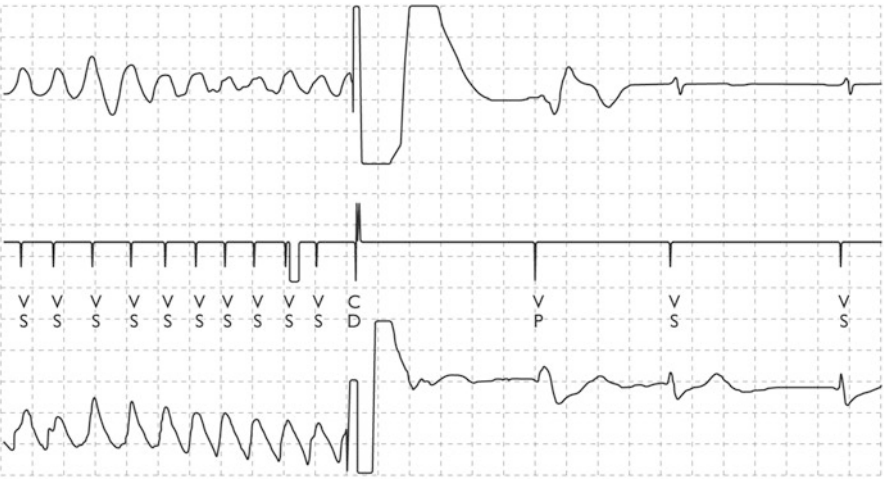
Time Dependent Interventions

- The most time-sensitive issue to address is any current ischemia.

Overall Principles of Treatment

- Medical therapy of heart failure:
  - ACE inhibitors.
  - Beta-blockers.
  - Statin as part of secondary prevention of established coronary heart disease.
  - Loop diuretic and dietary salt restriction in patients with fluid volume overload.
  - Removal of drugs that adversely affect systolic dysfunction like nonsteroidal anti-inflammatory drugs, antiarrhythmic drugs, certain calcium channel blockers.

- Device therapy:
  - Implantable cardioverter-defibrillator for prevention of sudden cardiac death.



Intracardiac electrogram of implantable cardioverter-defibrillator (ICD) shock terminating ventricular fibrillation in patient with ischemic cardiomyopathy. The ICD is the most effective therapy for prevention of sudden death in patients with heart failure. The use of the ICD for primary prevention of sudden cardiac death has provided the impetus for identification of individuals at highest risk of sudden death. In this example, the ICD accurately recognized ventricular fibrillation and terminated the rhythm with a shock. [Sauer W, Nayak H, Marchlinski F. Chapter 08. In: Shivkumar K, Weiss J, Fonarow G, Narula J, editors. Atlas of electrophysiology in heart failure. Philadelphia: Current Medicine; 2005. (Braunwald E, editor. Atlas of heart diseases; vol. 15); ISBN: 1-57340-225-7] *Caption from original*

- Biventricular pacing for patients in sinus rhythm, LVEF <35 %, prolonged QRS duration and symptoms despite medical therapy.
- Coronary artery bypass graft surgery or angioplasty may improve cardiac blood flow.
- Heart transplant may be tried if other treatments have failed.
- Risk reduction measures for secondary prevention is indicated in patient with ischemic cardiomyopathy includes aspirin, control of hypertension and diabetes, and cessation of smoking.

- Decision to proceed with medical therapy and/or surgical revascularization in patients with ischemic cardiomyopathy should be individualized.

Disease Course

- Ischemic cardiomyopathy is an independent predictor of mortality.
- Prognosis is related primarily to the degree of ventricular dysfunction and the extent of coronary artery disease.

Chapter 42
Kawasaki Disease

Richard M. Cantor, Charles V. Pollack, Jr., and Jaime Friel Blanck

Name and Synonyms

Kawasaki Disease

- Also known as mucocutaneous lymph node syndrome.

Incidence/Epidemiology

- One of the most common vasculitides of infancy and childhood.
- Its highest incidence is in East Asian children. One in 100 Japanese children will develop KD by age 5.
- Within the US, there is a winter-spring predominance of cases. Incidence estimates vary between ethnic groups in the US, with lowest rates reported amongst Caucasian children.
- Peak incidences occur before the age of one year. Eighty to 90% of cases affect children less than 5 years of age.
- The etiology of KD remains unknown. See legend.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_42

Single etiologic agent
Uncommon agent that immunologically cross-reacts with, common agent
Common agent with unusual host response
Multiple etiologic agents with final common pathway
Common agents with unusual host response

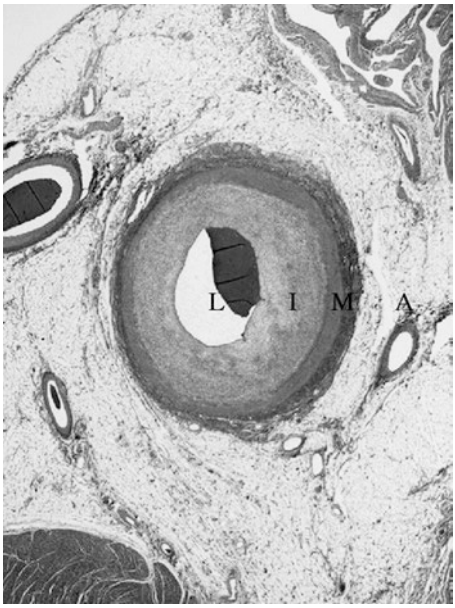
Paradigms for the cause of Kawasaki disease or syndrome. Debate continues as to whether Kawasaki disease is caused by a single etiologic agent ("disease") or by multiple different agents that result in a stereotyped host response ("syndrome"). [Burns J, Glodé M. Chapter 10. In: Wilfert CM, editor. Pediatric infectious diseases. Philadelphia: Current Medicine; 1999. (Mandell GL, editor. Atlas of infectious diseases; vol. 11). ISBN: 0-443-06526-8] *Caption from original*

Differential Diagnosis

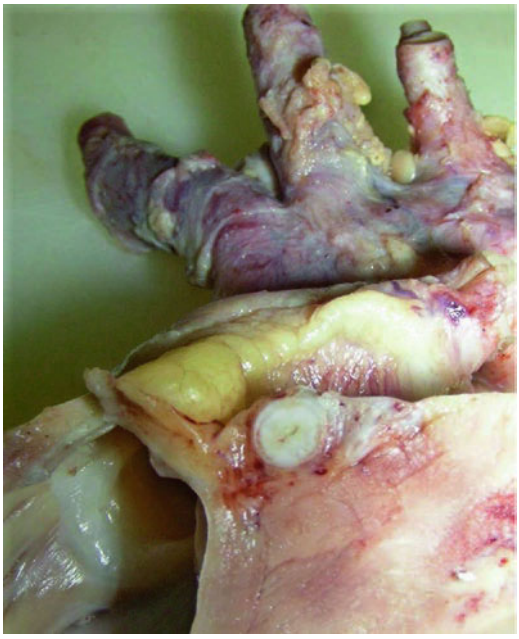
- Kawasaki Disease is accompanied by fever, an exanthema, profound mucous membrane involvement, and lymphadenitis. As such the differential diagnosis includes, but is not limited to:
  - Measles
  - Adenoviral infections
  - Scarlet fever
  - Echoviral infections
  - EBV infections
  - Rocky Mountain Spotted Fever
  - Systemic juvenile rheumatoid arthritis

Pathophysiology and Etiology

- The etiology of KD remains unknown.
- The basic pathology involves a widespread vasculitis, with particular involvement of medium-sized arteries (i.e., the coronaries).
- Coronary involvement will result in the development of aneurysms and generalized dilatation. See legend.



Coronary artery of a patient who died of pachymeningitis 9 months after contracting Kawasaki disease [Takahashi K, Oharaseki T, Yokouchi Y, Naoe S, Saji T. Kawasaki disease: basic and pathological findings. Clinical and Experimental Nephrology. 2013 Oct;17(5):690–3.] *Caption adapted from original*



Coronary artery vasculitis in a child with treatment-resistant Kawasaki disease and ischemic cardiomyopathy [Markelj G, Avčin T. Systemic Corticosteroids in Childhood Vasculitides. In: Cimaz R, editor. Systemic Corticosteroids for Inflammatory Disorders in Pediatrics [Internet]. Cham: Springer International Publishing; 2015 [cited 2015 Aug 28]. p. 77–94. Available from: http://link.springer.com/10.1007/978-3-319-16056-6_7] *Caption from original*

Presentation

Typical/"Classic"

- **Fever** is the most common presenting sign. It is usually present for more than 4 days, and generally unresponsive to antipyretic therapy. It is most often greater than 38.5° C.
- **Mucositis** involves the development of red, cracked lips and a strawberry tongue. See figure.

Strawberry tongue, mucosal redness, and cracked lips in a 3-year-old boy [Falcini F. Kawasaki Disease. In: Matucci-Cerinic M, Furst D, Fiorentino D, editors. Skin Manifestations in Rheumatic Disease [Internet]. New York, NY: Springer New York; 2014 [cited 2015 Sep 4]. p. 283–8. Available from: http://link.springer.com/10.1007/978-1-4614-7849-2_34, courtesy of Fernanda Falcini, MD] *Caption from original*

- **Conjunctival** involvement occurs in more than 85 % of patients. Though generally a superficial disease, some cases will go on to develop uveitis. See

Hemorrhagic conjunctivitis. A, In this case of conjunctivitis, the lids are not thickened and crusted but diffusely swollen. [Wald ER. Eye and Orbit Infections. In: Brook I, editor. Atlas of Upper Respiratory and Head and Neck Infections, 2e. Philadelphia: Current Medicine; 2000. (Mandell GL, editor. Atlas of infectious diseases; vol. 4). ISBN: 1-57340-140-4] *Caption from original*

- The **rash** is polymorphous. It usually involves the development of erythematous papules with variable distribution.
- One of the later findings is **induration** of the hands and feet. During the convalescent phase, distal **desquamation** occurs in 80 % of cases. See figure.

Kawasaki disease. Peeling of the top of the toes [Schneider R, Laxer R. Rheumatology. In: Laxer R, Ford-Jones EL, Friedman J, Gerstle T, editors. The Hospital for Sick Children: atlas of pediatrics. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-188-9] *Caption adapted from original*

Periungual desquamation during the convalescent phase of Kawasaki disease. The peeling is usually noted after the acute signs and symptoms of inflammation have subsided in the 2nd to 3rd week of the illness. [Burns J, Glodé M. Chapter 10. In: Wilfert CM, editor. Pediatric infectious diseases. Philadelphia: Current Medicine; 1999. (Mandell GL, editor. Atlas of infectious diseases; vol. 11). ISBN: 0-443-06526-8] *Caption from original*

Desquamating rash in child with Kawasaki disease. [Watts RA, Scott DGI. Kawasaki Disease. In: Watts RA, Scott DGI, editors. Vasculitis in Clinical Practice [Internet]. Cham: Springer International Publishing; 2015 [cited 2015 Aug 28]. p. 117–26. Available from: http://link.springer.com/10.1007/978-3-319-14871-7_11] *Caption from original*

- The presence of **lymphadenopathy** is the least consistent finding of KD.

Atypical

- There is a subcategory of KD, namely incomplete, or atypical KD. It is important for the clinician to recognize this entity, since early treatment of KD will prove cardioprotective.

- Studies of children with incomplete KD demonstrate the following variances from the typical findings:
  - Cervical adenopathy was absent in 90 % of infants.
  - Fifty percent have no rash.
  - Peripheral extremity changes were absent in 40 % of patients.
- Consistent findings seen in both typical and atypical KD include fever and mucous membrane involvement.

Primary Differential Considerations

- The most common differential considerations for KD are acute focal infections such as:
  - Orbital cellulitis
  - Lymphangitis
  - Retropharyngeal or peritonsillar abscess
- The rash of KD may look similar to:
  - Measles

Typical erythematous maculopapular rash of measles. Measles is an acute febrile infection caused by the rubeola virus and characterized by a prodrome of fever and upper respiratory symptoms followed by the characteristic measles exanthem. The rash, which is erythematous and maculopapular, usually begins on the head and spreads

downward to involve the trunk and upper and lower extremities. [Gilsdorf J, Shope T. Viral exanthems of childhood. In: Fekety R, editor. External manifestations of systemic infections. Philadelphia: Current Medicine; 1996. 237 p. (Mandell GL, editor. Atlas of infectious diseases; vol. 6.) ISBN: 0-443-07760-6] *Caption from original*

- Rocky Mountain Spotted Fever

Petechial lesions in Rocky Mountain spotted fever. [Woodward T, Sexton D, Walker D, Bleck T. Chapter 09. In: Stevens DL, editor. Skin, Soft Tissue, Bone and Joint Infections. Philadelphia: Current Medicine; 1995. 250 p. (Mandell GL, editor. Atlas of Infectious Diseases; vol. 2.) ISBN: 1-878132-44-X] *Caption adapted from original*

- Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome. A faint macular erythema is present on the trunk and arms of a febrile 4-year-old girl. The redness is accentuated in the skinfolds of the upper arms and the antecubital area. This disease occurs from the effects of epidermolytic toxins produced by some strains of *S. aureus*, most commonly group II phage types. The patients are usually children less than 5 years of age, in whom the staphylococci commonly colonize the mucous membranes of the nasopharynx, vagina, or conjunctivae, from which the toxin is readily absorbed. This disorder is rare in adults, apparently because they can inactivate or eliminate the

toxins by immunologic mechanisms or urinary excretion. Affected adults usually have had suppurative infections, rather than just mucosal colonization, and severely compromised renal or immune function. [Hirschmann J, Bleck T. Chapter 02. In: Stevens DL, editor. Skin, Soft Tissue, Bone and Joint Infections. Philadelphia: Current Medicine; 1995. 250 p. (Mandell GL, editor. Atlas of Infectious Diseases; vol. 2.) ISBN: 1-878132-44-X] *Caption from original*

- Toxic Epidermal Necrolysis

Toxic epidermal necrolysis in a female patient covering more than 30% of the total body surface area. A special critical care infrastructure such as that provided in burn centers with positive pressure units providing a constant environmental temperature of more than 30° C and an adjustable atmospheric humidity of 70% should be considered in the early course of the disease [Struck MF, Hilbert P, Mockenhaupt M, Reichelt B, Steen M. Severe cutaneous adverse reactions: emergency approach to non-burn epidermolytic syndromes. Intensive Care Medicine. 2010 Jan;36(1):22–32.] *Caption from original*

History and Physical Exam

- Most children will seek medical care due to the presence of high fevers. They will be irritable, paradoxically (i.e., not wanting to be touched). There will be a history of a rash, red eyes, and cracked lips. The rash, if present, will often be a chief complaint.

Findings That Confirm Diagnosis

- Commonly accepted diagnostic criteria for Kawasaki disease include the presence of fever for at least 5 days AND at least 4 of the 5 following criteria:
  - Conjunctival injection
  - Oral mucous membrane changes (fissured lips, strawberry tongue)
  - Peripheral extremity changes (erythema of palms/soles, edema of hands and feet, periungual desquamation)
  - Polymorphous rash
  - Cervical lymphadenopathy
- Laboratory findings consistent with a diagnosis of KD include:
  - Elevated ESR or CRP
  - Elevated WBC
  - Anemia (normochromic/normocytic)
  - Thrombocytosis (< 450,000 after 5 days)
  - Pyuria
  - Elevated liver enzymes
- Decreased serum albumin

Factors That Suggest Diagnosis

- In all published reports, the presence of fever for more than 5 days, in any pediatric age group, should raise suspicion for atypical forms of KD.

Factors that Exclude Diagnosis

- The absence of fever essentially rules out KD.

Ancillary studies

Laboratory

- The use of the laboratory is mandatory when evaluating all cases of suspected KD.

- Recommended tests include:
  - ESR or CRP
  - CBC with differential
  - Urinalysis
  - Liver function tests
  - Serum albumin

Electrocardiography

- ECG findings are not helpful.

Cardiac Enzymes

- Not indicated.

Special Populations

Age

- There have been reported cases of KD in adolescents.

Co-morbidities

- Case reports have described associated arthritis in older patients with KD.

Pitfalls in Diagnosis

- One must consider KD (in any form) when evaluating infants and children with prolonged febrile illnesses.
- Early consultation with Pediatric Cardiology is mandatory in suspected cases.

Critical Steps Not to Miss

- When presented with a patient with irritability, fever, and rash, always consider KD in your differential.

Mimics

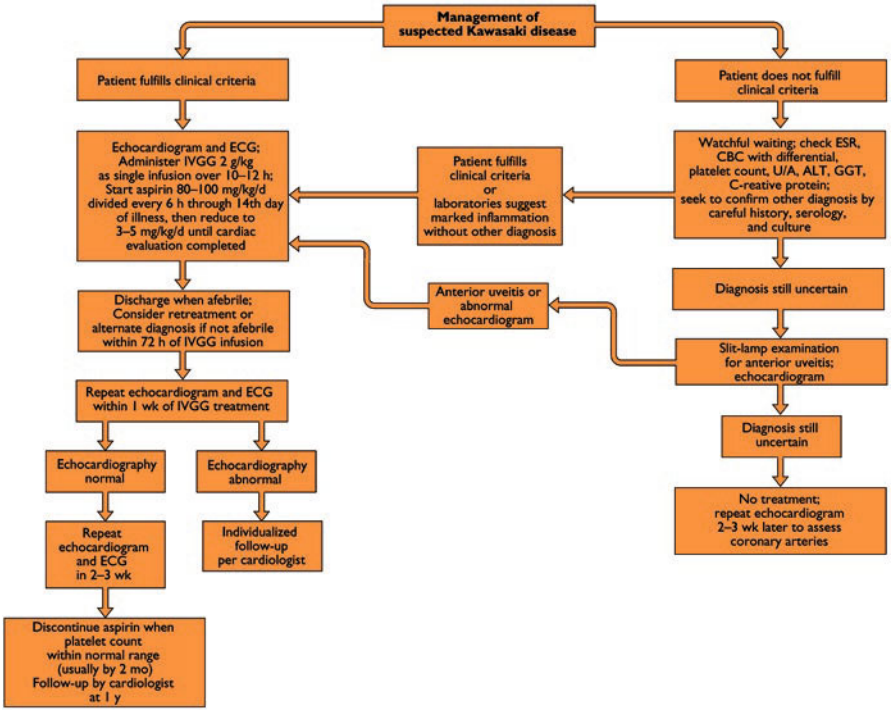
- Measles
- Adenoviral infections
- Scarlet fever
- Echoviral infections
- EBV infections
- Rocky Mountain Spotted Fever
- Systemic juvenile rheumatoid arthritis

Time-Dependent Interventions

- Obtaining a Pediatric Cardiology consult is always indicated.
- Recommended pharmacologic treatments include:
  - Administration of a single dose of IV immunoglobulin (IVIG) (2 mg/kg) over 8 to 12 hours.
  - Administration of aspirin. The recommended initial dose is 80 to 100 mg/kg/day in 4 divided doses.

Overall Principles of Treatment

- The primary goals of KD management are to prevent the development of coronary lesions and to relieve symptoms.



Algorithm for management of patients with suspected Kawasaki disease. The current recommended therapy for patients with Kawasaki disease who present within the first 10 days of illness is intravenous gamma globulin (IVGG), 2 g/kg as a single infusion over 10 to 12 hours, in conjunction with aspirin (80 to 100 mg/kg/d divided into four doses through illness day 14, then 3 to 5 mg/kg/d until cardiac evaluation is completed). The mechanism of action of IVGG has not been elucidated, although downregulation of the inflammatory response after treatment has clearly been demonstrated. ALT—alanine aminotransferase; CBC—complete blood count; ECG—electrocardiogram; ESR—erythrocyte sedimentation rate; GGT—γ-glutamyl transferase; U/A—urinalysis.[Burns J, Glodé M. Chapter 10. In: Wilfert CM, editor. Pediatric infectious diseases. Philadelphia: Current Medicine; 1999. (Mandell GL, editor. Atlas of infectious diseases; vol. 11). ISBN: 0-443-06526-8] *Caption adapted from original*

TARGETS OF THERAPY IN KAWASAKI DISEASE

LIFESTYLE MODIFICATIONS	PHARMACOLOGIC THERAPY	SURGICAL INTERVENTION
Implementation of heart-healthy diet, with specific recommendations guided by serum liqid profile	Goals	CABG
Prevention or cessation of smoking	Decrease overall prevalence and size of coronary artery aneurysms	PTCA
Physical activity guided by status of coronary arteries and use of antithrombolytic therapy (see Figs. 9-29–9-34 for stratified recommendations)	Prevent coronary artery thrombosis in patients with aneurysms	Stents
Maintenance of healthy weight	Treat ischemic heart disease in patients with coronary aneurysms	Cardiac transplantation

Targets of therapy for Kawasaki disease (KD). Children with KD and their parents should receive lifestyle modification counseling. This is especially important because various follow-up studies in children with coronary aneurysms in the acute phase have indicated that even when these aneurysms regress, there is persisting vascular dysfunction. This may put these children at risk for accelerated atherosclerosis in adulthood. [Taubert K, Newburger J. Kawasaki Disease. In: Creager MA, editor. Atlas of Vascular Disease. 2e, Philadelphia: Current Medicine; 2003. (Braunwald E, series editor, vol 07). ISBN: 1-57340-191-9] *Caption adapted from original*

Disease Course

- Long-term outcomes for children treated early with IVIG and salicylates are very favorable.

Chapter 43
Laryngospasm

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Laryngospasm

Incidence/Epidemiology

- Incidence is 8.6/1000 in adults.
- Higher incidence of 27.6/1000 was noted in children perioperatively.
- Overall incidence is just under 1 % in both adult and pediatric anesthesia.
- Increased in infants

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_43

Differential Diagnosis

- Epiglottitis
- Croup
- Tracheitis
- Retropharyngeal abscess
- Infectious mononucleosis
- Aspirated foreign body
- Laryngeal trauma
- Anaphylaxis
- Angioedema
- Vocal cord dysfunction
- Congenital anomalies

Pathophysiology and Etiology

- Acute manifestation of vocal cord dysfunction beyond the normal airway protective reflex
- Usually precipitated by irritation of the vocal cords
- May be incomplete or complete
- May occur as a complication of anesthesia, especially with ketamine
- May occur during intubation procedures or post extubation

Partial laryngospasm is not uncommon during and at the end of a bronchoscopic procedure [Goudra BG, Singh PM, Borle A, Farid N, Harris K. Anesthesia for

Advanced Bronchoscopic Procedures: State-of-the-Art Review. Lung. 2015 Aug;193(4):453–65.] *Caption from original*

Presentation

Typical/"Classic"

- Patient will describe a choking sensation and be unable to breathe or speak.
- Patient may have stridor.
- Episode may last only minutes.

Atypical

- If prolonged, may lead to hypoxia and hypercapnea
- Vocal cord dysfunction usually is chronic, and worsening of stridor may be a clue to a progressive anatomic problem.

Primary Differential Considerations

- Angioedema
- Asthma
- Epiglottitis
- Croup
- Laryngomalacia
- Tracheal foreign body
- Vocal cord paralysis or tumor

History and Physical Exam

Findings That Confirm Diagnosis

- The diagnosis is made clinically (as below), then attention is turned to the underlying cause.

Factors That Suggest Diagnosis

- Lack of upper airway patency
- Inspiratory stridor if partial obstruction
- Decreased chest wall movement
- Fever suggests an infectious etiology
- Sensation of choking and inability to breathe or speak
- Increased respiratory effort
- Tracheal tug
- Paradoxic respiratory effort
- Oxygen desaturation with or without bradycardia

Factors That Exclude Diagnosis

- A patent trachea with no increased breathing effort excludes significant laryngospasm, but stridor, even in the presence of normal respiratory effort, warrants further evaluation for a fluid or evolving clinical scenario.

Ancillary Studies

Imaging

- Imaging should never interfere with stabilization of a critical obstruction.
- Soft tissue radiographs of the neck may help diagnose epiglottitis/croup/foreign body.

Special Populations

Age

Co-morbidities

- Those with reactive airway disease are more prone to laryngospasm during intubation.

Pediatric Considerations

- Seen mainly in children, especially in infants 1–3 months of age.
- Has been reported in association with ketamine use; however, this is thought to be idiosyncratic in etiology.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Triggering factors:
  - Painful stimulation
  - Primary vagal hypertonicity
  - Insufficient depth of anesthesia on endotracheal intubation
  - Irritants:
  - Blood
  - Mucus
  - Laryngoscope blade
  - Suction catheter
  - Surgical debris or other foreign body

Mimics

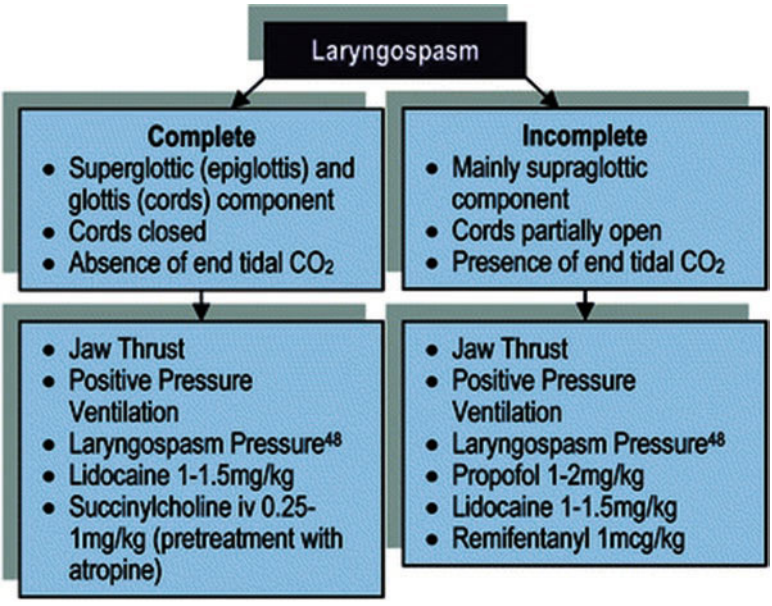
- Other causes of upper airway obstruction, such as a foreign body, may cause a clinical picture similar to that of laryngospasm, but with normal vocal cord action.

Time-Dependent Interventions

- Acute upper airway compromise/obstruction may be a life-threatening emergency.
- Prompt recognition is needed.

Overall Principles of Treatment

- Factors influencing the choice of treatment:
  - Degree of airway compromise
  - Etiology of laryngospasm
  - Presence of fever
  - Acuteness of symptom onset
  - History of injury
  - Age
- Treatment options:
  - Suctioning of foreign material from the oropharynx
  - Removal or avoidance of painful stimuli
  - "Jaw thrust" at the angle of the mandible while applying positive pressure ventilation with oxygen by bag and mask
  - Laryngospasm pressure
  - Lidocaine: 1 to 1.5 mg/kg intravenously (IV)
  - Topical lidocaine: direct administration to vocal cords
  - Succinylcholine: recommended dose varying from 0.25 to 1 mg/kg IV or 4 mg/kg intramuscularly; must be followed by definitive airway and ventilation management

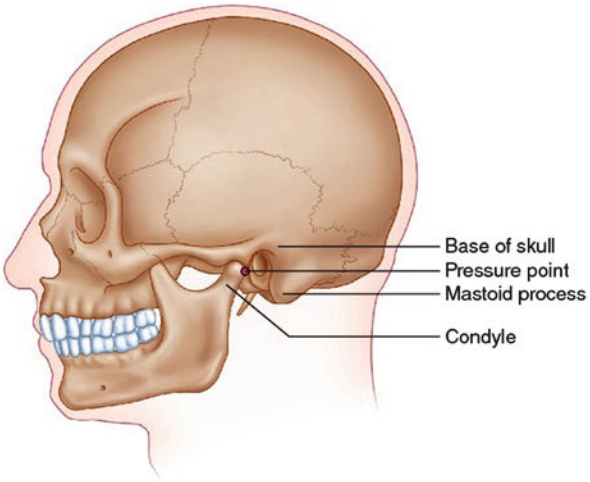


Classification and treatment options of laryngospasm [Finucane BT, Tsui BCH, Santora AH. Principles of airway management [Internet]. New York: Springer;

2010. Chapter 10, Pediatric airway management; [cited 2015 Aug 13]; p. 415–513. Available from: http://link.springer.com/10.1007/978-0-387-09558-5_10] *Caption from original*

1.	Identification and removal of the noxious stimulus (blood, secretions)
2.	Chin lift and jaw thrust
3.	Positive airway pressure with 100 % oxygen
4.	Intravenous succinylcholine (0.5–1 mg/kg) or intramuscular (1–4 mg/kg) if no IV access
5.	Deepen anesthesia with propofol or inhalational agent
6.	Endotracheal intubation if required

Treatment of laryngospasm [Adams MC, Bittner EA. Ear, Nose, and Throat Surgery. In: Sikka PK, Beaman ST, Street JA, editors. Basic Clinical Anesthesia [Internet]. New York, NY: Springer New York; 2015 [cited 2016 May 16]. p. 489–99. Available from: http://link.springer.com/10.1007/978-1-4939-1737-2_37] *Caption from original*



Laryngospasm notch [Gal JS, Yudkowitz FS, Rothschild MA. Pediatric otolaryngology. In: Levine AI, Govindaraj S, DeMaria, S, editors. Anesthesiology and otolaryngology [Internet]. New York: Springer; 2013 [cited 2015 Aug 13]. p. 333–64. Available from: http://link.springer.com/10.1007/978-1-4614-4184-7_20] *Caption from original*

Disease Course

- People experiencing laryngospasm describe a sensation of choking and cannot breathe or speak.
- As the airways slowly open, the person may have stridor.
- The episode may last only a minute or two before breathing returns to normal.
- Some people lose consciousness during these episodes.
- Underlying pathology will determine extended course and risk of recurrence.

Chapter 44
Mallory-Weiss Syndrome

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Mallory-Weiss Syndrome

- Mallory-Weiss Tear

Incidence/Epidemiology

- Mallory-Weiss tears are the fourth most common cause of upper gastrointestinal bleeding in adults.
- They account for 5 % of all upper gastrointestinal (UGI) bleeding cases.
- Three percent of deaths from UGI bleeding are the result of Mallory-Weiss tears.
- It is much less common in children.
- Mortality may be up to 3 %, but most mortality is associated with significant co-morbidities, such as portal hypertension, known coagulopathy, or older age.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_44

Differential Diagnosis

- Chest pain typically occurs with Mallory-Weiss tears, but is usually overshadowed in the presentation by the complaint of hematemesis. Mallory-Weiss tears cause UGI bleeding.
- All the causes of acute UGI bleeding need to be considered, including:
  - peptic ulcer disease (gastric and duodenal ulcers and erosions)
  - esophageal varices
  - esophagitis
  - duodenitis
- Older patients who may have coronary artery disease may develop angina from the exertion of vomiting or from the anemia that results from blood loss.
- Esophageal rupture, which only rarely causes UGI bleeding, may present with chest pain.

Pathophysiology and Etiology

- A Mallory-Weiss tear is a 1- to 4-cm longitudinal tear through the mucosa and submucosa of the esophagus or cardiac region of the stomach. The tear causes pain that may radiate into the chest.
- Bleeding results from extension of the tear into the submucosal arterial or venous plexus.
- It is usually associated with sudden increases in intra-abdominal pressure, especially from forceful vomiting.
- It also may be seen after other events that result in large increases in intra-abdominal pressure, such as straining, coughing, and seizures. It also has been noted after colonoscopy preps containing PEG (polyethylene glycol).
- Most will stop spontaneously and heal within 24–48 hours.

Presentation

Typical/"Classic"

- Acute onset of bright red hematemesis, typically following several episodes of forceful vomiting.
- May be associated with chest pain, epigastric pain, and/or back pain.
- Patient often has a history of recent, heavy alcohol use (40–80 %) or a known history of a hiatal hernia.
- Most often, patients are hemodynamically stable. A minority of cases present with bleeding significant enough to cause hemodynamic instability.

Atypical

- May be found incidentally on endoscopy performed for other reasons.

Primary Differential Considerations

- Upon initial presentation of bright red hematemesis, more serious diagnoses should be considered before attributing the findings to a Mallory-Weiss tear, such as:
  - Esophageal rupture
  - Gastric or peptic ulcer bleeding
  - Consideration should also be given to posterior epistaxis.

History and Physical Exam

Findings That Confirm Diagnosis

- There are no pathognomonic findings on history and physical exam that confirm the diagnosis.
- The diagnosis can be confirmed by upper endoscopy.

Factors That Suggest Diagnosis

- The acute onset of bright red hematemesis after prolonged, forceful vomiting associated with hemodynamic stability will strongly suggest the diagnosis.

Factors That Exclude Diagnosis

- The finding on endoscopy of another cause for UGI bleeding.

Ancillary Studies

Laboratory

- There are no laboratory tests that are specific to the diagnosis.
- Blood loss is often minimal, so the hemoglobin may be mildly reduced.

Imaging

- No specific imaging study helps in making the diagnosis, but imaging may help exclude other causes.
- Upper endoscopy is the study of choice to confirm the diagnosis and also for therapeutic intervention if indicated.

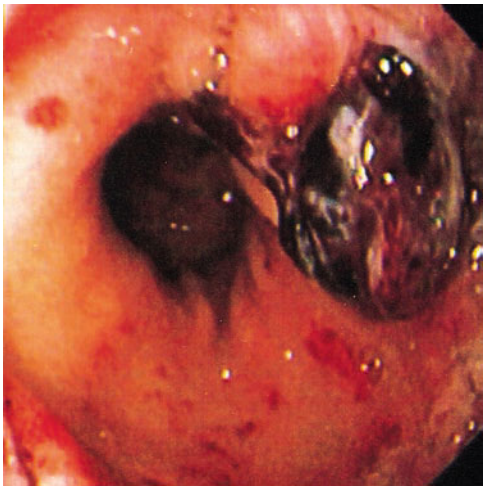
New York: Springer; 2010. p. 79–84. Available from: http://link.springer.com/10.1007/978-1-4419-1693-8_7] *Caption from original*



A Mallory-Weiss tear with an adherent clot. [Bozymski E, Kenney C, Orlando R, Feldman M. Gastroenterology and hepatology. In: Orlando RC, Feldman M, editors. Atlas of esophageal diseases. 2nd ed. Philadelphia: Current Medicine; 2002. 248 p. ISBN: 1-57340-181-1] *Caption adapted from original*

Special Populations

Age

- Slightly more common in older individuals.
- Uncommon in children, except perhaps in patients with cyclic vomiting disorders.

Co-morbidities

- Up to 80 % of cases are associated with alcoholism.
- Also associated with hiatal hernia.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is important to initially consider the more serious causes of UGI bleeding.

Mimics

- Mallory-Weiss tears can mimic other causes of UGI bleeding, such as peptic ulcers and esophageal variceal bleeding.

Time-Dependent Interventions

- Any patient with hemodynamic instability should be resuscitated, as would any patient in shock.
- Most patients are stable, and there are no time-dependent interventions.

Overall Principles of Treatment

- Most Mallory-Weiss tears stop spontaneously and do not cause physiologically significant bleeding.
- Ninety percent heal spontaneously within 24–48 hours.
- It is most important to distinguish Mallory-Weiss tears from more severe causes of UGI bleeding.
- Treatment is usually supportive, and most patients will be started on acid suppressive therapy.
- Less than 10 % of patients will have significant bleeding. These patients are given treatment similar to that of patients with other causes of UGI bleeding, with resuscitation and stabilization, and transfusions as needed.
- Endoscopic-guided therapies are usually the treatment of choice in patients with more significant bleeding. Endoscopic therapies include thermal coagulation, local injection of epinephrine or vasopressin, or balloon tamponade. In very rare cases, interventional radiologic embolization may be indicated, and even more rarely, surgical management may be indicated.
- Most patients should be admitted or observed for at least 24 hours to document stability and to allow time for endoscopy to confirm the diagnosis.

Disease Course

- The course is usually mild and self-limited.
- Ninety percent will heal spontaneously within 24–48 hours.
- Up to 7 % may re-bleed. Risk factors for re-bleeding include portal hypertension and coagulopathy.

Chapter 45
Mediastinal Masses

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Mediastinal masses

- Mediastinal tumors

Incidence/Epidemiology

- Mediastinal masses often are incidental findings of chest imaging performed for other reasons.

Differential Diagnosis

- Many neoplasms may present as mediastinal masses.
- They may be either benign or malignant lesions.
- The differential diagnosis is guided by location (anterior, middle, posterior) within the mediastinum.

C. J. Rees
Emergency Department, Pennsylvania Hospital, Philadelphia, PA, USA

R. M. Cantor
Department of Emergency Medicine and Pediatrics, State University of New York Upstate Medical University, Syracuse, NY, USA

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_45

Pathophysiology and Etiology

- The anterior mediastinum is the anatomic space that extends from the posterior aspect of the sternum to the anterior aspect of the great vessels and pericardium. Contained within the anterior mediastinum are the thymus, lymph nodes, and internal mammary arteries and veins. It is the most common location for mediastinal masses in adults. The most common masses found within the anterior mediastinum (in decreasing order of prevalence) are thymomas, teratomas (germ-cell tumors), lymphoma, and thyroid masses that extend into the anterior mediastinum.
- The middle mediastinum extends from the anterior pericardium to the posterior pericardium. It contains the heart, great vessels, airway, lymph nodes, and phrenic nerve. The most common cause of a mass within the middle mediastinum is lymphadenopathy from lymphoma, sarcoidosis or other granulomatous diseases, infectious processes, and metastatic lung cancer.
- The posterior mediastinum extends from the posterior aspect of the pericardium and trachea to the spine. It contains the descending thoracic aorta, esophagus, thoracic duct, azygous veins, posterior lymph nodes, spinal ganglia, and sympathetic chain. Neurogenic tumors are the most common posterior mediastinal tumors, especially in children.

Presentation

Typical/"Classic"

- Masses within the mediastinum are often asymptomatic.
- They commonly are found while undergoing diagnostic studies for other reasons.
- Symptoms, if present, usually result from direct compression from tumors or direct infiltration into surrounding structures.
- Compression, obstruction, or infiltration of airway structures may lead to cough, stridor, hemoptysis, shortness of breath, or pain. Hoarseness may result from phrenic nerve compression. Dysphagia may result from compression (either intrinsic or extrinsic) of the esophagus.
- Superior vena cava syndrome is a symptom complex due to compression or infiltration of the superior vena cava by a pathologic process in a contiguous structure. The most common causes are malignancies (either primary or metastatic) within the mediastinum. Dyspnea is the most common symptom, but facial swelling and "fullness" and arm swelling usually are present. The most characteristic exam finding is distension of the veins in the arm and neck.
- Malignant masses are more likely to be symptomatic.
- Many tumors, especially the lymphoproliferative tumors, may cause constitutional symptoms such as fevers, night sweats, and weight loss.

Atypical

- Mediastinal masses are often asymptomatic. More dramatic presentations, such as acute dyspnea, pneumonia with hemoptysis, or severe pain, are less common.

Primary Differential Considerations

- When evaluating a patient suspected of having a mediastinal mass, one also should consider these differential diagnoses:
  - Cysts
  - Enlarged thyroid
  - Aneurysm (aortic arch or proximal great vessels)
  - Loculated pleural effusion
  - Pneumonia

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical exam findings that can confirm the diagnosis.
- The diagnosis usually is confirmed by imaging studies, most commonly CT scan of the chest. Biopsies may also be needed to confirm specific pathology.

Factors That Suggest Diagnosis

- These are often asymptomatic and found incidentally when performing diagnostic imaging studies for other reasons.
- Symptoms are nonspecific, but any of the symptoms reviewed in the classic presentation section above should suggest the diagnosis. Often, persistence of nonspecific symptoms results in the diagnostic study that leads to the diagnosis.

Factors That Exclude Diagnosis

- If a mediastinal mass is suspected, imaging (CT or magnetic resonance [MR]) with or without biopsy is required to exclude it or establish an alternative diagnosis.

Ancillary Studies

Laboratory

- Laboratory studies are often nonspecific.
- Lymphoproliferative tumors may be associated with anemia and other hematopoietic cell line abnormalities.
- Some specific tumors will have biologic tumor marker abnormalities.

Imaging

- Most mediastinal masses are found incidentally while performing diagnostic imaging of the chest for other reasons.
- They most often are discovered on either plain chest x-ray or CT scan of the chest.
- The diagnostic study of choice is usually a contrast-enhanced CT scan of the chest.

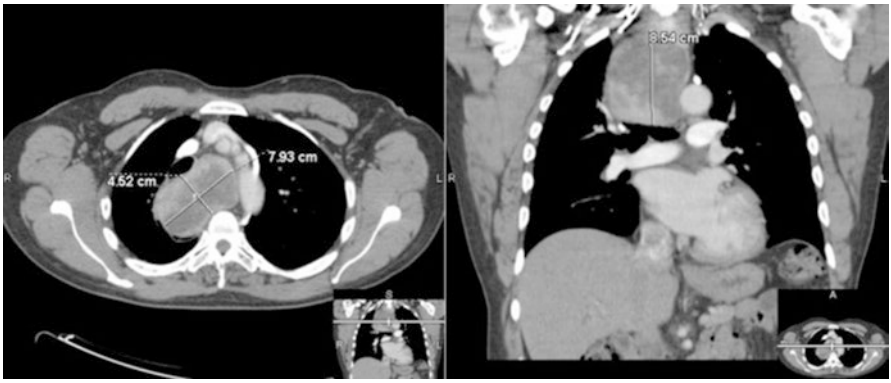
CT scan demonstrating a large anterior mediastinal mass. [Szokol J, Vender J. Respiratory emergencies (pulmonary aspiration of gastric contents, acute epiglottis, anterior mediastinal mass). In: Tremper KK, editor. Principles of anesthetic techniques and anesthetic emergencies. Philadelphia: Current Medicine; 1998. 195 p. (Miller RD, editor. Atlas of anesthesia; vol. 4). ISBN: 0-443-07903-X]



CT of the chest revealing a posterior mediastinal mass that extends all the way down to the aortic arch with tracheal compression and deviation. [From article: Novel thoracoscopic approach to posterior mediastinal goiters: report of two cases. Journal of Cardiothoracic Surgery. 2008;3(1):55. https://doi.org/10.1186/1749-8090-3-55, at http://link.springer.com/article/10.1186%2F1749-8090-3-55/fulltext.html; by Faisal Al-Mufarrej, Marc Margolis, Barbara Tempesta, Eric Strother, Farid Gharagozloo, © Al-Mufarrej et al; licensee BioMed Central Ltd. 2008; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*

Special Populations

Age

- The etiologies of mediastinal masses differ in children and adults as per the etiology section above.
- Most mediastinal masses in children are discovered on routine chest radiographs.
- Warning signs in pediatric mediastinal masses are similar to those seen in adults, such as weight loss, cough, shortness of breath, or localized wheezing. Inexperienced readers are often concerned about the normal mediastinal silhouette of the thymus in young patients.

Co-morbidities

- Expected co-morbidities depend on the cell type of the mass.
- The clearest associations are between thymoma and myasthenia gravis and between chronic lung disease and pulmonary tumors.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Advanced imaging (CT/MR) will guide the diagnostic evaluation.

Mimics

- Thyroid enlargement and pulmonary infections are the diagnoses most likely to initially be confused with a mediastinal mass.

Time-Dependent Interventions

- Patients with respiratory or cardiovascular insufficiency (uncommon at presentation) must be stabilized.

Overall Principles of Treatment

- Treatment depends on the type of neoplasm and whether any symptomatic obstruction or compression exists.
- As with most neoplasms, a tissue diagnosis must be confirmed to guide appropriate treatment. This commonly can be achieved by percutaneous biopsy guided by imaging of the appropriate anatomic area, such as CT scan, endoscopy (both endobronchial and esophageal), and echocardiography. In rare cases, video-assisted mediastinoscopy or thoracoscopy will need to be performed.

Disease Course

- The disease course depends on the specific diagnosis.

Chapter 46
Mediastinitis

Christopher J. Rees, Richard M. Cantor, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Mediastinitis

Incidence/Epidemiology

- Acute necrotizing mediastinitis is a life-threatening infection of the mediastinum.
- Historically, it was an uncommon but deadly complication of retropharyngeal space infections that tracked downward from the prevertebral fascia into the posterior mediastinum. Currently, acute mediastinitis occurs most often after cardiovascular or thoracic surgery.
- It also may result from esophageal perforation/rupture.
- The incidence postoperatively ranges from 0.5–5 %, but most large, experienced centers have rates lower than 2 %.

C. J. Rees

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_46

- The incidence is higher for heart transplant patients and those with cardiac assist devices in place.
- The mortality approaches 25 %, even with appropriate treatment.

Differential Diagnosis

- The differential diagnosis is broad and includes any cause of sepsis syndrome, especially during the postoperative period.

Pathophysiology and Etiology

- The pathophysiology of postoperative mediastinitis is complex, but the final common pathway appears to be intraoperative wound contamination. It may occur even in the presence of meticulous surgical technique and sterile preparation. It seems to be related more to host factors than surgical technique.
- Recognized risk factors for postoperative mediastinitis include:
  - Diabetes or perioperative hyperglycemia
  - Obesity
  - Peripheral vascular disease
  - Tobacco use
  - Prior cardiac surgery
  - Dissection of the internal mammary artery
  - Procedure longer than 5 hours
  - The need to return to the operating room within 4 days
  - Prolonged postoperative ICU stay
- A single organism causes most cases.
- Virtually any organism can cause mediastinitis, but the most commonly reported are:
  - Methacillin-sensitive *Staphylococcus aureus* (MSSA), 45 %
  - Methacillin-resistant *S. aureus* (MRSA), 16 %
  - Gram-negative rods, 17 %
  - Coagulase-negative staphylococci, 13 %
  - Streptococci, 5 %
- Mediastinitis also may result from esophageal rupture, with direct spread of esophageal contents into the mediastinum.
- Other (uncommon) causes include:
  - complication of retropharyngeal space infection
  - rupture of a mediastinal abscess
  - direct extension of empyema into the mediastinum
- Bacteremia is present in more than 50 % of cases.

Presentation

Typical/"Classic"

- Classically, patients with postoperative mediastinitis will have fever, tachycardia, chest pain, sternal instability from a sternal wound infection, and/or purulent wound drainage from the sternal area. Patients with nonoperatively related mediastinitis also often present with a sepsis-like syndrome or frank sepsis.

Atypical

- Patients may present with postoperative fever alone.
- Patients may be found to have asymptomatic postoperative bacteremia.
- Patients may show signs only of superficial wound infection.
- The infection may take a more indolent course, with vague symptoms.

Primary Differential Considerations

- Early in the evaluation of patients with symptoms of mediastinitis, consider the following important differential diagnoses:
  - Acute coronary syndrome
  - Aortic dissection
  - Pulmonary embolism
  - Acute pericarditis
  - Pneumothorax
  - Deep neck infection
  - Pneumonia
  - Esophageal rupture

History and Physical Exam

Findings That Confirm Diagnosis

- Intraoperative findings of purulent discharge with necrotizing infection can confirm the diagnosis.
- Patients who present within two weeks of cardiovascular or thoracic surgery with fever, tachycardia, chest pain, sternal wound instability, and sternal wound infection may be considered to have mediastinitis, and treatment should be initiated immediately.

Factors That Suggest Diagnosis

- Patients presenting postoperatively with sepsis or a sepsis-like syndrome with no other obvious source, especially if there is bacteremia.

Factors That Exclude Diagnosis

- A normal, uncomplicated postoperative course excludes the diagnosis.

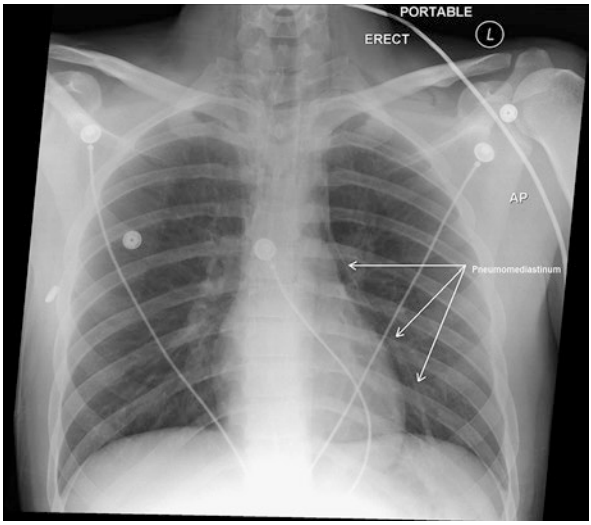
Ancillary Studies

Laboratory

- Patients often manifest the laboratory abnormalities associated with sepsis or an acute infectious process, such as leukocytosis with bandemia or leftward shift, acidosis, and an elevated lactate level.
- Bacteremia is present in more than 50 % of cases.

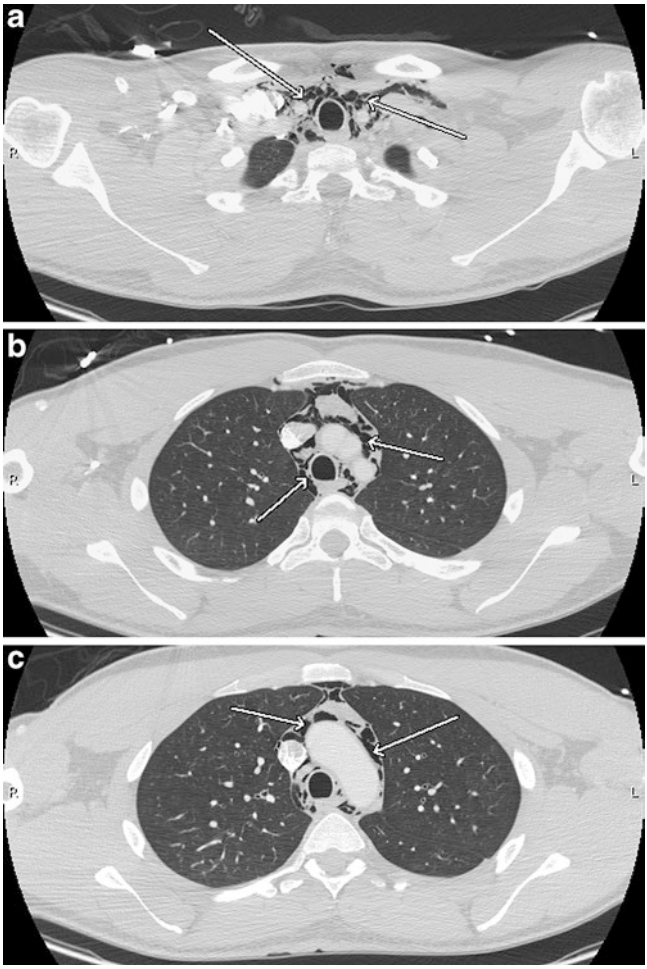
Imaging

- Plain chest radiography is sometimes helpful in suggesting alternative causes for the fever, such as pneumonia or atelectasis. The x-ray also may reveal findings that increase suspicion for mediastinitis in the correct clinical setting, such as pleural or pericardial effusion, empyema, and pneumomediastinum, all of which may result from mediastinitis.



Chest X-ray showing pneumomediastinum. [From article: Pneumomediastinum from nasal insufflation of cocaine. International Journal of Emergency Medicine. 2010 Dec;3(4):435–7. https://doi.org/10.1007/s12245-010-0205-9, at http://link.springer.com/article/10.1007%2Fs12245-010-0205-9; by Brian T. Kloss, Claire E. Broton, Elliot Rodriguez, © Springer-Verlag London Ltd 2010; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption adapted from original*

- CT of the chest with intravenous contrast is the study of choice if the diagnosis is in question. CT is most helpful in the following situations:
  - In patients with systemic signs and symptoms (fever, tachycardia, hypotension, chest pain), with or without bacteremia, when there are no signs of a sternal wound infection or instability
  - When there is clinical evidence of a sternal wound infection but no systemic signs or symptoms
  - In the evaluation of asymptomatic, postoperative bacteremia



Contrast-enhanced CT with arrows showing pneumomediastinum [From article: Pneumomediastinum from nasal insufflation of cocaine. International Journal of Emergency Medicine. 2010 Dec;3(4):435–7. https://doi.org/10.1007/s12245-010-0205-9, at http://link.springer.com/article/10.1007%2Fs12245-010-0205-9; by Brian T. Kloss, Claire E. Contrast-enhanced CT scan of descending necrotizing mediastinitis at the lower neck shows brachiocephalic vein thrombosis (arrow), increased density of the middle mediastinal space (white asterisk), and bilateral pleural effusion. In addition, swelling of the left soft tissues of the thorax is evident (black asterisk) [Scaglione M, Pinto A, Romano S, Giovine S, Sparano A, Romano L. Determining optimum management of descending necrotizing mediastinitis with CT; experience with 32 cases. Emerg Radiol. 2005 Jul;11(5):275–80.] *Caption adapted from original*

Special Populations

Age

- Mediastinitis may occur at any age but is most common in older patients after cardiac or thoracic surgery.
- Mediastinitis also may occur in the pediatric population as a complication of cardiovascular or thoracic surgery, or as a complication of retropharyngeal abscess.
- Soft tissue neck infections in children (parapharyngeal abscess, peritonsillar abscess, retropharyngeal abscess, dental abscess, etc.) also contribute to the development of mediastinitis.

Co-morbidities

- Review of the etiologies of acute mediastinitis will indicate co-morbidities of interest. Diabetes, obesity, tobacco use, peripheral arterial disease, and prior cardiac/thoracic surgery are the most concerning.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Consideration of the diagnosis is the first critical step. Patients who present with sepsis or sepsis-like syndrome postoperatively or those with evidence of a sternal wound infection need urgent resuscitation and institution of broad-spectrum antibiotic coverage while a more definitive diagnosis is pursued.

Mimics

- Many other infectious processes can mimic mediastinitis. Pneumonia and empyema may occur in isolation but also may coexist or be a complication of mediastinitis.
- Superficial sternal wound infection may mimic mediastinitis.

Time-Dependent Interventions

- Consideration of the diagnosis and adequate resuscitation and antibiotic coverage are critical.
- Mortality increases as the infection and necrosis progress.

Overall Principles of Treatment

- Adequate resuscitation and antibiotic coverage are critical.
- Definitive treatment usually involves surgical debridement and continued antibiotics.

Disease Course

- The mortality of postoperative mediastinitis may approach 50 %, even with adequate treatment.
- The occurrence of postoperative mediastinitis is associated with an increased mortality rate that continues for 10 years postoperatively.

Chapter 47
Mitral Valve Prolapse

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Mitral Valve Prolapse (MVP); systolic click-murmur syndrome; Barlow's syndrome

Incidence/Epidemiology

- MVP is the most common heart valve abnormality, found in about 3–5% of the US population.
- The clinical syndrome associated with MVP is quite variable, but it is usually benign.

Differential Diagnosis

- The primary differential considerations for chest pain associated with MVP are mitral regurgitation and anxiety/panic attacks.
- Older patients with chest pain and palpitations should be evaluated for possible ACS.

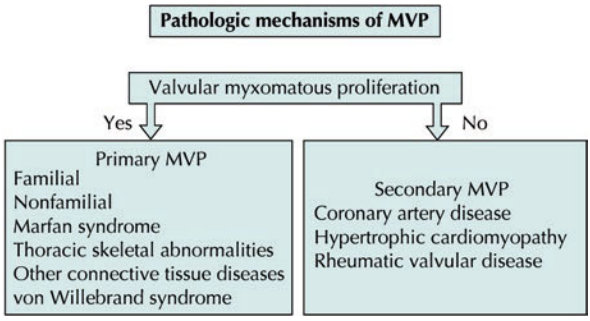
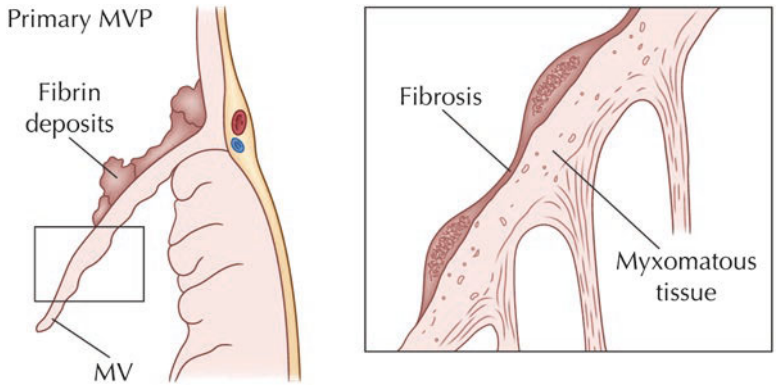
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_47

Pathophysiology and Etiology

- Mitral valve prolapse is a ballooning of a competent (or minimally incompetent) mitral valve into the left atrium during left ventricular systole. This anatomic defect may result from:
  - Redundant mitral leaflet tissue (myxomatous degeneration)
  - Elongated or redundant chordae tendineae
  - Inherited connective tissue disorders such as Marfan's and Ehler-Danlos syndromes



Causes of mitral valve prolapse. A variety of pathologic mechanisms involving any of the functional components of the mitral valve apparatus can result in MVP. Prominent among these is valvular collagen disruption and myxomatous infiltration, termed primary MVP. In most cases, primary MVP is an inherited disorder; it can also occur in a nonfamilial, isolated form. Less commonly, primary MVP is associated with connective tissue diseases. The most important of these is Marfan syndrome, where it can be detected echocardiographically in greater than 90% of affected patients. Thoracic skeletal abnormalities (pectus excavatum, pectus carinatum, straight back syndrome, scoliosis) are also associated with primary MVP. Primary MVP may be a manifestation of a generalized disorder of connective tissue, with a variable range of phenotypic expression within and outside of the cardiovascular system. For example, it can also be associated with myxomatous changes and prolapse of the tricuspid (40%), pulmonic (10%), and aortic valves (2%). The histologic changes are similar to those seen in the mitral valve. Other associated conditions include ostium secundum atrial septal defect and Wolff-Parkinson-White syndrome. Secondary MVP occurs in the absence of myxomatous valvular proliferation and can occur in patients with hypertrophic cardiomyopathy and occasionally as a result of coronary artery disease. Prior rheumatic fever may result in secondary MVP, especially of the anterior leaflet. [Prabhu S, O'Rourke R, Rahimtoola S. Chapter 10. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. 200 p. ISBN: 1-878132-30-X] *Caption adapted from original*



Primary mitral valve prolapse. Histopathology of primary mitral valve prolapse (MVP). A, The normal mitral valve (MV) is composed of three layers: 1) the atrialis, a thin layer of collagen and elastic tissue along the atrial aspect of the leaflet; 2) the fibrosa (ventricularis), a denser layer of collagen along the ventricular aspect; and 3) the spongiosa, the fine myxomatous connective tissue layer between the two. B, In primary MVP, dissolution of collagen bundles occurs primarily with secondary myxomatous proliferation of the spongiosa and interruption of the fibrosa and fibrosis of the atrial and ventricular surfaces of the valve. These secondary effects appear to occur as a response to repeated stress on the valve apparatus. Focal endothelial disruption occurs commonly and may provide a site for thrombus formation. Fibrin deposits often form at the MV–left atrial angle. Similar histologic changes can occur in the chordae tendineae and result in chordal thinning and rupture. Myxomatous degeneration of the annulus can occur as well, especially in patients with connective tissue disorders, resulting in annular dilation and calcification and worsening of mitral regurgitation. [Prabhu S, O'Rourke R, Rahimtoola S. Chapter 10. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. 200 p. ISBN: 1-878132-30-X] *Caption adapted from original*

- The ballooning often causes a click that is audible on cardiac auscultation. If there is any incompetence to the overlapping leaflets, a murmur will also result.
- The chest pain associated with MVP, which is typically described as sharp or stabbing, is *not* anginal in origin. MVP is not associated with coronary artery disease nor does it have any other direct relation to myocardial ischemia.
- Chest pain in MVP is often associated with anxiety or panic disorder.
- Besides chest pain and anxiety, MVP is also associated with a variety of symptoms that can prompt acute presentation, including:
    - Autonomic dysfunction
    - Palpitations from both supraventricular and ventricular premature beats
    - Lightheadedness
    - Syncope

- Very rarely, the redundant valve leaflets in MVP can be a nidus for vegetations of endocarditis. This is (relatively) much more common in the frankly regurgitant mitral valve.

Presentation

Typical/"Classic"

- Many patients with MVP are asymptomatic. Chest pain due to MVP is most often described as sharp and stabbing, associated with anxiety, and is occasionally accompanied by palpitations.

Palpitations
Chest pain
Dyspnea
Fatigue
Syncope and lightheadedness
Focal neurologic events
Anxiety

Symptoms in mitral valve prolapse. The most common symptom is palpitations, which often correlates poorly with arrhythmias on ambulatory electrocardiographic monitoring. Chest pain is usually atypical and does not resemble angina pectoris. The etiology is unknown. It has been suggested that the prolapsing mitral valve places undue tension on the papillary muscles and results in subendocardial ischemia. Dyspnea and fatigue may occur without mitral regurgitation or objective impairment of exercise tolerance. Syncope and presyncope may occur in association with postural hypotension and arrhythmias but often are present without any clinical correlates. Transient neurologic events occur with greater frequency in patients with MVP, although the overall incidence is quite low. These may be the result of platelet and fibrin emboli occurring at sites of endothelial disruption and at the mitral valve–left atrial junction. The true association of MVP and neuropsychiatric syndromes remains controversial. [Prabhu S, O'Rourke R, Rahimtoola S. Chapter 10. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. 200 p. ISBN: 1-878132-30-X] *Caption adapted from original*

- Patients may or may not report a previously detected click or murmur.

Atypical

- Typical anginal features (pressure-like pain, midsternum perhaps radiating to jaw or left upper extremity, related to exertion) would be very unusual in describing pain caused by MVP.

Primary Differential Considerations

- When evaluating a patient suspected of having MVP, one should also consider the following differential diagnoses:
  - Mitral regurgitation
  - Anxiety

History and Physical Exam

Findings That Confirm Diagnosis

- The diagnosis of MVP is typically made upon cardiac auscultation. There is usually a mid-systolic ejection click thought to be caused either by the tensing of the elongated chordae or by the snapping of the redundant valve leaflet tissue at the peak of systole.

https://www.youtube.com/watch?v=PsmGx2XMxF8
Audio of mid-systolic click

- The murmur, which is less consistently identified than the click, is usually high-pitched, crescendo-decrescendo, and heard best at the apex.

https://www.youtube.com/watch?v=MMJBSd5Z_Uc&list=PL85424CD4340A8D55
Audio of mitral regurgitation murmur

- The click and murmur occur earlier and louder with standing and with Valsalva, and occur later and more quietly (and indeed may disappear) with squatting and isometric exercise.

https://www.youtube.com/watch?v=AHBzu5zhFuA
Video on mitral valve prolapse and mitral regurgitation. Offers animation of blood flow and muscle movement.

Factors That Suggest Diagnosis

- The click and murmur are suggestive of MVP even without chest pain.
- Other body habitus characteristics of connective tissue disease may be helpful.

Thoracic skeletal abnormalities
Arachnodactyly
High-arched palate
Low body weight (< 90% ideal)
Low blood pressure (< 120 mm Hg systolic)
Orthostatic hypotension and tachycardia

Physical findings in mitral valve prolapse. General physical findings in MVP. Thoracic skeletal abnormalities can be seen in association with MVP. Arachnodactyly may be seen without other evidence for Marfan syndrome and these cases may represent formes frustes of this disorder. Patients with MVP tend to have low body weight, low systolic blood pressure, and postural hypotension and tachycardia. These signs may be related to a combination of autonomic dysfunction and reduced intravascular volume in these patients. [Prabhu S, O'Rourke R, Rahimtoola S. Chapter 10. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. 200 p. ISBN: 1-878132-30-X] *Caption adapted from original*

Factors That Exclude Diagnosis

- No history or physical findings can definitively exclude MVP; an echocardiogram is required.

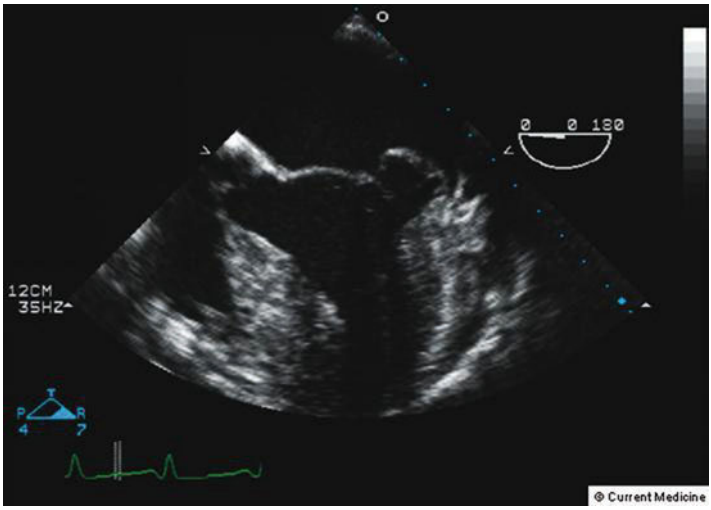
Ancillary Studies

Laboratory

- There are no diagnostic laboratory studies for MVP.

Imaging

- Echocardiography can confirm or refute the diagnosis of MVP and can differentiate it from mitral regurgitation.



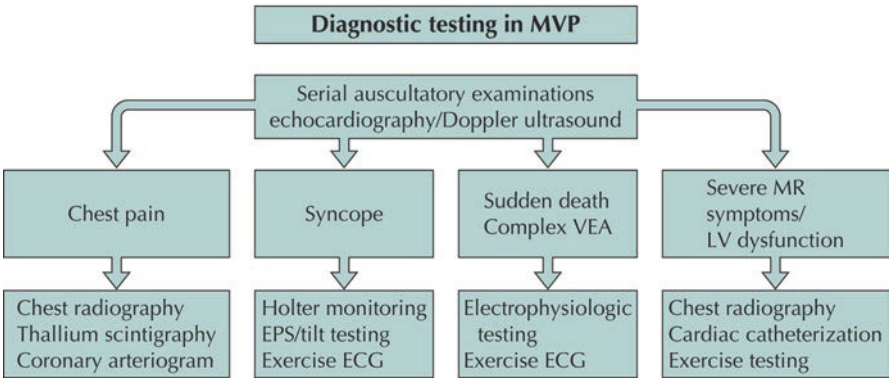
Mitral valve prolapse: transesophageal echocardiogram. Transesophageal echocardiogram showing prolapse of the mitral valve. [Greer DM, Kamalian S, Silverman SB, Mitha AP, Kinnecom CE, Sanborn DY, Greenberg SM, Ogilvy CS, Lev MH, Kistler JP, Furie KL, Camargo ECS de. Cerebrovascular Disease. In: Rosenberg RN, editor. Atlas of Clinical Neurology [Internet]. Current Medicine Group; 2009 [cited 2015 May 20]. p. 133–214. Available from: http://link.springer.com/chapter/10.1007/978-1-57340-359-7_5] *Caption adapted from original*

B, Doppler color flow image of the same valve with a large regurgitant jet (arrow) directed away from the prolapsed leaflet. LA—left atrium; LV—left ventricle; RA—right atrium; RV—right ventricle. [Clements F, de Bruijn N,

Bennett-Guerrero E, Newman M, Reves JG. Chapter 1. In: Miller RD, Muravchick S, editors. Atlas of Anesthesia: Subspecialty Care, Volume 5, 1e. Philadelphia: Current Medicine; 1998. 236 p. ISBN: 0-443-07905-6] *Caption from original*

https://www.youtube.com/watch?v=h6aJSuUTVb0
Video depicting echocardiography of mitral valve prolapse.

- It has been thought in the past that echocardiographic studies "overdiagnosed" MVP. This concern can be alleviated at least in part by relying on the parasternal long-axis view.
- Other imaging or tests are sometimes helpful.



Diagnostic testing in mitral valve prolapse (MVP). The diagnosis of MVP is based on the presence of typical auscultatory findings detected during carefully performed serial examinations. Echocardiography (M-mode, two-dimensional, and Doppler) is the single most useful test in the definition of MVP. It is used to assess natural history and prognosis, the presence of associated conditions (e.g., atrial septal defect, hypertrophic cardiomyopathy), the need for antibiotic prophylaxis, and the degree of mitral regurgitation (MR). Echocardiography should not supplant the physical examination in the diagnosis of MVP; up to 10% of patients diagnosed with MVP by typical auscultatory findings will have a non-diagnostic two-dimensional echocardiogram. Electrocardiography (ECG) is routinely performed to assess for ventricular preexcitation and resting ST- and T-wave abnormalities. The tests listed in the lowest level of the flow diagram are not required for the diagnosis of MVP, but they are useful in assessing certain symptoms and complications that can occur in this disorder. EPS—electrophysiology; LV—left ventricular; MR—mitral regurgitation; VEA—ventricular ectopic arrhythmia. [Prabhu S, O'Rourke R, Rahimtoola S. Chapter 10. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. 200 p. ISBN: 1-878132-30-X] *Caption from original*

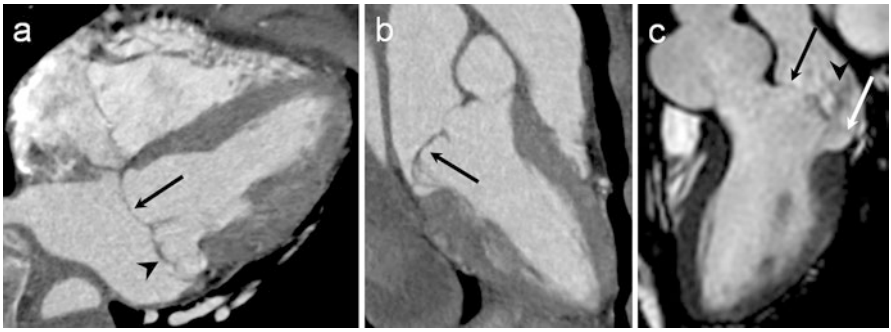
Special Populations

Age and Gender

- MVP is more common in females than males.
- It is most commonly diagnosed in the second or third decade of life.
- MVP in children most often presents with palpitations.
- Children will often describe a "butterfly" in their chest.

Co-morbidities

- Connective tissue diseases such as Marfan's are often associated with MVP.



A 33-year-old woman with Marfan syndrome and mitral valve prolapse. a, b Four- (a) and two-chamber (b) CT images in systole show entire anterior mitral leaflet prolapse (arrows) and P2 prolapse in the posterior mitral leaflet (arrowheads). c Three-chamber balanced-steady state precession cine cardiac MRI in systole demonstrates bileaflet mitral prolapse (arrows) and a dephasing jet from mitral regurgitation (arrowhead) [Ko SM, Song MG, Hwang HK. Evaluation of the aortic and mitral valves with cardiac computed tomography and cardiac magnetic resonance imaging. Int J Cardiovasc Imaging. 2012 Nov 9;28(2):109–27.] *Caption from original*

Pitfalls in Diagnosis

Critical Steps Not to Miss

- There are no critical steps in diagnosing MVP. The clinical situation is more important if mitral regurgitation has developed. Either way, an echocardiogram is diagnostic.

Mimics

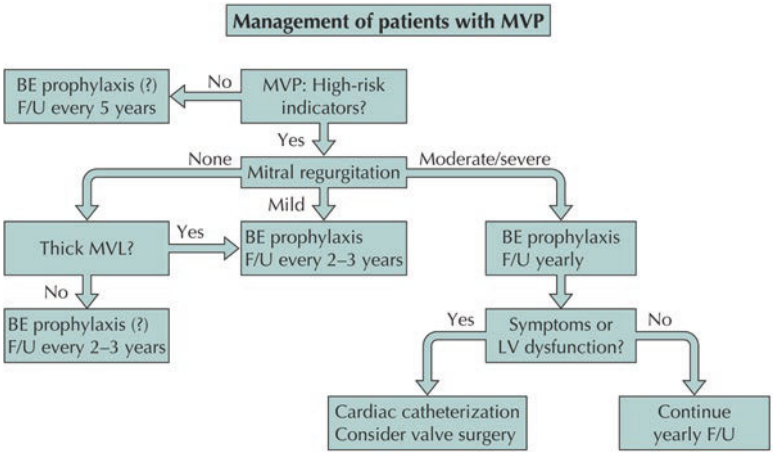
- Acute anxiety or panic disorder can mimic MVP, especially if there is a coincident heart murmur or history thereof.
- It is unlikely that chest pain associated with MVP will be confused with anginal pain.

Time-Dependent Interventions

- There are no time-dependent interventions in the diagnosis and management of MVP.

Overall Principles of Treatment

- For most cases of MVP, reassurance of the benign nature of the valve abnormality is sufficient.

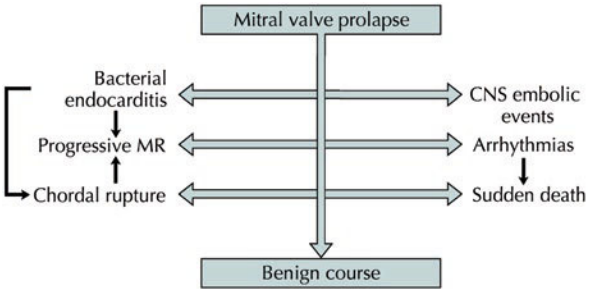


Management of mitral valve prolapse. Management of patients with mitral valve prolapse (MVP). High-risk characteristics in MVP patients are additive, that is, the more indicators present, the greater the total risk. The majority of patients with MVP are asymptomatic and have no or minimal high-risk indicators. They are treated with reassurance and can lead a normal life. Clinical and echocardiographic assessment every 5 years is reasonable to determine passage into a higher risk group. If any high-risk indicators are present, patients can be further stratified based on the presence of mitral regurgitation (MR). Some authorities advocate prophylaxis for bacterial endocarditis (BE) only if MVP is associated with MR or thickened mitral valve leaflets (MVL). However, given the variability of physical findings and the dynamic nature of MR in MVP, prophylaxis may be reasonable in all patients with MVP. Patients with MVP and severe MR should be managed in the same manner as patients with severe MR due to other causes. The decision to proceed with valve surgery is based on the presence of symptoms or impairment of left ventricular (LV) systolic function. Mitral valve reconstructive surgery can often be used in lieu of valve replacement to correct regurgitant floppy valves. Compared with valve replacement, valve repair is associated with a lower operative and late mortality, lower long-term thromboembolic risk, and lower BE risk. F/U—follow-up. [Prabhu S, O'Rourke R, Rahimtoola S. Chapter 10. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. 200 p. ISBN: 1-878132-30-X] *Caption adapted from original*

- For patients with frequent chest pain, palpitations, or other autonomic manifestations, beta-adrenergic blockage may provide symptomatic relief.
- An echocardiogram will provide a basis for deciding whether or not patients with MVP should receive antibiotic prophylaxis prior to dental procedures or other procedures that could result in transient bacteremia.
- Patients with mitral regurgitation should be managed by a cardiologist.

Disease Course

- MVP generally runs a benign course.



Clinical course in mitral valve prolapse. Overview of the clinical course in MVP. The majority of patients with MVP follow a benign course and their age-adjusted survival is similar to persons without MVP. However, serious complications can occur in 10% to 20% of patients. These include infective endocarditis, chordal rupture, progressive mitral regurgitation (MR), life-threatening arrhythmias, neurologic and embolic events, and sudden death. The risk of infective endocarditis is five to eight times greater in patients with MVP than in the general population and MVP is the leading underlying diagnosis in patients with endocarditis. Progressive MR is often accelerated by infective endocarditis or chordal rupture. The overall incidence of ophthalmologic and central nervous system (CNS) embolic events is generally low. An increase in risk for CNS events associated with MVP is detectable in patients who do not have other cerebrovascular risk factors, especially young women. Sudden death is the least common complication of MVP and occurs mainly in patients with significant MR, reduced ventricular function, and malignant ventricular arrhythmias. [Prabhu S, O'Rourke R, Rahimtoola S. Chapter 10. In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. 200 p. ISBN: 1-878132-30-X] *Caption adapted from original*

- Patients should be evaluated intermittently to assess for progression to mitral regurgitation.

Chapter 48
Mitral Valve Regurgitation

Charles V. Pollack, Jr. and Jaime Friel Blanck

Name and Synonyms

Mitral valve regurgitation
Mitral valve incompetence
Mitral valve insufficiency

Incidence/Epidemiology

- Mitral valve disorders are the second-most common valvulopathies (aortic valve is most common).
- Mitral regurgitation (MR) may be acute or chronic. The chronic form is most often related to prior rheumatic fever, the incidence of which is decreasing in the industrialized world. The acute form is most often a complication of acute inferior wall myocardial infarction, and is rare but potentially catastrophic.
- MR is more common in females.

Differential Diagnosis

- The differential diagnosis of MR includes
  - Endocarditis
  - Aortic regurgitation/insufficiency
  - Ventricular septal defect

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_48

Pathophysiology and Etiology

- The explicit pathophysiology of MR is reduced resistance to emptying of the left ventricle (LV), with regurgitant return of LV blood to the left atrium (LA).

Primary mitral regurgitation:
Mitral valve prolapse: the most common cause of mitral regurgitation in developed countries
Rheumatic disease: more common in underdeveloped countries. Usually manifests as mitral stenosis or double mitral lesion
Annular calcification: associated with aging. Does not cause severe mitral regurgitation
Infective or marantic endocarditis (associated with connective tissue disease)
Trauma that may produce rupture of the *chordae tendinae* and acute mitral regurgitation
Congenital anomalies, principally mitral cleft
Secondary to drugs: anorexigens, carbergoline, pergolide or ergotamine
Secondary mitral regurgitation:
Dilation and dysfunction of the left ventricle that causes stretching and distortion on the mitral valve annulus leading to centrally directed mitral regurgitation
Ischaemic heart disease, usually as a result of ischaemia or necrosis of the posterior papillary muscle, which can lead to acute mitral regurgitation
Hypertrophic obstructive cardiomyopathy, caused by the movement of the mitral valve anterior leaflet due to the "Venturi effect" caused by outflow tract obstruction

Causes of mitral regurgitation. [Suárez-Mier MP, Morentin B, Cobo M, Castedo E, García-Pavía P. Pathology of the Heart Valves. In: Lucena JS, García-Pavía P, Suarez-Mier MP, Alonso-Pulpon LA, editors. Clinico-Pathological Atlas of Cardiovascular Diseases [Internet]. Cham: Springer International Publishing; 2015 [cited 2016 Apr 4]. p. 171–200. Available from: http://link.springer.com/10.1007/978-3-319-11146-9_7] *Caption from original*

- In acute MR, this typically results from rupture of the papillary muscles that connect the chordae tendinae to the cardiac wall. Loss of papillary muscle function leads to incompetence of one or more of the valve leaflets. When the LV contracts, its contents flow both ante- and retrograde, significantly reducing forward cardiac output and disrupting LA function.

	Primary ("Organic")	Secondary ("Functional")
Acute	Papillary muscle ischemia	Acute ischemic LV dilatation
	Ruptured papillary muscle (trauma, infarction)	
	Flail mitral valve leaflet	
	Ruptured chordae tendinae	
	Endocarditis (leaflet perforation)	
Chronic	Flail mitral valve leaflet	Chronic ischemic mitral regurgitation (CIMR)
	Mitral valve prolapse	Non-ischemic LV dilatation (failure of leaflets to coapt)
	Ruptured chordae tendinae	Non-ischemic LV systolic dysfunction
	Degeneration (myxomatous, endocarditis, calcification)	Hypertrophic cardiomyopathy
	Rheumatic	Right ventricular pacing
	Congenital	Aortic insufficiency [1]

Classification of mitral regurgitation by mechanism and acuity [From article: Echocardiographic assessment of ischemic mitral regurgitation. Cardiovasc Ultrasound. 2014 Dec 1;12(1):46. https://doi.org/10.1186/1476-7120-12-46, at https://link.springer.com/article/10.1186%2F1476-7120-12-46; by David M Dudzinski, Judy Hung, © Dudzinski and Hung 2014; licensee BioMed Central Ltd.; licensed under Creative Commons Attribution License BY 4.0 http://creativecommons.org/licenses/by/4.0] *Caption from original*

- In chronic MR, damage to the valve apparatus (as in rheumatic heart disease) leads gradually to LA and LV enlargement and the patient remains largely asymptomatic until LV systolic dysfunction develops. Fatigue, dyspnea, and diminished exercise tolerance ensue. Frank heart failure may follow over time. With LV dilatation, the risk of atrial fibrillation and its attendant risk of thromboembolic complications rises.

Pathophysiology of acute mitral regurgitation (AMR). A, AMR. Left ventricular (LV) sarcomere length (SL) is increased, but afterload (as estimated by end-systolic stress [ESS]) is initially reduced, as the LV ejects into the low impedance left atrium (LA). Contractile function (CF) is unchanged, but ejection fraction (EF) increases. The regurgitant fraction (RF) in this example is 50%. Forward stroke volume (FSV) is reduced from 100 to 70 mL. Pressure in the unprepared and relatively noncompliant LA rises abruptly to 25 mm Hg. [O'Gara P. Chapter 9. In: Libby P, editor. Essential Atlas of Cardiovascular Disease. 4th ed. Philadelphia: Current Medicine Group; 2009.] *Caption adapted from original*

- Chronic MR can also be caused by a host of other diseases, especially connective tissue disorders such as lupus and scleroderma.
- MR is distinct from mitral valve prolapse (MVP), in which there is ballooning of the mitral valve leaflets during LV systole, but there is no valve incompetence

Presentation

Typical/"Classic"

- The presentation of MR depends on whether it is acute or chronic. Acute MR, which often occurs proximal to an inferior wall myocardial infarction (MI) or as a complication of infective endocarditis, classically presents with
  - Shortness of breath
  - Chest pain
  - Orthopnea
  - Pulmonary edema
- Chronic MR may be asymptomatic for years, prior to presenting with decreased exercise tolerance and orthopnea.

Atypical

- Patients with acute MR may present hemodynamically unstable, requiring immediate intervention including use of a balloon pump.
- The damaged valve leaflets in MR are at risk for bacterial vegetations and endocarditis.
- MR may present with thromboembolism, from thrombi that form as a result of concomitant atrial fibrillation.

Primary Differential Considerations

- Consider the following diagnoses:
  - Aortic stenosis
  - Aortic insufficiency
  - Ventricular septal defect

History and Physical Examination

- Check for a thrill at the cardiac apex.
- Check for a brisk carotid upstroke.
- On cardiac auscultation, check for
  - Wide splitting of S2
  - Presence of an S3
  - Holosystolic, high-pitch, blowing murmur best heard over the apex

https://www.med.ucla.edu/wilkes/MRmain.htm

Rales. [Rales Lung Sounds; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

- Peripheral findings of heart failure, including a hypoperfused state, may be apparent in acute MR.

Findings That Confirm Diagnosis

- The echocardiogram confirms the diagnosis. The MR murmur in the context of MR symptoms (starting with exertional dyspnea), should prompt the imaging study.

Factors That Suggest Diagnosis

- Prior to diagnostic confirmation with echo, presence of two or more of the symptoms cited above suggests MR.
- The lack of a history of rheumatic fever does not exclude the diagnosis.
- Signs of pulmonary hypertension or right heart failure in the presence of a holosystolic murmur are suggestive of MR.

Factors That Exclude Diagnosis

- MR is definitively excluded only by an echocardiogram showing competence of the mitral valve.

Ancillary Studies

Laboratory

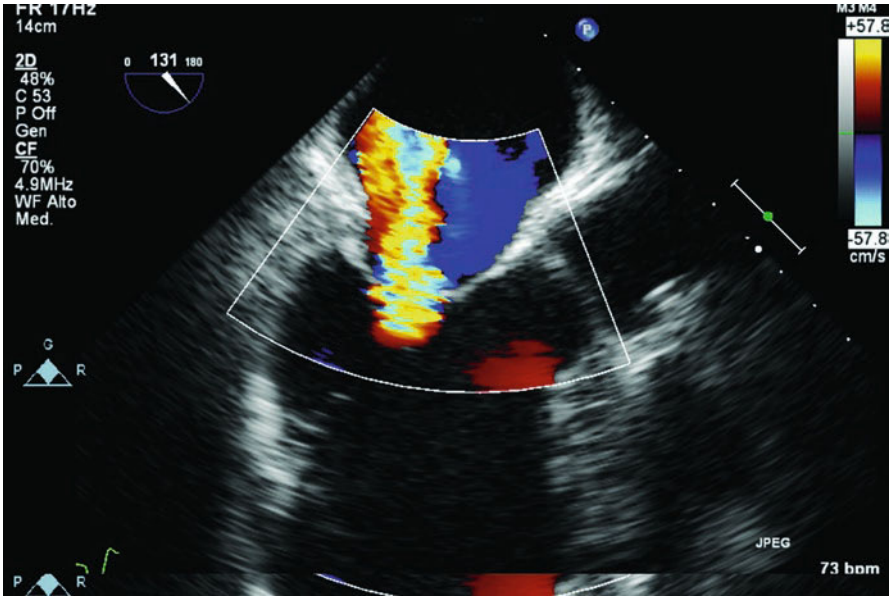
- It is helpful to send routine laboratory studies such as basic chemistries and a complete blood count to evaluate for other causes of the patient's symptoms.
- There may be value to checking a brain-type natriuretic peptide (BNP) level, especially if the patient has heart failure symptoms.

Electrocardiography

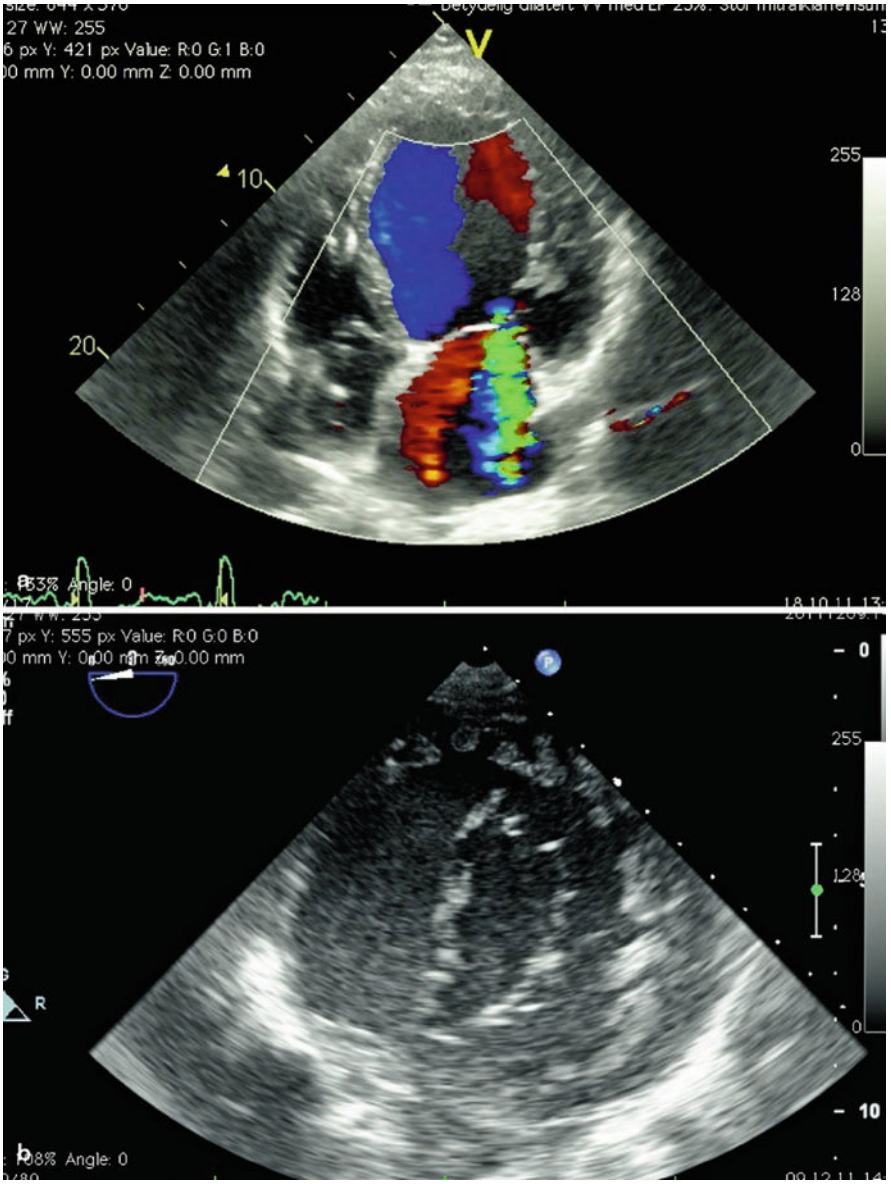
- The ECG should be obtained and interpreted promptly. Findings on electrocardiography may include the following:
  - Ischemic changes or new Q-waves in the inferior leads.
  - Left ventricular hypertrophy.
  - Left atrial enlargement as manifest by wide P-waves in II, III, and aVF.

Imaging

- The chest x-ray may be helpful in the evaluation of possible MR. Look for straightening of the left border of the cardiac silhouette or a double shadow in the right cardiac silhouette. Frank cardiomegaly and signs of pulmonary edema may be evident in acute MR or in late stages of chromic MR, but usually does not occur until fairly late in the disease progression.
- Echocardiography is the most sensitive and specific noninvasive test for MR. Transthoracic 2-D echo can usually confirm the diagnosis, and with Doppler echo and color jet imaging the degree of incompetence can be clearly delineated.



Transesophageal echocardiography (TEE) long-axis view. The picture shows severe ischemic mitral regurgitation (vena contracta 0.67 cm) [Colombo A, Godino C, Agricola E. The Degree and Type of Mitral Regurgitation Present at the Baseline Is Not Always a Good Predictor of the Procedural Technical Needs or of the Final Result. In: Feldman T, Franzen O, Low R, Rogers J, Yeo KK, editors. Atlas of Percutaneous Edge-to-Edge Mitral Valve Repair [Internet]. Springer London; 2013 [cited 2017 May 3]. p. 521–3. Available from: http://link.springer.com/chapter/10.1007/978-1-4471-4294-2_41] *Caption from original*



Transesophageal echo demonstrated very extensive mitral regurgitation located centrally between A2 and P2, dilated mitral annulus (4.4 × 4.8 cm) with malcoaptation of leaflets due to tenting of the leaflets. Coaptation depth 13 mm, coaptation length 2 mm. Four-chamber view (a) showing a very large, central mitral regurgitation reaching the roof of the left atrium. In the transgastric, short axis view (b) we measured the opening area of the mitral orifice to be more than 4 cm2. [Dahle G, Andersen KA, Brekke M, Rein KA. Functional Mitral Regurgitation with a Wide Extension of the Central Regurgitant Jet. In: Feldman T, Franzen O, Low R, Rogers

J, Yeo KK, editors. Atlas of Percutaneous Edge-to-Edge Mitral Valve Repair [Internet]. Springer London; 2013 [cited 2017 May 3]. p. 525–32. Available from: http://link.springer.com/chapter/10.1007/978-1-4471-4294-2_42] *Caption adapted from original*

Special Populations

Age

- Acute onset MR follows the age distribution for myocardial infarction, although infective endocarditis may cause MR at younger ages.
- Chronic MR usually becomes symptomatic later in life.

Co-morbidities

- The most important co-morbidities are underlying cardiopulmonary disease, including coronary artery disease and heart failure. Atrial fibrillation increases the risk of thromboembolic complications in MS.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- An echocardiogram should be obtained early in the evaluation of patients with signs and symptoms suggestive of MR.
- Stabilize patients who present with hemodynamic compromise and poor oxygenation.

Mimics

- The echocardiogram will resolve differential considerations.

Time-Dependent Interventions

- The most important intervention is to stabilize patients with hemodynamic instability.
- Recognition of acute MR and heart failure may require life-saving intervention, including resuscitation and placement of a balloon pump.

Overall Principles of Treatment

- Afterload reduction is key in acute resuscitation.
- Biventricular pacing and an aortic balloon pump may be required.

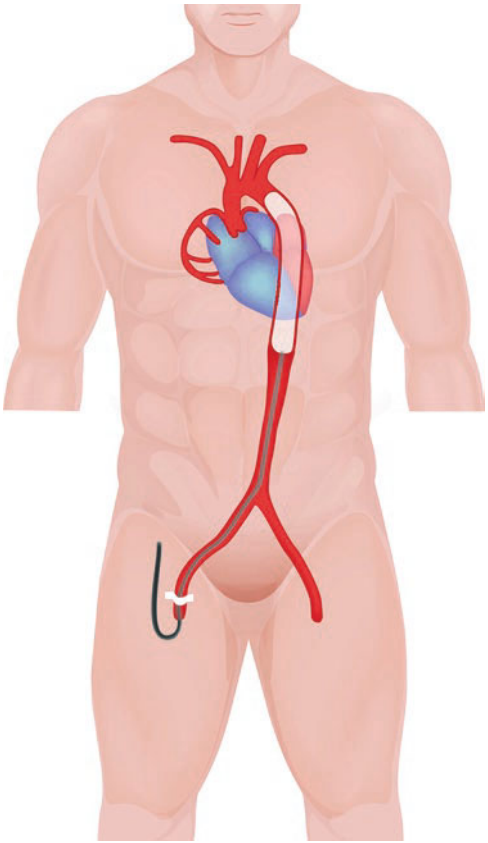


Illustration of an intra-aortic balloon pump [Baker ZP, Keenan JB, Khalpey Z. Difficult Decisions in Cardiothoracic Surgery: Acute Cardiogenic Shock. In: Surgical Decision Making [Internet]. Springer International Publishing; 2016 [cited

2017 May 3]. p. 165–75. Available from: http://link.springer.com/chapter/10.1007/978-3-319-29824-5_16] *Caption from original*

- In chromic MR, nitrates, diuretics, and beta-blockers may be helpful in controlling MR symptoms.
- Sodium restriction with or without diuretic therapy can help ease symptoms of pulmonary vascular congestion.
- Rate control and thromboembolic protection should be provided to MS patients with atrial fibrillation.
- Surgical repair or mitral valve replacement may be required in severe cases.

Disease Course

- Prognosis is dependent on the severity of the MR and underlying co-morbidities.
- Co-morbid heart failure or atrial fibrillation worsens the course.

Chapter 49
Mitral Valve Stenosis

Charles V. Pollack, Jr. and Jaime Friel Blanck

Name and Synonyms

Mitral valve stenosis

Incidence/Epidemiology

- Mitral stenosis (MS), a narrowing of the channel between the left atrium and left ventricle, is most often a late sequela of acute rheumatic fever; it is occasionally congenital.
- The incidence of rheumatic fever is steadily diminishing in the US and the developed world.
- About two-thirds of patients with rheumatic MS are female.
- Symptoms usually manifest during the third or fourth decade of life and most patients are unaware that they ever had rheumatic fever.

Differential Diagnosis

- MS can be diagnosed definitively with echocardiography, so it can therefore be confirmed expeditiously if suspected. The symptoms associated with MS can overlap with those of a handful of other syndromes, such as:
  - Endocarditis
  - Left atrial myxoma
  - Atrial septal defect

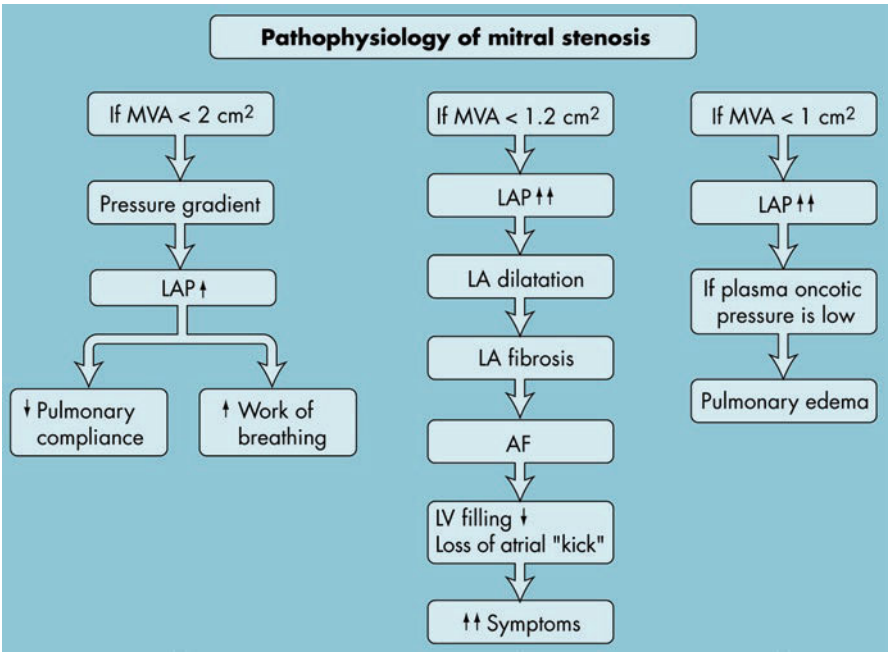
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_49

Pathophysiology and Etiology

- In MS, the valve leaflets are thickened and coarsened by fibrous tissue and/or calcific deposits. The mitral commissures eventually fuse and the valve cusps become rigid. The chordae tendineae also fuse and shorten, and eventually the aperture of the funnel-shaped valve narrows.



Pathophysiology of mitral valve stenosis. AF—atrial fibrillation; LA—left atrial; LAP—left atrial pressure; MVA—mitral valve area. [Clements F, de Bruijn N, Bennett-Guerrero E, Newman M, Reves JG. Chapter 1. In: Miller RD, Muravchick S, editors. Atlas of Anesthesia: Subspecialty Care, Volume 5, 1e. Philadelphia: Current Medicine; 1998. 236 p. ISBN: 0-443-07905-6] *Caption from original*

- The damage to the valve caused by the initial rheumatic insult is exacerbated over years by inflammatory and traumatic changes that occur because of altered flow patterns across the leaflets.
- MS eventually becomes symptomatic as the left atrium must generate higher and higher pressures to empty into the left ventricle across the narrower and narrower valve. In adults, the normal valve diameter is 4–6 cm^2. Symptoms usually are not apparent until the diameter is 2–2.5 cm^2. The left atrial pressure required to pump blood across that opening begins to increase dramatically at

that point, and patients may experience dyspnea and/or tachycardia on exertion. With severe MS, marked by a valve diameter of 1 cm^2 or less, a left atrial pressure of 25 mm Hg or more is required to maintain a normal cardiac output. This level of pressure in turn increases pulmonary venous and capillary pressures and further reduces pulmonary compliance, resulting in worsening dyspnea. Symptoms are worse with physical stress or exertion that increases heart rate because in tachycardia, diastole is shortened disproportionately compared to systole, leaving less time available for flow across the mitral valve.

- As left atrial, pulmonary capillary, and pulmonary arterial pressures rise, it becomes more difficult for the right ventricle to empty its full volume into the lungs for oxygenation, ultimately reducing cardiac output.
- When severe, pulmonary hypertension results in tricuspid and pulmonic valve incompetence and right-sided heart failure, or "cor pulmonale." With pulmonary hypertension there is also an increased risk of atrial fibrillation and its attendant thromboembolic complications.

Presentation

Typical/"Classic"

- The presentation of MS varies along a continuum, determined by the extent of valve narrowing and presence of pulmonary hypertension. Patients are usually asymptomatic for decades, but then symptoms typically progress continuously over a period of 2–3 years once dyspnea or cough with exertion begins to occur. The symptoms that suggest MS include:
  - Shortness of breath
  - Chest pain
  - Palpitations
  - Hemoptysis
  - Decreased exercise tolerance

Atypical

- Patients with advanced MS may have signs of right heart failure, such as severe dependent edema, liver congestion, and ascites.
- Hoarseness may develop from compression of the left recurrent laryngeal nerve by the enlarged left atrium as it hypertrophies to overcome the pressure gradient in the stenotic mitral valve.

- The damaged valve leaflets in MS are at risk for bacterial vegetations and endocarditis.
- MS may present with thromboembolism, from thrombi that form in the enlarged atrial appendages of patients with advanced MS.

Primary Differential Considerations

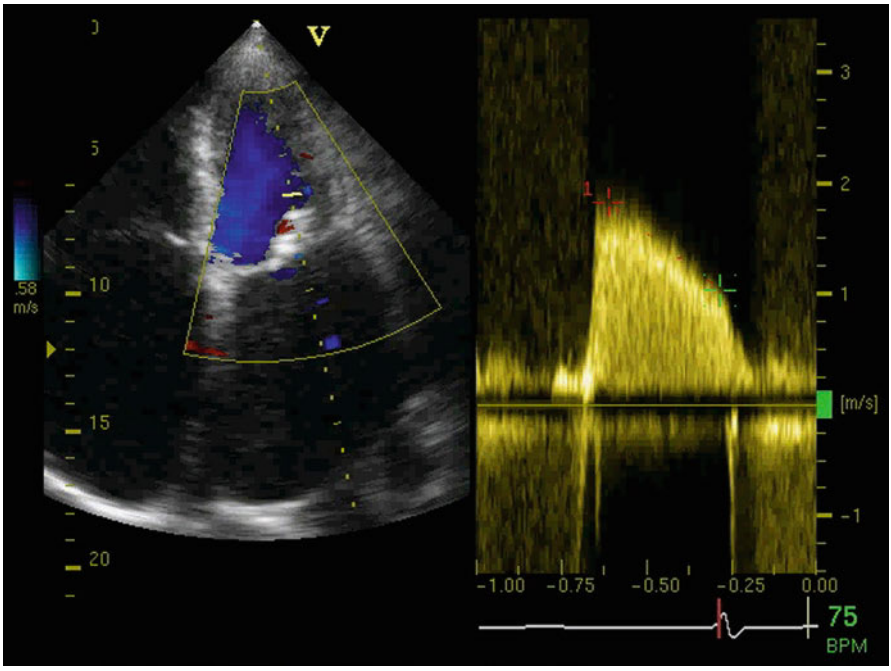
- Mitral stenosis, once symptomatic, may prompt searches for primary pulmonary causes of dyspnea, such as bronchitis, pneumonia, pulmonary edema, or pulmonary hypertension of other etiology.
- Other cardiac diagnoses to be considered are limited to atrial myxoma, atrial septal defect, heart failure, and arrhythmia. Early echocardiography can establish the culprit.

History and Physical Examination

- "Mitral facies"—purplish patches on the cheeks—has been described as being commonly seen in these patients.
- Ask about dyspnea, chest pain, or palpitations with exertion; ask about previous echocardiograms or a history of heart murmur.
- Ask about hemoptysis.
- Inquire about a history of rheumatic fever.
- Listen carefully over the heart for a low-pitched, rumbling, diastolic murmur, accentuated by exercise and diminished by Valsalva. Other suggestive findings on cardiac auscultation include:
  - Loud, snapping first heart sound.
  - Opening snap of the mitral valve, heard best in exhalation at or just medial to the cardiac apex.
- A diastolic thrill may be palpable at the cardiac apex. Check with the patient in the left lateral recumbent position.
- Look for pedal edema, jugular venous distension, or ascites as indications of right heart involvement.

Findings That Confirm Diagnosis

- The echocardiogram confirms the diagnosis. The MS murmur, opening snap, and diastolic thrill noted above, particularly in the context of MS symptoms (starting with exertional dyspnea), should prompt the imaging study.



Rheumatic mitral stenosis. Continuous-wave Doppler flow recording demonstrates a pressure half-time of 220 μsec yielding an estimated orifice area of 1 cm^2. [Garcia M, Liu Z. Chapter; In: Vannan MA, Lang RM, Rakowski H, Tajik AJ, Braunwald E, editors. Atlas of Echocardiography. 1e. Philadelphia, PA: Current Medicine Group; 2005. 312 p. ISBN: 1-57340-217-6] *Caption from original*

https://www.easyauscultation.com/cases?coursecaseorder=14&courseid=31
Mitral stenosis murmur. [Mitral Stenosis (Diastolic Murmur); Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

Factors That Suggest Diagnosis

- Prior to diagnostic confirmation with echo, presence of two or more of the symptoms cited above suggests MS.
- The lack of a history of rheumatic fever does not exclude the diagnosis.
- Signs of pulmonary hypertension or right heart failure in the presence of a diastolic murmur are suggestive of MS.

Factors That Exclude Diagnosis

- MS is definitively excluded only by an echocardiogram showing unimpeded flow across the mitral valve.

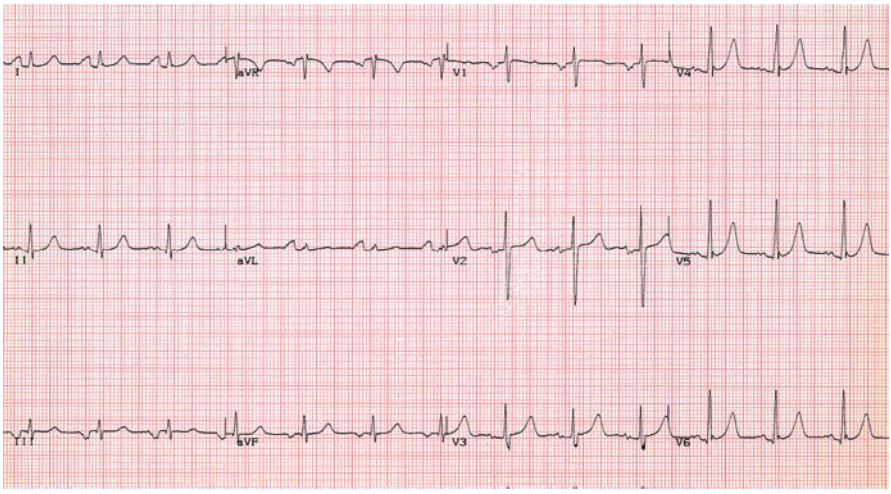
Ancillary Studies

Laboratory

- It is helpful to send routine laboratory studies, such as basic chemistries and a complete blood count, to evaluate for other causes for the patient's symptoms.
- There may be value to checking a brain-type natriuretic peptide (BNP) level, especially if the patient has heart failure symptoms.
- Liver and renal function should be evaluated.

Electrocardiography

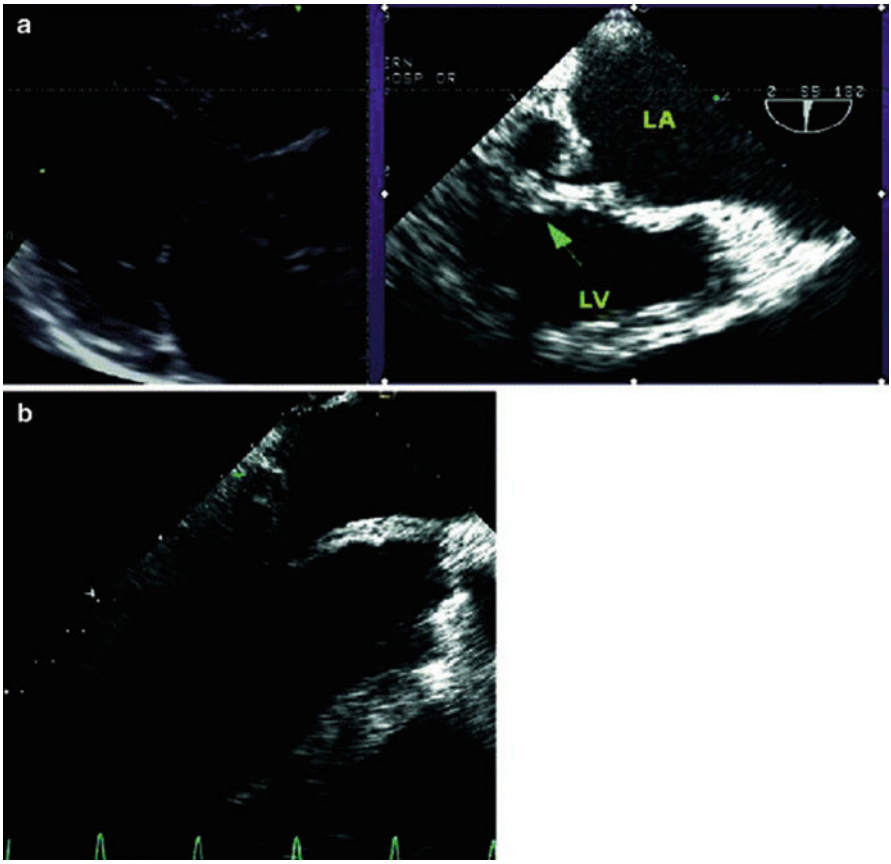
- The ECG should be obtained and interpreted promptly. If MS is suspected, look for a tall and peaked P-wave in lead II and an upright P-wave in lead V_1. These findings are more prominent with more advanced MS.



Electrocardiographic (ECG) signs in MS. A, The ECG findings from a patient with MS and regular sinus rhythm is normal except for signs of left atrial (LA) enlargement, that is, a P wave widened to 0.12 second or more. In lead II, the P wave has a double peak often characterized by an M-shaped configuration. In lead V1, the late negative portion of the P wave is characteristically increased in both width and depth. The P-wave changes are also called "P mitrale." [Kawanishi D, Rahimtoola S. Chapter; In: Braunwald E, editor. Atlas of Heart Disease: Valvular Heart Disease, Volume 11, 1e. St. Louis, Mo.: Current Medicine; 1997. 200 p. ISBN: 1-878132-30-X] *Caption adapted from original*

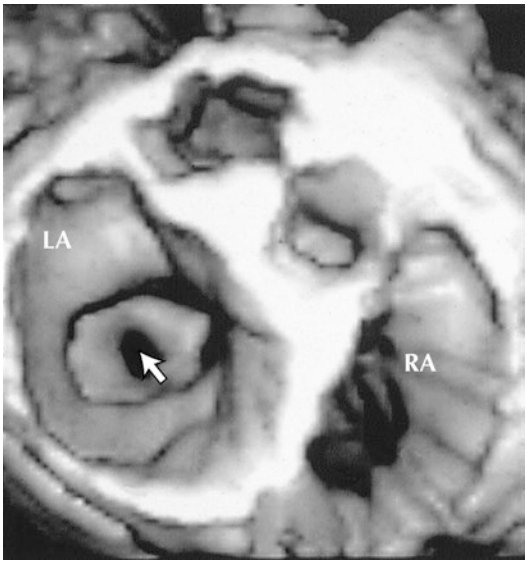
Imaging

- The chest x-ray may be helpful in the evaluation of possible MS. Look for straightening of the left border of the cardiac silhouette and prominence of the main pulmonary arteries. Prominence of the upper lobe pulmonary vasculature may be seen. In rare cases, a calcified mitral valve may be seen. Frank cardiomegaly usually does not occur until fairly late in the disease progression.
- Echocardiography is the most sensitive and specific noninvasive test for MS. Transthoracic 2-D echo can usually confirm the diagnosis, and with Doppler echo and color flow imaging the actual size and function of the valve can be assessed. In the past, cardiac catheterization was used to determine a therapeutic plan—i.e., whether surgery is required—but latest-generation echo now usually suffices.



Echocardiographic features of mitral stenosis. (a) Rheumatic mitral stenosis. This figure demonstrates typical findings of rheumatic mitral stenosis (MS). The left panel shows hockey stick deformity of the anterior leaflet of the mitral valve

in diastole. This appearance is a manifestation of the preferential involvement of the tips of the leaflets with the inflammatory/fibrosis process. This leads to relatively preserved mobility of the body with restricted mobility of the tip and the typical appearance. The right panel is a TEE from a different patient. The green arrow shows severe thickening and shortening of the chordae tendinae. Another common feature of rheumatic mitral stenosis is commissural fusion. The presence of commissural fusion may be a good predictor of who will respond to balloon valvuloplasty. (b) Other etiologies of mitral stenosis. Other etiologies of mitral stenosis include radiation and connective tissue disorders. Systemic lupus erythematosus causes diffuse thickening of the body of the valve leaflet as opposed to the tips in rheumatic heart disease [Akhter N, Mikati IA. Mitral Prolapse Regurgitation and Mitral Stenosis. In: Abraham T, editor. Case Based Echocardiography [Internet]. Springer London; 2010 [cited 2017 May 4]. p. 195–218. Available from: http://link.springer.com/chapter/10.1007/978-1-84996-151-6_17] *Caption adapted from original*



Three-dimensional echocardiographic (3DE) images of mitral valve (MV) from a patient with mitral stenosis. A, The MV as seen from above the left atrium (LA). The right atrium (RA) is seen to the right of LA and aorta anteriorly adjoining both atria. This type of 3DE sections displays MV and the narrowed MV orifice (arrow) in a view that stimulates intraoperative visualization [Hsu T, Yao J, De Castro S, Pandian N. Chapter; In: Lee RT, Braunwald E, editors. Atlas of Cardiac Imaging. Philadelphia: Current Medicine; 1998. ISBN: 0-443-07567-0] *Caption adapted from original*

Special Populations

Age

- Onset of MS symptoms is usually in the third or fourth decades of life.

Co-morbidities

- The most important co-morbidities are underlying cardiopulmonary disease, including heart failure and pulmonary hypertension. Atrial fibrillation increases the risk of thromboembolic complications in MS.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- An echocardiogram should be obtained early in the evaluation of patients with signs and symptoms suggestive of MS.
- Stabilize patients who present with hemodynamic compromise and poor oxygenation.

Mimics

- The echocardiogram will resolve differential considerations.

Time-Dependent Interventions

- The most important intervention is to stabilize patients with hemodynamic instability.
- Recognition of pulmonary hypertension and right heart failure will prompt immediate therapy.

Overall Principles of Treatment

- The goals of medical treatment for MS are to:
  - Protect against recurrent rheumatic fever.
  - Protect against infective endocarditis.
  - Provide symptomatic relief.

- Sodium restriction with or without diuretic therapy can help ease symptoms of pulmonary vascular congestion.
- Beta-blockers may also provide some symptomatic relief for patients in sinus rhythm by prolonging diastolic filling time.
- Rate control and thromboembolic protection should be provided to MS patients with atrial fibrillation.
- Rheumatic fever prophylaxis with antibiotics providing Group A beta-hemolytic strep protection should be considered, as should antibiotic prophylaxis for infective endocarditis in association with interventions that may seed the bloodstream with bacteria, such as some dental procedures.
- Percutaneous balloon commissurotomy is the procedure of choice when medical therapy is insufficient to provide symptom relief.
- Surgical repair or mitral valve replacement may be required in severe cases or those in which commissurotomy does not provide relief.

Disease Course

- Prognosis is dependent on the severity of the MS.
- Co-morbid heart failure or atrial fibrillation worsens the course.
- The availability of percutaneous commissurotomy has improved the course of symptomatic MS.

Chapter 50
Myocarditis

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Myocarditis

- Carditis, cardiac inflammation

Incidence/Epidemiology

- There are many diverse causes of myocarditis, and disease severity varies widely; therefore, the overall incidence of the disease is unknown.
- It is estimated that as many as 1–3 % of patients with acute viral infections may develop at least subclinical viral myocarditis.
- Overall, myocarditis is an unusual cause of acute chest pain. Although usually benign and self-limited, severe myocardial injury may occur.

Differential Diagnosis

- The differential considerations for myocarditis include all other causes of acute chest pain. These include, in particular, the potentially life-threatening diagnoses of acute coronary syndrome (ACS; unstable angina, NSTEMI, STEMI), pulmonary embolism, and aortic dissection.

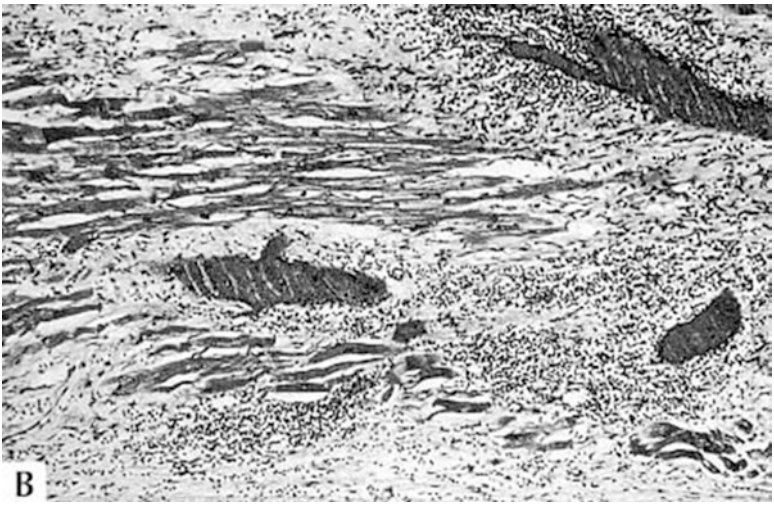
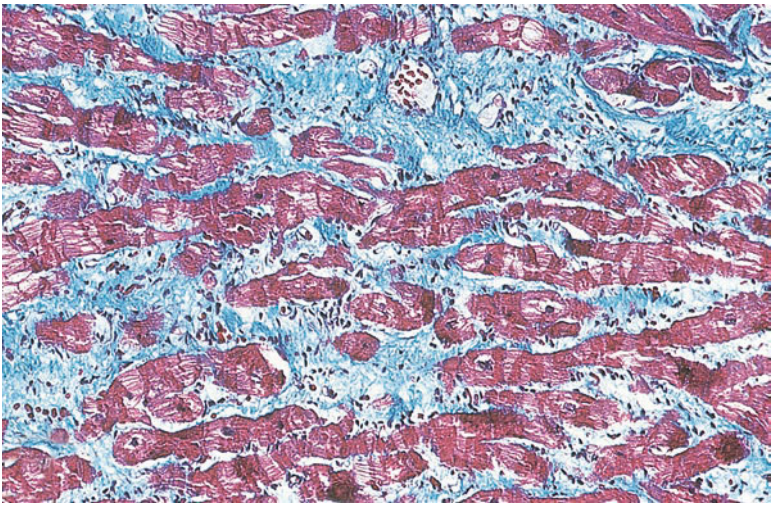
https://doi.org/10.1007/978-3-319-63895-9_50

- Pneumonia, pleurisy, and pneumothorax should also be considered.
- Some patients with myocarditis have transient (or persistent) myocardial dysfunction, which brings heart failure, arrhythmias, and pericarditis into the differential.

Pathophysiology and Etiology

- Myocarditis is inflammation of the cardiac muscle. It may result from infection, secondary reaction, autoimmune problems, or exposures as follows:





c

Gross autopsy specimen and photomicrographs of myocarditis. A, Gross autopsy specimen of a heart with fulminant myocarditis. The right ventricle is cut along the long axis to demonstrate an apical mural thrombus. B, Low-power photomicrograph of the myocardium revealing extensive mononuclear inflammation, which has replaced large clusters of myocytes that have undergone necrosis. Fulminant myocarditis is characterized by a nonspecific, severe influenza-like illness and the distinct onset of cardiac involvement. The patient's condition deteriorates rapidly, and the disorder frequently results in profound hemodynamic compromise and multisystem failure. Endomyocardial biopsies from fulminant myocarditis patients demonstrate unequivocal active myocarditis and are particularly notable for very extensive inflammatory infiltrates and numerous foci of myocyte necrosis. Within 1 month, the patients usually recover left ventricular function completely or die [045]. In contrast, acute myocarditis describes the clinical spectrum of the largest group of patients with active or borderline myocarditis. These patients have minimally dilated, hypokinetic left ventricles on presentation. The onset of cardiac symptoms is frequently indistinct, and some patients provide a vague history consistent with (but not diagnostic of) an antecedent viral illness. Active or borderline myocarditis is present on initial (but not subsequent) endomyocardial biopsies. Some patients in this group appear to respond to immunosuppressive therapy [046], while others experience either partial recovery of ventricular function or continue to deteriorate to end-stage dilated cardiomyopathy. (045. Rockman HA, Adamson RM, Dembitsky WP, et al. Acute fulminant myocarditis: long-term follow-up after circulatory support with left ventricular assist device. Am Heart J. 1991; 121:922 -926.) (046. Jones SR, Herskowitz A, Hutchins GM, et al. Effects of immunosuppressive therapy in biopsy-proved myocarditis and borderline myocarditis on left ventricular function. Am J Cardiol. 1991; 68:370 -376). C, Masson's trichrome (which stains collagen blue) of an endomyocardial biopsy of a patient with

chronic active myocarditis. Note the extensive collagen deposition characteristically seen in end-stage dilated cardiomyopathy. Patients with chronic active myocarditis usually have a vague clinical presentation. Such patients have a slowly progressive course that inevitably deteriorates but may be punctuated by brief, often-dramatic but unsustained responses to immunosuppressive therapy. Serial endomyocardial biopsies demonstrate ongoing myocarditis with the development of extensive interstitial fibrosis. Inflammatory infiltrates in this subgroup of myocarditis patients may contain multinucleated giant cells. [Herskowitz A, Ansari A, Abelmann W. Myocarditis. In: Lee RT, Braunwald E, editors. Atlas of cardiac imaging. Philadelphia: Current Medicine; 1998. Chapter 9. (Braunwald E, editor. Atlas of heart diseases; vol. 2). ISBN: 0-443-07567-0; 2002-01-23] *Caption from original*

Etiologies of Human Myocarditis: Infectious

Viral	Protozoal and metazoal
Coxsackievirus (A and B)	Trypanosomiasis
Parvovirus	Toxoplasmosis
Echovirus	Malaria
Influenza	Schistosomiasis
Cytomegalovirus	Trichinosis
Hepatitis	Bacterial
Mumps	Diphtheria
Herpes simplex	Tuberculosis
Rabies	Legionella
EBV	Brucella
HIV	Clostridium
Rickettsial	Salmonella/shigella
Q fever	Meningococcus
Rocky Mountain spotted fever	Yersinia
Scrub typhus	Spirochetal
Fungal	Borrelia (Lyme)
Cryptococcus	
Candidiasis	
Histoplasmosis	
Aspergillus	

Infectious causes of human myocarditis. Most cases of myocarditis are clinically idiopathic and likely represent the largest subgroup of cases of human myocarditis (Liu PP, Mason JW. Advances in the understanding of myocarditis. Circulation. 2001; 104:1076 -1082.). EBV—Epstein-Barr virus. [Baughman K. Etiologies of human myocarditis: infectious, viral, protozoal, and metazoal. - Acute rheumatic fever
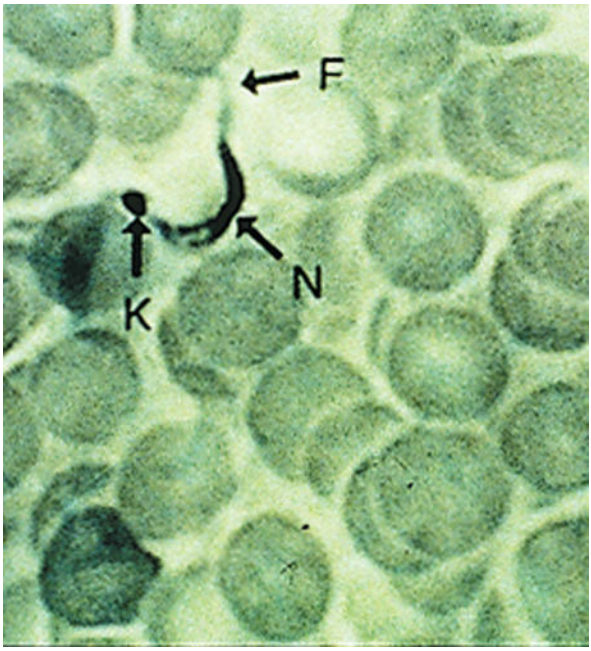
- Protozoal infection, including but not limited to
  - Chagas disease

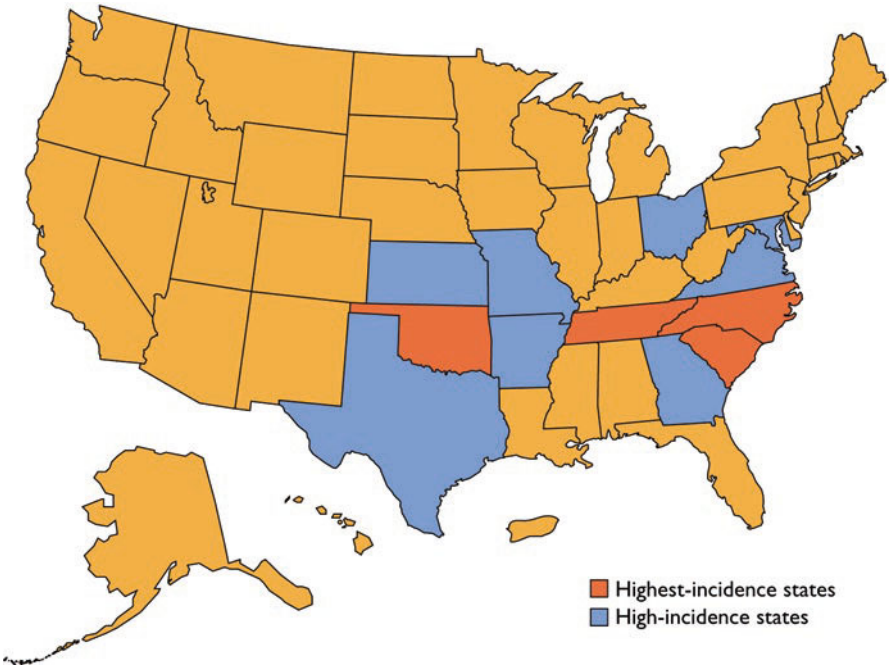


American trypanosomiasis (Chagas' disease): myocarditis. The most common infection of the heart worldwide is Chagas' disease, caused by the protozoan parasite Trypanosoma cruzi, which is spread by reduviid insects (Kirchhoff LV. American trypanosomiasis (Chagas' disease): a tropical disease now in the United States. N Engl J Med. 1993; 329:639 -644.). Infection with T. cruzi is endemic in Latin America and is now increasingly observed in the United States. Acute Chagas' disease is characterized by the systemic spread of the parasites to muscle, including myocardium. A, T. cruzi isolated from the blood of a patient with Chagas' disease. The trypomastigote is shown in mouse blood (Giemsa stain, × 2000). B, Histopathology of acute Chagas' myocarditis with a mononuclear infiltration. The arrows denote myocytes containing amastigote forms of the parasites (hematoxylin and eosin, × 360). C, High magnification of an infected myocyte (hematoxylin and eosin, × 900). F—flagellum; K—kinetoplast of amastigotes; N—nucleus. American trypanosomiasis (Chagas' disease): myocarditis [Hare J. Pathologic etiologies of heart failure. In: Colucci WS, editor. Atlas of heart failure. 5th ed. Philadelphia: Current Medicine; 2008. Chapter 3. (Braunwald E, editor. Atlas of heart diseases; vol. 4). ISBN: 1-57340-261-3; 2008-04-23] *Caption from original*

- toxoplasmosis
- Spirochetal infection, including but not limited to
    - Syphilis
    - Lyme disease

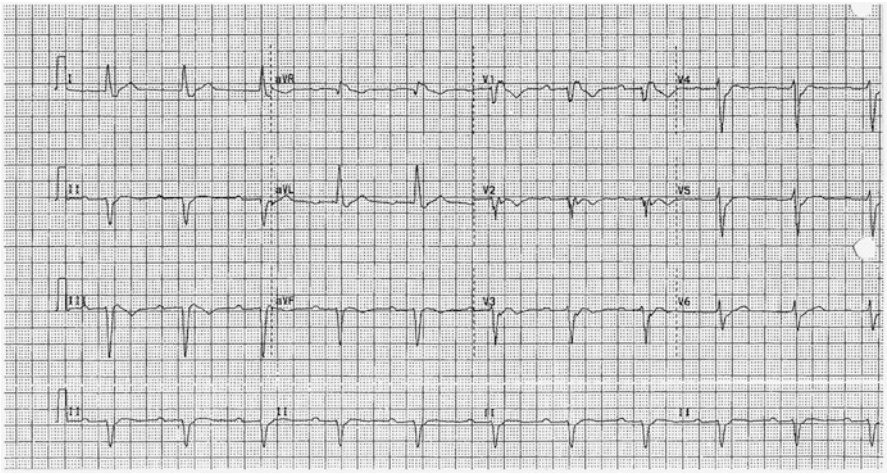
Borrelia burgdorferi in human myocardium: Lyme myocarditis. Detection of the spirochete Borrelia burgdorferi (arrow) in human myocardium (modified Steiner's silver stain). Lyme disease, a multisystem disorder caused by infection with B. burgdorferi, produces cardiac disease, notably arrhythmias and myocarditis, as a tertiary manifestation [045]. Here the spirochete is demonstrated in myocardium from a patient with a 4-year history of dilated cardiomyopathy and a serologic profile consistent with chronic Lyme disease. [Hare J. Pathologic etiologies of heart failure. In: Colucci WS, editor. Atlas of heart failure. 5th ed. Philadelphia: Current Medicine; 2008. Chapter 3. (Braunwald E, editor. Atlas of heart diseases; vol. 4). ISBN: 1-57340-261-3; 2008-04-23] *Caption from original*

- Rickettsial infection, including but not limited to
  - Rocky Mountain spotted fever



Incidence of Rocky Mountain spotted fever in the United States. High and medium incidence rates of Rocky Mountain spotted fever (RMSF) in the United States. Although RMSF has now been reported in almost every state, four states (North Carolina, South Carolina, Tennessee, and Oklahoma) have reported the highest number of cases in recent years. Other high incidence states in recent years include Maryland, Virginia, Georgia, Tennessee, Ohio, Missouri, Arkansas, Texas, and Kansas. Certain focal regions, such as Cowan and Rowan counties in North Carolina, are considered hyperendemic. [Spach D. Chapter 14. In: Wilfert S, editor. Pediatric infectious diseases. Philadelphia: Current Medicine; 1998. (Mandell GL, editor. Atlas of infectious diseases; vol. 11). ISBN: 0-443-06526-8; 2002-01-23] *Caption from original*

- Fungal infection, including but not limited to
  - Candidiasis
  - Histoplasmosis
- Systemic inflammatory disease, including but not limited to
  - Giant cell myocarditis
  - Sarcoidosis



Sarcoidosis of the heart. Resting ECG in a patient with advanced sarcoidosis. The tracing shows evidence of first-degree atrioventricular block as well as a right bundle branch block pattern. Echocardiography showed no evidence of regional wall motion abnormality and an estimated left ventricular ejection fraction of 40%. The patient underwent cardiac catheterization, which demonstrated no evidence of coronary artery disease. Based on the prior history of pulmonary sarcoidosis and the presence of conduction system abnormalities and cardiomyopathy in the absence of coronary artery disease, the patient was felt to have cardiac sarcoidosis. The patient underwent electrophysiologic study, which demonstrated inducible sustained ventricular tachycardia. An implantable cardio-defibrillator device was placed. [Tanoue L, Elias J. Sarcoidosis. In: Crapo J, editor. Bone's atlas of pulmonary medicine. 3rd ed. Philadelphia: Current Medicine; 2005. Chapter 12; ISBN: 1-57340-211-7; 2005-01-14] *Caption adapted from original*

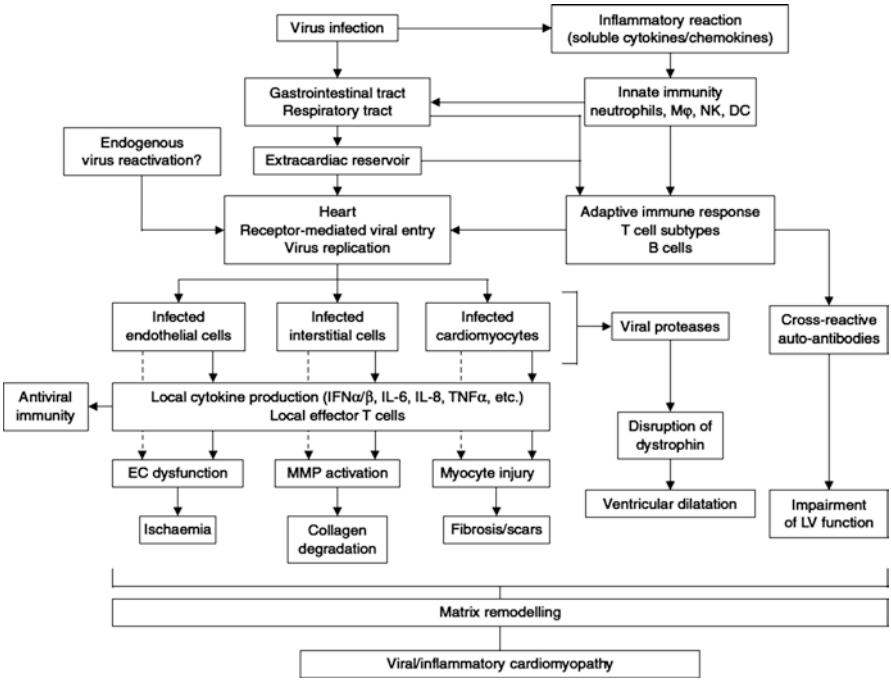
- Postpartum
- Idiopathic
- The common denominator of all these diverse causes is inflammation and potential dysfunction of myocardial cells, the consequences of which may range from subclinical to life threatening. Damage to the adjacent cardiac conduction system is common, with arrhythmias the potential result. Exploration of possible underlying causes is important to determine specific treatments beyond basic support of heart function.



Causes of myocardial injury in viral and post-infectious heart disease. Myocardial tissue injury emerges during different phases of infectious myocarditis from direct virus-associated and/or immune-mediated tissue injury. DC = dendritic cells; EC = endothelial cells; IFN = interferon; IL = interleukin; LV = left ventricular; Mφ = monocytes; MMP = matrix metalloproteinase; NK = natural killer cells; TNFα = tumour necrosis factor-α. [Kühl U, Schultheiss HP. Viral myocarditis. Drugs. 2009 Jul;69(10):1287-302. https://doi.org/10.2165/00003495-200969100-00001; Published: 2009-07-01] *Caption from original*

Presentation

Typical/"Classic"

- Because of the broad range of etiologies, there is no "classic" presentation of myocarditis. Common features that may prompt presentation for care include:
  - Acute or chronic heart failure
  - Chest pain
  - Arrhythmias
  - Exercise intolerance
  - Fever, chills, and other signs and symptoms of systemic illness
- Signs and symptoms range from quite mild to life threatening.

Aspecific	1. Gastrointestinal: nausea and vomiting, cramp, diarrhea, appetite loss, abdominal and epigastric pain 2. Respiratory: cough, pharyngeal pain 3. General: increased fever, general fatigue, arthralgia and myalgia, headache, and back pain
Cardiac	1. Chest pain or discomfort (particularly common in young patients with coronary vasospasm), concomitant pericarditis, syncope, palpitations, dyspnea 2. Heart failure: generalized fatigue, intolerance to exercise and dyspnea. Subsequently acute or fulminant cardiogenic shock 3. Sinus tachycardia (most common, especially out of proportion with concomitant fever), premature atrial and ventricular contraction, atrial fibrillation, and ventricular tachycardia. I and II degree, up to complete AV block (more common with infiltrative and GCM), RBBB, and LBBB

Clinical presentation of myocarditis. [Cortinovis B, Scanziani M, Celotti S. ECMO in myocarditis and rare cardiomyopathies. In: Sangalli F, Patroniti N, Pesenti A, editors. ECMO-extracorporeal life support in adults. Milan: Springer; 2014. p. 137-49; Book https://doi.org/10.1007/978-88-470-5427-1; Chapter: 12; Chapter https://doi.org/10.1007/978-88-470-5427-1_12; Published: 2014-01-01] *Caption from original*

Atypical

- Because of the broad range of etiologies and co-morbidities, atypical or distracting presentations of myocarditis are common.

Primary Differential Considerations

- Prompt consideration also should be given to the possible diagnosis of ACS, pulmonary edema, cardiac tamponade, and cardiomyopathy.

History and Physical Exam

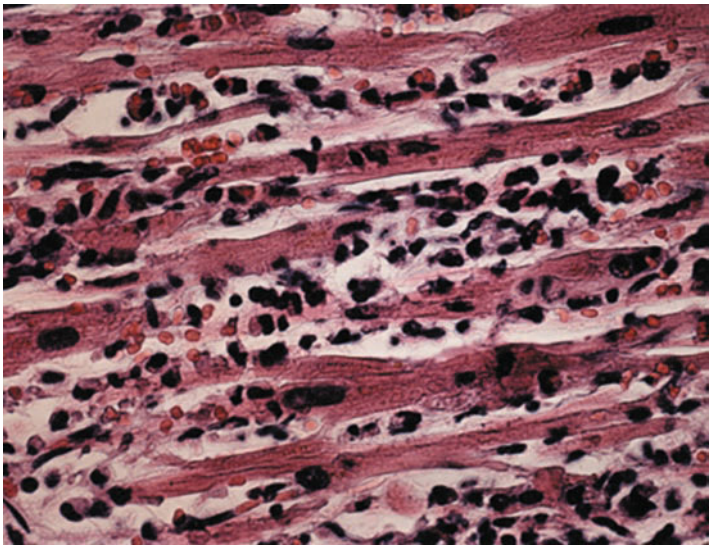
Findings That Confirm Diagnosis

- The diagnosis of myocarditis is usually presumptive, based on recognition of the combination of suggestive symptoms, a potential exposure, and clinical suspicion.

Diagnostic test	Common features
Chest radiography	Cardiomegaly, pulmonary vascular congestion, and/or pleural effusion (depending on right ventricular and tricuspid valve dysfunction). No specific abnormalities
ECG	Completely normal or with minor, aspecific abnormalities to markedly abnormal Brady- and tachyarrhythmias, conduction abnormalities, ST and T wave alterations, abnormal Q wave, low voltage, and poor R wave progression. Patterns of infarction or pericarditis. Presence of Q wave associated with a severe course, higher early cardiac enzymes, worse LV function, and higher incidence of cardiogenic shock, but not necessarily with a worse long-term outcome (31)
Cardiac enzymes	CPK MB, TnT, and TnI may be elevated (reflecting the extent of myocardial injury). TnI probably superior to CPK MB early in the disease, TnT levels correlating with more extensive damage
Echocardiography	Highly variable, from a completely normal to a markedly abnormal Various degrees of hypokinesis most commonly (mild hypokinesis limited to areas of focal infiltration, segmental wall motion abnormalities or diffuse involvement, with severe hypokinesis) LVEF or FS reduced, not necessarily with LV dilatation
Magnetic resonance imaging	Areas of inflammation and infiltration, mostly focal within the first 2 weeks, more diffuse within 4 weeks. Extent of the lesion correlates with LV dysfunction
Endomyocardial biopsy	5–10 samples from RV septum. Submit 4–5 to light microscopic examination. Transmission electron microscopy may be useful but reserved to infiltrative disorders Routine viral genome testing only for referral centers Several patterns of infiltration (histiocytic and mononuclear), varying in severity and structural abnormalities of myocardium

Diagnostic test results in myocarditis. [Cortinovis B, Scanziani M, Celotti S. ECMO in myocarditis and rare cardiomyopathies. In: Sangalli F, Patroniti N, Pesenti A, editors. ECMO-extracorporeal life support in adults. Milan: Springer; 2014. p. 137-49; Book https://doi.org/10.1007/978-88-470-5427-1; Chapter: 12; Chapter https://doi.org/10.1007/978-88-470-5427-1_12; Published: 2014-01-01] *Caption adapted from original*

- The diagnosis cannot be fully confirmed without endomyocardial biopsy.



Severe myocarditis. Infiltrative disorders. A, Histologic section of myocardium showing severe myocarditis (hematoxylin-eosin stain ×50). Panel A shows the histology of the heart of a college student who came home for the winter holidays and died suddenly during Christmas dinner with her family. She was apparently asymptomatic in spite of the presence of severe myocarditis. B, Endomyocardial biopsy of a young woman who was successfully resuscitated from an episode of sudden death. At the time of electrophysiologic studies, an endomyocardial biopsy was obtained that showed non-necrotizing granulomas (arrow), leading to the diagnosis of isolated cardiac sarcoidosis. [Fishbein M, Chen PS. Structural substrates for arrhythmias in heart failure. In: Shivkumar K, Weiss J, Fonarow G, Narula J, editors. Atlas of electrophysiology in heart failure. Philadelphia: Current Medicine; 2005. Chapter 2. (Braunwald E, editor. Atlas of heart diseases; vol. 15); ISBN: 1-57340-225-7; Published: 2005-07-18; Braunwald, Eugene] *Caption adapted from original*

Factors That Suggest Diagnosis

- Systemic illness, chest pain, and exposure to an etiologic concern are suggestive and should prompt consideration of the diagnosis. Detection of arrhythmia in this setting is more suggestive.
- Associated pericarditis may result in an audible friction rub.

http://www.easyauscultation.com/myocarditis

Myocarditis heart sounds. [Myocarditis Page; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

- Patients with more significant or advanced disease may have an audible S3 heart sound.
- One might arrive at the diagnosis by first recognizing the underlying cause (such as toxic drug exposure, viral infection, or systemic inflammatory disease) and then attributing cardiac symptoms to the myocarditis.

Factors That Exclude Diagnosis

- No history or physical findings can definitively exclude myocarditis.

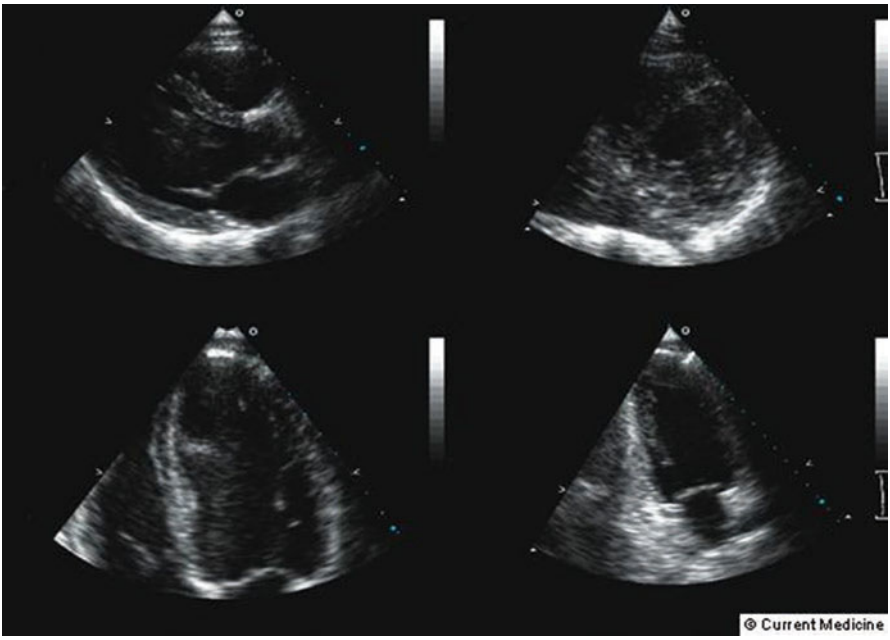
Ancillary Studies

Laboratory

- There are no diagnostic laboratory studies for myocarditis other than endomyocardial biopsy, which demonstrates inflammation of the myocardial cells.
- Some laboratory studies may be helpful in raising suspicion of myocarditis, evaluating causative/co-morbid conditions, or both. These may include:
  - Complete blood count
  - Erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP)
  - Cardiac enzymes (CPK-MB and/or troponin)
  - Viral antibody titers
  - Rheumatologic studies

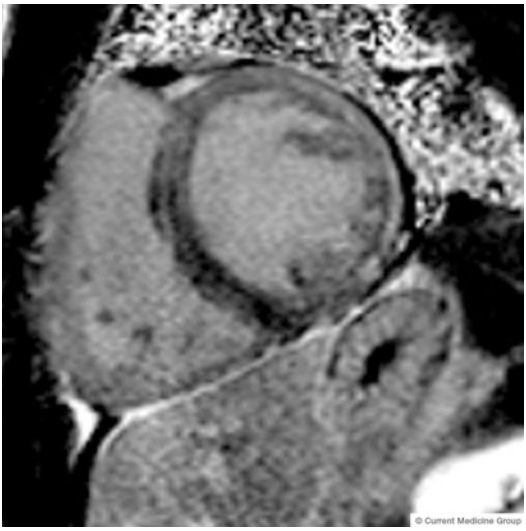
Imaging

- Echocardiography may be used to evaluate the extent of heart failure.



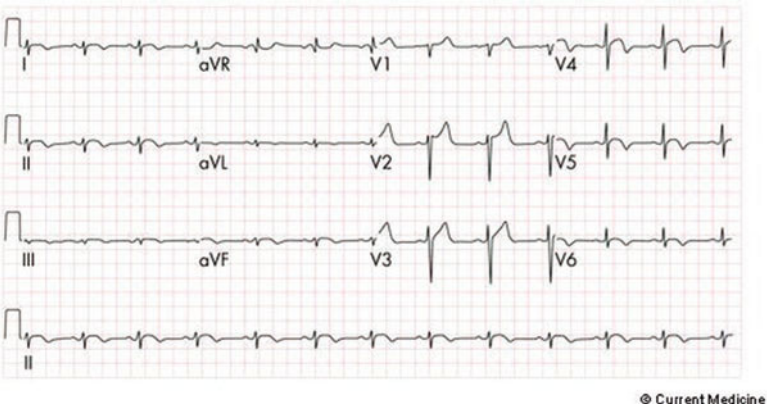
Transthoracic echocardiography in suspected acute myocarditis. Transthoracic echocardiography: Three long axis views (upper left and lower panels) and one short axis view (upper right panel) are shown. Severely reduced ejection fraction with preserved left ventricular size is demonstrated; valvular function was normal, as was the right ventricular size and function. [Strohm O, Friedrich M. Chapter 12. In: Manning WJ, editor. Atlas of cardiovascular magnetic resonance. Philadelphia: Current Medicine; 2009; ISBN: 978-1-57340-299-6; Published: 2009-01-16] *Caption from original*

- Magnetic resonance scanning with gadolinium may identify areas of myocardial inflammation.



Acute myocarditis. A 20-year-old male student who was previously healthy developed an influenza-like illness while visiting Mexico. He developed worsened dyspnea and was found to have severe depression of left ventricular (LV) global systolic function and moderate LV dilatation. At hospital admission, he had frequent nonsustained ventricular tachycardia, physical findings consistent with cardiogenic shock, with an LV ejection fraction (LVEF) quantified by volumetric cine cardiac magnetic resonance (CMR) to be 25% (A). Serial blood and urine cultures revealed no bacterial pathogens. Endomyocardial biopsy revealed moderate interstitial fibrosis only. Contrast-enhanced late gadolinium enhancement (LGE) imaging demonstrated diffuse and patchy enhancement of the anterolateral and inferolateral wall (B). These CMR findings are consistent with diffuse acute myocardial inflammation and edema presumably from acute viral myocarditis. The patient fortunately followed a stable and then progressively improving clinical course in the months following initial presentation. [Kwong R. Cardiac magnetic resonance imaging. In: Libby P, editor. Essential atlas of cardiovascular disease. Philadelphia: Current Medicine; 2009. Chapter 16. ISBN: 978-1-57340-309-2; Published: 2009-05-21;] *Caption from original*

- Electrocardiographic findings are usually nonspecific but may suggest ACS.



ECG in suspected acute myocarditis. 12-Lead electrocardiogram at presentation, demonstrating nonischemic changes in the ST and T segments. Physical examination revealed severe chest pain and shortness of breath (New York Heart Association III), blood pressure 98/58 mm Hg, and heart rate 97 bpm. aVF—augmented voltage, unipolar left leg lead; aVL—augmented voltage, unipolar left arm lead; aVR—augmented voltage, unipolar right arm lead. [Strohm O, Friedrich M. Chapter 12. In: Manning WJ, editor. Atlas of cardiovascular magnetic resonance. Philadelphia: Current Medicine; 2009; ISBN: 978-1-57340-299-6; Published: 2009-01-16] *Caption from original*

Special Populations

Age and Gender

- Perhaps owing to the diverse etiologies of the disease, there is no age or gender predilection for myocarditis in general. Obviously, some causes affect specific groups, such as postpartum myocarditis in women and viral myocarditis in younger patients.
- In the pediatric population, viral etiologies predominate, specifically enteroviral (Coxsackie B), parvovirus B19, adenovirus, and human herpes 6.
- In children, the mean age at diagnosis is 9 years, with bimodal peaks at 9 months of age and 16 years.
- Affected infants will manifest signs of congestive heart failure, including tachypnea, tachycardia, and increased work of breathing and diaphoresis when feeding.

Co-morbidities

- The list of etiologies provided above signifies the major co-morbidities of interest.
- Of particular note are HIV disease—in which myocarditis may be caused by direct viral infection; associated opportunistic infections, such as toxoplasmosis; or related disorders, such as Kaposi's sarcoma—and malignancies treated with doxorubicin or anthracyclines, which are particularly cardiotoxic.
- Lyme disease is complicated by myocarditis in about 10 % of cases.
- Chagas' disease bears mention because it is one of the most common forms of heart disease in Central and South America. Most patients with this infection (cased by the protozoan *Trypanosoma cruzi*) develop chronic cardiomyopathy and heart failure without an acute phase of myocarditis, but it should still be considered in migrants from or visitors to endemic areas.
- Because viral etiologies of myocarditis are common, it should be remembered that patients may give a history of a recent febrile illness, either upper respiratory or gastrointestinal.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Failing to consider the diagnosis of myocarditis, especially in patients with more severe presentations, may be costly. The disease may be mistaken for ACS, viral syndrome, pneumonia, and fatigue associated with co-morbid conditions.

Mimics

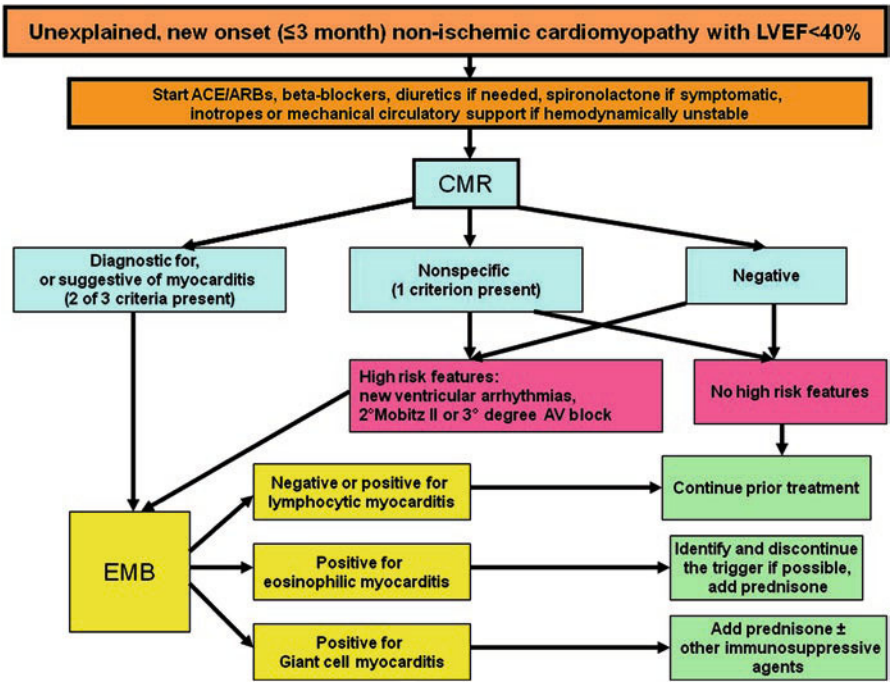
- Many of the mimics and causes of myocarditis are themselves treatable. Preoccupation with such management may lead the clinician to overlook the specific myocardial involvement.

Time-Dependent Interventions

- Patients who present with fulminant heart failure, symptoms consistent with ACS, a pneumonia-like syndrome, or significant arrhythmias must be quickly evaluated and stabilized as the work-up proceeds.

Overall Principles of Treatment

- Treatment of myocarditis is in large part dependent on the cause. Usually—but not always—treating the etiology improves the patient's myocardial function.
- Treat infections if possible (with viral myocarditis, only supportive therapy may be feasible)
- Remove the offending agent/drug if it can be identified
- Treat heart failure, if present, with diuretics, nitrates, and inotropes as needed.

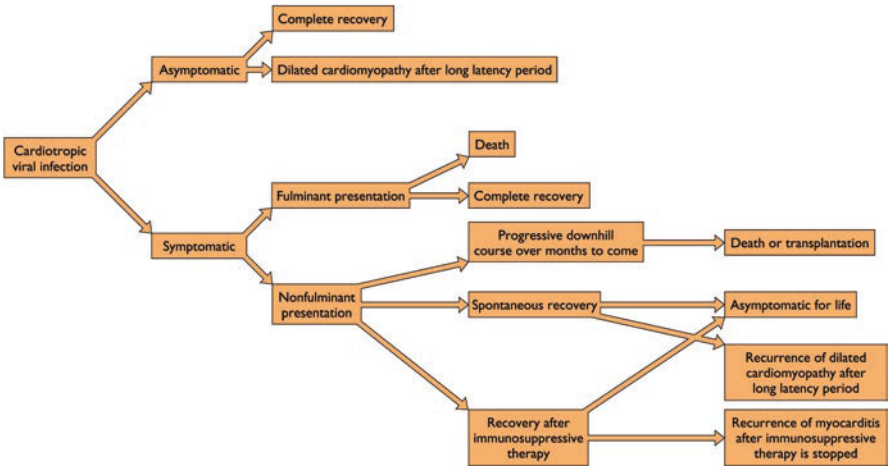


Algorithm for diagnostic work-up and treatment of myocarditis. CMR cardiac magnetic resonance, LVEF left ventricular ejection fraction, EMB endomyocardial biopsy. [Guglin M, Nallamshetty L. Myocarditis: diagnosis and treatment. Curr Treat Options Cardiovasc Med. 2012 Dec;14(6): 637-51; https://doi.org/10.1007/s11936-012-0204-7; Published: 2012-12-01] *Caption adapted from original*

- Specific antiarrhythmic therapy is usually not helpful, but if arrhythmias persist after correction of any oxygenation and electrolyte derangements, antiarrhythmics may be used. Digoxin is not recommended in the treatment of myocarditis.

Disease Course

- Myocarditis is a self-limited disease in most cases.



Natural history of human myocarditis [Herskowitz A, Ansari A. Myocarditis. In: Abelmann WH, editor. Cardiomyopathies, myocarditis, and pericardial disease. Philadelphia: Current Medicine; 1996. (Braunwald E, editor. Atlas of heart diseases; vol. 2).] *Caption from original*

- Dilated cardiomyopathy and chronic heart failure may result from severe cases of acute myocarditis.
- Arrhythmias associated with myocarditis can rarely be fatal.

Chapter 51
Neuromuscular Disease: Myasthenia Gravis, Guillain-Barré, Amyotrophic Lateral Sclerosis

Charles V. Pollack, Jr. and Jaime Friel Blanck

Name and Synonyms

Neuromuscular Disease, inclusive of:

- myasthenia gravis (MG)
- Guillain-Barre syndrome (GBS)
- amyotrophic lateral sclerosis (ALS) or Lou Gehrig's Disease

This diverse group of neurologic diseases can, through different mechanisms, cause disordered breathing. MG is a disease of the neuromuscular junction, GBS is a demyelinating neuropathy, and ALS is a motor-neuron degenerative disorder.

Incidence/Epidemiology

- MG has an incidence of around 20/100,000 patients. Women are affected more commonly than men, with the typical MG patients being females in their 20s and 30s and males in their 50s and 60s.
- GBS is rare, with an incidence of about 1/100,000 patients. Males are more commonly affected than females, and the incidence increases with age. There have also been occasional transient increases in incidence attributable to the use of specific influenza vaccines.
- ALS is rare, with an incidence of fewer than 3/100,000 patients. Males are somewhat more frequently affected than females.

Differential Diagnosis

- The differential diagnosis for MG includes
  - Botulism
  - Multiple sclerosis (MS)
  - Lambert-Eaton Syndrome

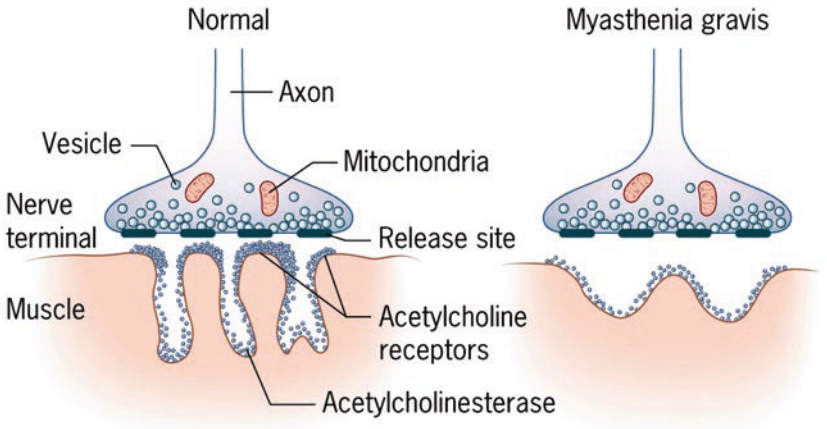
Feature	Myasthenia gravis	Eaton–Lambert syndrome
Most commonly associated malignancy	Thymoma (40%)	Small cell lung cancer (1–3%)
Antibody target	Acetylcholine receptor	Voltage-gated calcium channel
Area of NMJ affected	Postsynaptic membrane	Presynaptic membrane
Common presenting feature	Ocular and bulbar weakness	Limb weakness, oculomotor sparing
Ocular and bulbar muscle involvement	Common	Rare
Autonomic dysfunction	None	Common
Deep tendon reflexes	Normal	Reduced
Strength improved by	Rest, sleep	Exercise

Myasthenia gravis vs. Lambert–Eaton syndrome. [Chelico L, McRae K. Thymic Surgery and Paraendocrine Syndromes. In: Slinger, MD, FRCPC P, editor. Principles and Practice of Anesthesia for Thoracic Surgery [Internet]. New York, NY: Springer New York; 2011 [cited 2016 Mar 29]. p. 211–23. Available from: http://link.springer.com/10.1007/978-1-4419-0184-2_15] *Caption from original*

- The differential diagnosis for GBS includes
  - Botulism
  - MG
  - MS
  - Spinal cord tumor
  - Lyme disease
- The differential diagnosis for ALS includes
  - Spinal cord disease/tumor/compression
  - Myopathy
  - Lead or mercury poisoning

Pathophysiology and Etiology

- MG is characterized by weakness and rapid fatigability of skeletal muscle. It is a result of ineffective nerve firing activity at the neuromuscular junction (NMJ), which in turn is caused by a decrease in the number of available acetylcholine (ACh) receptors. ACh is the neurotransmitter at the NMJ, and the receptors are decreased in number because of an antibody-mediated autoimmune disorder.



Myasthenia gravis. Myasthenia gravis affects approximately 25,000 patients or 50 to 125 cases per million. Features of myasthenia gravis are weakness (focal or generalized) and skeletal and muscle fatigability, which generally increases with repeated activity and improves with rest. An example is ptosis, which is improved with 3 minutes of eye closure (rest). Approximately three quarters of patients with myasthenia gravis have abnormalities of the thymus (thymic lymphoid hyperplasia [85%] or thymoma [15%]). A thymectomy frequently improves the symptoms of myasthenia gravis, but this has been more common in patients with hyperplasia than with thymoma. [Loehrer Sr, P. Henley, J. Johnson, D. Chapter 30. In: Markman, M, editor: Volume 3: Atlas of Cancer. 1 edition. Philadelphia: Current Medicine Group; 2002. ISBN: 0-7817-4280-3] *Caption adapted from original*

- GBS is a demyelinating neuropathy. Myelin is a protein that covers nerve sheaths and greatly increases nerve conduction velocities. GBS is a "polyneuropathy," meaning that many peripheral nerves in the body are affected. The muscles at the periphery—in the hands and feet—are affected first, because the nerve sheaths supplying them are the longest, and therefore the problems with "insulation" are more pronounced there. This is probably an autoimmune process, but the specific etiology remains obscure.
- ALS is the most common form of progressive and likely the most devastating of the motor neuron diseases. ALS gradually affects both upper motor neurons (motor cortex and corticospinal cells) and lower motor neurons (anterior

horn cells in the spinal cord and brainstem motor cells that innervate the bulbar muscles). As these nerve cells die, the innervated muscle fibers atrophy and lose function.

Presentation

Typical/"Classic"

- MG typically presents with:
  - Extraocular muscle weakness leading to ptosis.

Left-sided ptosis in a patient with myasthenia gravis before initiation of therapy with cholinergic drugs and immunosuppressants. [Finsterer J. Ptosis: Causes, Presentation, and Management. Aesthetic Plastic Surgery. 2003 Jun 1;27(3):193–204.] *Caption from original*

- Bulbar and facial muscle weakness.
- Inability to hold head up.
- Easy fatigability of routine and repetitive tasks.
- Exacerbations of this chronic disease may be prompted by such diverse stimuli as:
  - Acute illness
  - Medications
  - Emotional stress
  - Menstruation
  - Immunization
- GBS typically presents with the following characteristics:
  - "Ascending weakness"; that is, feet before hands, and then extremities toward trunk. The cranial nerves are usually affected later in the course, leading to double vision and difficulties speaking and swallowing.

- Ultimately, in severe cases, patients are quadriplegic and have ventilatory failure.
- Most patients complain of numbness or burning paresthesias prior to the onset of weakness.
- More than half of patients with GBS complain of severe pain, especially in proximal muscle groups.
- Autonomic nerves are often involved as GBS progresses, leading to orthostatic hypotension, tachy- or bradycardia, and facial flushing.
- Cardiac arrhythmias may develop.
- There is usually a benign viral prodrome 2–4 weeks before the onset of weakness.

- ALS typically presents with:
  - Progressive loss of strength and function.
  - Limb involvement first, then with bulbar involvement (the latter manifests as difficulty swallowing and voice changes).
  - "Pseudobulbar" manifestations—exaggerated emotions, sometimes inappropriate emotional responses.

Atypical Presentations

- MG may sometimes present with:
  - Isolated muscle weakness and no extraocular or bulbar involvement.
  - Acute respiratory failure without preceding ocular or bulbar worsening.
- GBS may sometimes present with:
  - Weakness in the cranial nerves *prior to* the extremities. This is called the Miller-Fisher variant of GBS.
  - Asymmetric or incomplete weakness, which may delay consideration of the diagnosis.
  - No history of viral prodrome or influenza vaccination.
- ALS may sometimes present with:
  - Bulbar involvement preceding limb involvement.
  - Numbness and paresthesias (sensory function is ordinarily preserved in ALS).

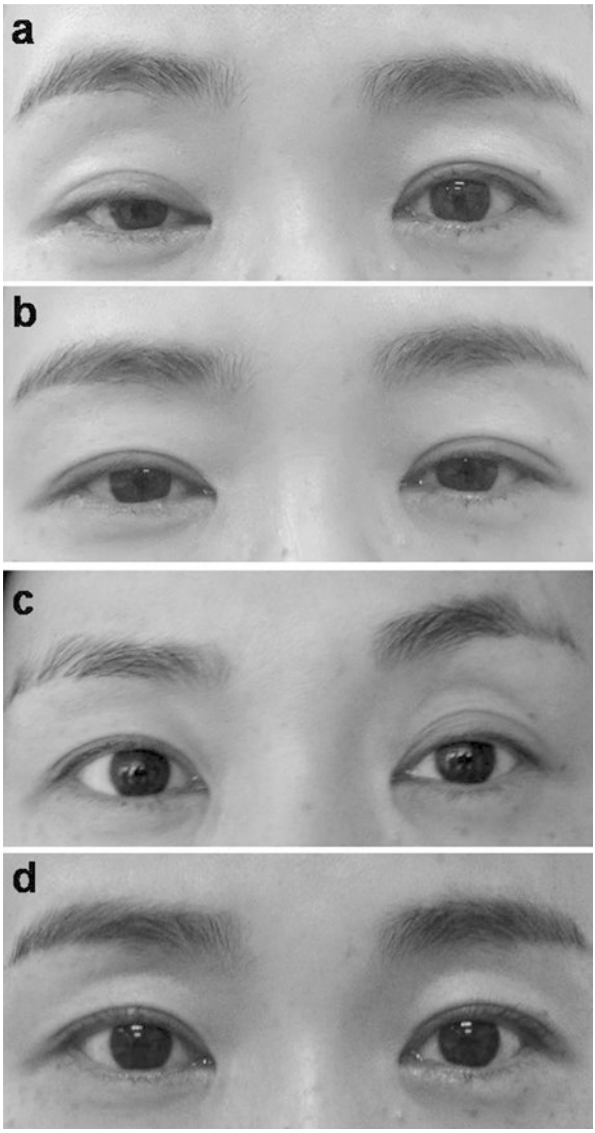
Primary Differential Considerations

- These are unusual diseases. The differential diagnosis for each is usually limited to other neural or neuromuscular diseases as described above. These patients do not ordinarily present with primary cardiorespiratory symptoms.

History and Physical Exam

Findings That Confirm Diagnosis

- The diagnosis of MG is confirmed with laboratory demonstration of antibodies to acetylcholine receptors. Electromyography (EMG) and nerve conduction studies (NCS) are also used to confirm the diagnosis.
- The edrophonium test can be performed at the bedside and has reasonably high sensitivity.



Ptosis in a patient with ocular myasthenia gravis. The patient showed right ptosis when referred to our hospital (a). Edrophonium injection improved right ptosis and induced minor left ptosis (b). After intravenous methylprednisolone therapy, right ptosis was satisfactorily relieved, however, left ptosis got appeared (c). Left ptosis was resolved after 1-month observation without additional immunosuppressive therapy (d)[Nishijima H, Ueno T, Suzuki C, Baba M, Tomiyama M. Eyelid ptosis enhanced after steroid pulse therapy in ocular myasthenia gravis: a case report. Neurological Sciences. 2015 Jun;36(6):1055–6.] *Caption from original*

- On physical exam the disease is characterized by weakness in repetitive activities that improves with rest.
- The "ice bag test" for ptosis may be used to evaluate for MG.
- The diagnosis of GBS cannot be confirmed at the bedside. EMG and NCS are helpful, as is evaluation of the cerebrospinal fluid.
- The diagnosis of ALS is often challenging. EMG and NCS are useful. There are no confirmatory bedside tests.

Factors That Suggest Diagnosis

- MG:
  - Positive edrophonium test
  - Positive ice-bag test
  - Ptosis in the absence of thyroid disease
  - Ventilator capacity can be assessed by testing negative inspiratory force (NIF)
- GBS:
  - Symmetric ascending weakness
  - Viral-like prodrome or immunization 2-4 weeks prior to onset of weakness

Factors That Exclude Diagnosis

- In patients with weakness, no historical or physical examination factors can completely exclude these diagnoses at all stages.

Ancillary Studies

Laboratory

- For MG:
  - Ordinary baseline lab studies are not helpful.
  - Serologic testing for antibodies to ACh receptors should be performed.

- For GBS:
  - Ordinary baseline lab studies are not helpful.
  - Evaluate cerebrospinal fluid (from lumbar puncture) for protein levels, which are ordinarily high (unless patient has HIV) in GBS.
  - Liver function tests are abnormal in one-third to one-half of GBS patients.
- For ALS:
  - Ordinary baseline lab studies are not helpful.

Imaging

- MG:
  - Chest radiography or CT chest may show a thymoma. A normal chest radiograph does not exclude MG.
- GBS:
  - MRI with gadolinium contrast may show enhancement at the nerve root, but this is not a consistent finding in patients diagnosed with GBS.
- ALS:
  - Imaging studies are needed only to exclude other etiologies of weakness.

Other

- MG:
  - As above, the following tests are potentially useful:
  - Ice-pack test
  - EMG
  - NCS
  - serology
- GBS:
  - Serology
  - Lumbar puncture
  - EMG
  - NCS
- ALS:
  - Genetic testing (familial in a small number of cases)
  - EMG
  - NCS

Special Populations

Age

- MG:
  - MG can occur at any age.
  - It typically occurs earlier in females than males.
- GBS:
  - Incidence increases with increasing age
- ALS:
  - Slightly more common in men than in women.

Co-morbidities

- MG:
  - The most common co-morbidities are thyroid disease, lupus, and rheumatoid arthritis.
- GBS:
  - The most common co-morbidities are COPD, diabetes, and obesity.
- ALS:
  - The most common co-morbidity is cardiovascular disease.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- These are unusual diseases. Early consideration to the diagnosis should be given or it may be missed on multiple presentations.

Mimics

- Other neuropathies
- Other neuromuscular disorders
- Botulism

Time-Dependent Interventions

- Time-dependent interventions are present only in the rare case of presentation with ventilator failure.

C	Conduction block, bradycardia, asystole
R	Rapid progression of motor weakness
I	Infection
T	Tachyarrhythmias
I	Intensive care monitoring of respiratory and autonomic dysfunction
C	Complications of critical illness: pulmonary embolism, myocardial infarction
A	Airway: ventilatory failure, bulbar weakness
L	Labile blood pressure: hypertension/hypotension

The word "critical" is used as a mnemonic for the different indications

Clinical Indications for admission to the ICU in patients with Guillain-Barré Syndrome [Cordova FC, Lim MRC, Criner GJ. Neuromyopathies in the Critically Ill. In: Criner GJ, Barnette RE, D'Alonzo GE, editors. Critical Care Study Guide [Internet]. New York, NY: Springer New York; 2010 [cited 2016 Mar 29]. p. 541–70. Available from: http://link.springer.com/10.1007/978-0-387-77452-7_29] *Caption from original*

Overall Principles of Treatment

- MG:
  - MG is a chronic disease.
  - Symptoms can be generally managed with anticholinesterase medications and immunosuppressants.
  - Plasmapherseis can be used in severe or recurrent exacerbations.
  - Thymectomy may be considered.
  - Intravenous immunoglobulin is generally beneficial
- GBS:
  - GBS is generally managed with support only, although this may entail prolonged mechanical ventilation.
- ALS:
  - Treatment of ALS is supportive.

Disease Course

- MG:
  - With close medical management, MG can generally be well tolerated by patients.
- GBS:
  - The course of GBS may be prolonged, but patients usually substantially recover.
- ALS:
  - ALS is an inexorably fatal disease.

Chapter 52
Noncardiogenic Pulmonary Edema

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Noncardiogenic Pulmonary Edema (NCPE)

- Acute respiratory distress syndrome (ARDS), high-altitude pulmonary edema, neurogenic pulmonary edema, reperfusion pulmonary edema, re-expansion pulmonary edema

Incidence/Epidemiology

- Less common than cardiogenic pulmonary edema
- ARDS incidence is uncertain but has been on the decline.
- Overall mortality is 50–75 % and prognosis varies with the patient's age, the cause of ARDS, and the number of organs involved.
- No single variable has been found to predict patient outcome.
- Even the degree of hypoxemia has not been valuable in this regard.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_52

Differential Diagnosis

- Cardiogenic pulmonary edema
- High-altitude pulmonary edema
- Neurogenic pulmonary edema
- Reperfusion pulmonary edema
- Re-expansion pulmonary edema
- Opioid overdose
- Salicylate toxicity
- Pulmonary embolism
- Viral infections
- Pulmonary veno-occlusive disease
- Eclampsia
- Inhaled toxins
- Aspiration
- Disseminated intravascular coagulation
- Acute hemorrhagic pancreatitis
- Sepsis
- Smoke inhalation
- Oxygen toxicity

Pathophysiology and Etiology

- The clinical coincidence of bilateral alveolar infiltrates causing hypoxemia in the absence of pneumonia or congestive heart failure
- It is caused by various disorders responsible for protein and fluid accumulation in the alveoli.
- Unlike cardiogenic pulmonary edema, it is not caused by high pulmonary capillary pressure.
- Most common mechanism is an increase in pulmonary capillary permeability and elevated intravascular pressure.
- The major cause of NCPE is ARDS, followed by high-altitude and neurogenic pulmonary edema.
- A subset of NCPE, neurogenic pulmonary edema, may occur after seizure or stroke and is thought to be centrally mediated.

Presentation

Typical/"Classic"

- Patients classically present with profound dyspnea and diaphoresis.
- Onset often is sudden.

- Anxiety due to hypoxemia.
- Cough is common.
- Tachypnea and tachycardia.

Atypical

- Gradual onset (over 24 hours) is less common.
- Patients may complain only of paroxysmal nocturnal dyspnea or orthopnea.
- Chest pain more predominant than dyspnea would be atypical but has been reported.

Primary Differential Considerations

- Myocardial ischemia
- Pneumothorax
- Pulmonary edema of other causes (cardiogenic, neurogenic)
- Pulmonary embolism
- ARDS

History and Physical Exam

Findings That Confirm Diagnosis

- There are no clinical findings that confirm NCPE specifically; it is a combined clinical and radiographic diagnosis.

Factors That Suggest Diagnosis

- Earliest sign is increased respiratory rate.
- Shortness of breath is the most common symptom.
- A pulmonary artery wedge pressure less than 18 mm Hg favors NCPE over cardiogenic pulmonary edema.
- NCPE usually has bounding pulses, no gallop, and no jugular venous distention.
- Fine inspiratory rales are noted.
- Cough with frothy sputum may be present.

Factors That Exclude Diagnosis

- No clinical findings can exclude NCPE, but clear lung fields on auscultation make it unlikely.

Ancillary Studies

Laboratory

- B-type natriuretic peptide (BNP) has been used to distinguish heart failure from lung disease.
  - Intermediate values are not helpful.
  - Role of biomarker in pulmonary edema has limited utility.
- In NCPE, the ratio of pulmonary edema fluid protein to plasma protein concentration is 0.7 or greater.

Electrocardiography

- Usually does not show signs of ischemia

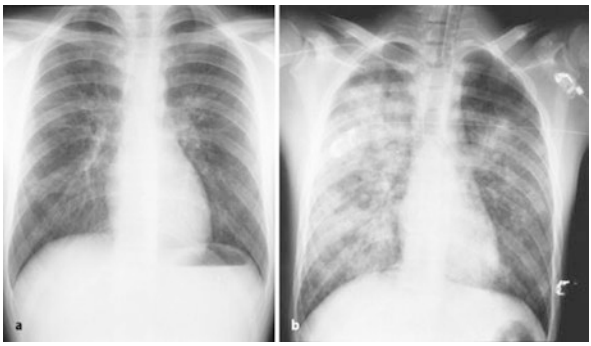
Imaging

- Chest x-ray:
  - Usually a normal cardiac silhouette.
  - Bilateral pulmonary edema, frequently in a "butterfly" pattern, is a consistent finding.
  - Air bronchograms often are seen, but Kerley lines are not.

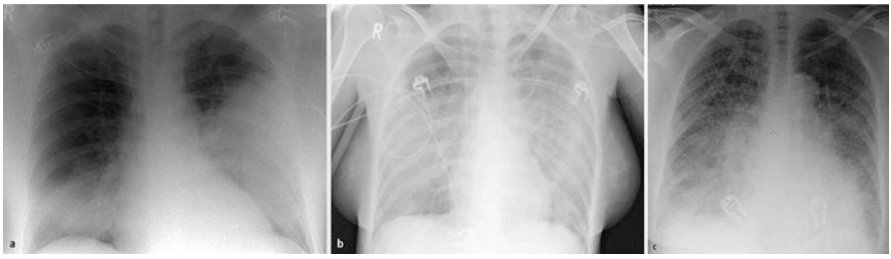
Cardiogenic	Noncardiogenic
Lower lobes	Peripheral
Perihilar	Patchy
No air bronchograms	Air bronchograms
Large heart and vascular pedicle	No cardiovascular enlargement
May be asymmetric in COPD	May be asymmetric in COPD*

*chronic obstructive pulmonary disease

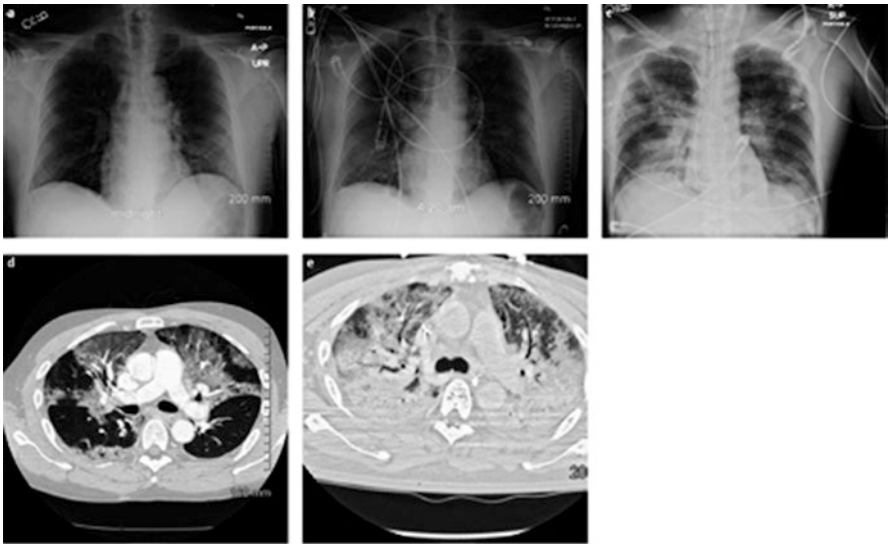
Chest radiograph in cardiogenic versus noncardiogenic pulmonary edema. [Vilar J, Andreu J. The lung parenchyma: radiological presentation of alveolar pattern. In: Coche EE, Ghaye B, de Mey J, Duyck P, editors. Comparative interpretation of CT and standard radiography of the chest [Internet]. Berlin Heidelberg: Springer; 2011 [cited 2015 Aug 13]. p. 221–45. Available from: http://link.springer.com/10.1007/978-3-540-79942-9_9] *Caption from original*



a. ARDS stage I. b. ARDS stage II. [Häuser H, Wohlgemuth WA. Bildgebende diagnostik des thorax bei intensivpatienten. Der Anaesthesist. 2005 Aug;54(8):827–48.]



The most common causes of hypoxemic ARI: a severe, community-acquired pneumonia; b ARDS during sepsis; c cardiogenic pulmonary edema [Westhoff M, Rosseau S. Nichtinvasive beatmung bei akuter respiratorischer insuffizienz: indikationen und grenzen. Der Pneumologe. 2010 Mar;7(2):89–99.] *Caption translated from original*



Acute respiratory distress syndrome (ARDS) following abdominal infection: imaging progression. a Relatively normal chest X-ray 12 h after abdominal surgery for sepsis. The patient was starting to experience dyspnea and some hypoxia. A normal chest X-ray is frequent in the early symptomatic stages of ARDS. b Four hours later, there is mild but definite interstitial thickening. c Thirty hours later, there is a dense bat's-wing consolidation in the perihilar areas. A Swan-Ganz catheter was inserted to rule out heart failure as a cause of the edema. d A computed tomography scan on day 3 shows the antigravity distribution of the ground-glass opacification that appeared to be perihilar on the chest X-ray. e In a different patient, 5 days after onset of ARDS, the edema is visible ventrally, whereas there is atelectasis, dorsally, in the gravity-dependent areas [Goodman LR. Imaging the intensive care patient. In: Hodler J, von Schulthess GK, Zollikofer CL, editors. Diseases of the heart, chest and breast 2011–2014 [Internet]. Milan: Springer; 2011 [cited 2015 Aug 13]. p. 66–9. Available from: http://link.springer.com/10.1007/978-88-470-1938-6_10] *Caption from original*

- CT:
  - CT scan is not required to make the diagnosis of NCPE.
  - When CT is performed, the scan looks similar to that of ARDS.

Special Populations

Age

- Because NCPE is a secondary event, it may occur across the age spectrum, but in general, it is more likely in elderly patients.

- In the pediatric patient, NCPE has been associated with any form of upper airway disease, including croup and epiglottitis, and choking episodes.

Co-morbidities

- Eclampsia in pregnancy may cause pulmonary edema.

Pitfalls in Diagnosis

- At times, both cardiogenic and NCPE may occur simultaneously.

Critical Steps Not to Miss

- Although pulmonary edema is the most prominent feature of ARDS, the two terms should not be used interchangeably.
- Hypoalbuminemia alone is not a cause of pulmonary edema.

Mimics

- The primary mimic of NCPE is cardiogenic pulmonary edema. Initial management of the two illnesses is similar and focuses on supporting oxygenation and reducing preload.

Time-Dependent Interventions

- Try to maintain a $Pa0_2$ of 60 mm Hg through use of oxygen and mechanical ventilation.

Overall Principles of Treatment

- Treatment varies depending on the underlying pathophysiology.
  - For example, descent to a lower altitude is the mainstay of treatment for high-altitude pulmonary edema.

- Currently, no known measures exist to correct the permeability abnormality in ARDS.
- Treatment is largely supportive and aimed at ensuring adequate ventilation and oxygenation.
  - Goal of treatment is to keep the $Pa0_2$ >60 mm Hg without injuring lungs with excessive O_2 or volutrauma/barotrauma.
- Lowering the pulmonary artery wedge pressure with diuretics and fluid restriction may improve pulmonary function in ARDS.
- Positive pressure ventilation is useful in severe NCPE.

Disease Course

- NCPE commonly develops within 24 hours of onset of the initial insult.
  - Presentation may be delayed 5 days.
- Begins with mild signs and symptoms that may progress rapidly to hypoxic respiratory failure
- Most patients require a high FiO_2 and will require mechanical ventilation.
- Ventilator-associated pneumonia is a frequent complication of ARDS.
- In severe cases, pulmonary scarring and diffuse alveolar damage may occur, especially if mechanical ventilation is used.

Chapter 53
Peptic Ulcer Disease

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Peptic Ulcer Disease (PUD)

- Gastric or Duodenal Ulcers

Incidence/Epidemiology

- Peptic ulcer disease (PUD) affects about 4 million adults in the United States, with an incidence of 0.09–0.3 % per patient year.
- Estimated annual cost to the health care system is around $15 billion, with an overall economic effect on the economy for health care, lost work, etc. of $50 billion.
- People who are infected with *Helicobacter pylori* have a lifetime prevalence of up to 20 %. Those who are uninfected have a lifetime prevalence of 5–10 %.
- The incidence of PUD has been falling steadily in the United States and all other developed nations.
- At one time, there was a decided male predominance; now, the rate is about equal in both genders.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_53

Differential Diagnosis

- The differential diagnosis of PUD is broad and includes all causes of chest and upper abdominal pain. All the causes of acute chest and abdominal pain, especially those that are immediately life threatening (e.g., acute myocardial infarction, pulmonary embolism, aortic dissection, perforated ulcer, perforated esophagus, acute cholecystitis, acute pancreatitis) must be considered first.
- In addition, there is a syndrome called non-ulcer dyspepsia that presents very similarly to PUD, but in which no ulcer or gastritis is found. The official criteria for diagnosis of non-ulcer dyspepsia is a chronic, recurrent upper abdominal pain or discomfort for at least 1 month that is present at least 25 % of the time and in which there is no evidence of organic disease. It is thought this condition may result from ulcers that are too small to be seen, acid hypersecretion, bile reflux, malabsorption, motility disorders, or sphincter of Oddi dysfunction, or that it may be functional.
- Gastritis (gastric mucosal inflammation without ulcer formation) also may have a presentation identical to that of PUD.
- *Peptic ulcer disease* refers to ulcers that develop within either the stomach (gastric) or duodenum. Although there may be subtle differences in presentation, risk factors, and natural history, the treatment remains very similar for both. Therefore, it often is not immediately necessary to refine the diagnosis to one or the other before beginning empiric treatment.

Pathophysiology and Etiology

- The upper gastrointestinal (GI) tract is regularly bathed in acid. Injury to the mucosal lining allows damage to underlying cells, which may result in ulceration and bleeding. There are a limited number of causes of PUD, including:
  - Infection with *H. pylori*, a bacterium whose growth disrupts the acid-protective barrier of the gastric mucosa:
    - *H. pylori* is more common in lower socioeconomic strata.
    - It is spread by the fecal–oral route.
    - It increases the risk of gastric carcinoma.
  - Use and abuse of nonsteroidal anti-inflammatory drugs (NSAIDs), which reduces mucosal protection from acid via interference with prostaglandin production in the upper GI mucosa.
  - Toxins such as cigarette smoke exposure and regular alcohol ingestion.
  - Hyperacidic states such as chronic anxiety.
  - Gastrin-producing tumor (Zollinger–Ellison syndrome) is a rare cause.

Presentation

Typical/"Classic"

- Chest or upper abdominal pain is typical, with the pain often described as burning or gnawing.
  - Pain may radiate to the back.
  - Pain usually occurs 2 to 3 hours after eating, at bedtime, or in the early morning hours, when gastric acid production levels are high.
  - Pain usually is relieved by eating.
  - Antacids often relieve the pain, but neither relief nor the absence of relief is pathognomonic.

Atypical

- Patients may describe only back pain; some duodenal ulcers may present with right scapular or shoulder pain.
- Patients may describe increased belching, but this is more typical of biliary tract disease.
- Vomiting is an atypical symptom of PUD. The presence of vomiting should raise concern for another diagnosis.
- Other symptoms that occasionally may be attributed to PUD but that should raise concerns for other conditions, especially malignancy, include weight loss, early satiety, dysphagia, unexplained anemia, and occult GI bleeding. Patients with any of these symptoms and those older than 55 years at first diagnosis should undergo endoscopy to exclude malignancy as the cause.

Primary Differential Considerations

- Patients with signs and symptoms of PUD may warrant an evaluation for:
  - Acute coronary syndrome
  - Esophagitis
  - Cholelithiasis and cholecystitis

History and Physical Exam

Findings That Confirm Diagnosis

- There are no historical or physical examination features that confirm the diagnosis.
- The diagnosis can be confirmed only by direct visualization through endoscopy.

Factors That Suggest Diagnosis

- A history as discussed in the presentation section may suggest the diagnosis.
- The absence of another cause of chest or abdominal pain may suggest the diagnosis.
- The initial diagnosis usually is clinical and treatment is started empirically, unless any of the "red flag" symptoms discussed under the atypical presentation section are present.

Factors That Exclude Diagnosis

- There are no historical or physical examination factors that exclude the diagnosis.
- Patients diagnosed with another cause of the initial symptoms may be acutely ill, which in and of itself is a risk factor for PUD.
- PUD may coexist with any other diagnosis.
- The only factor that excludes the diagnosis is a normal endoscopy that fully visualizes the stomach and duodenum.

Ancillary Studies

Laboratory

- Lab tests should include a complete blood count to look for anemia; measurement of serum electrolyte, blood urea nitrogen, and creatinine levels; liver function tests; and lipase testing to help evaluate for other diagnoses. In patients presenting with chest pain, cardiac biomarker testing may be indicated.
- Patients with a presumptive diagnosis of PUD should be tested for *H. pylori* infection.
    - The method for *H. pylori* testing depends on whether empiric treatment is to be initiated or the patient is proceeding to endoscopy.
    - Noninvasive tests for *H. pylori* include serologic testing for IgG. These tests have a low sensitivity and specificity; therefore, the positive predictive value of a positive test in a low-prevalence population (e.g., most of the United States) is low, limiting the usefulness of these tests. Urea breath tests have sensitivity and specificity above 95 %, so they are used frequently.

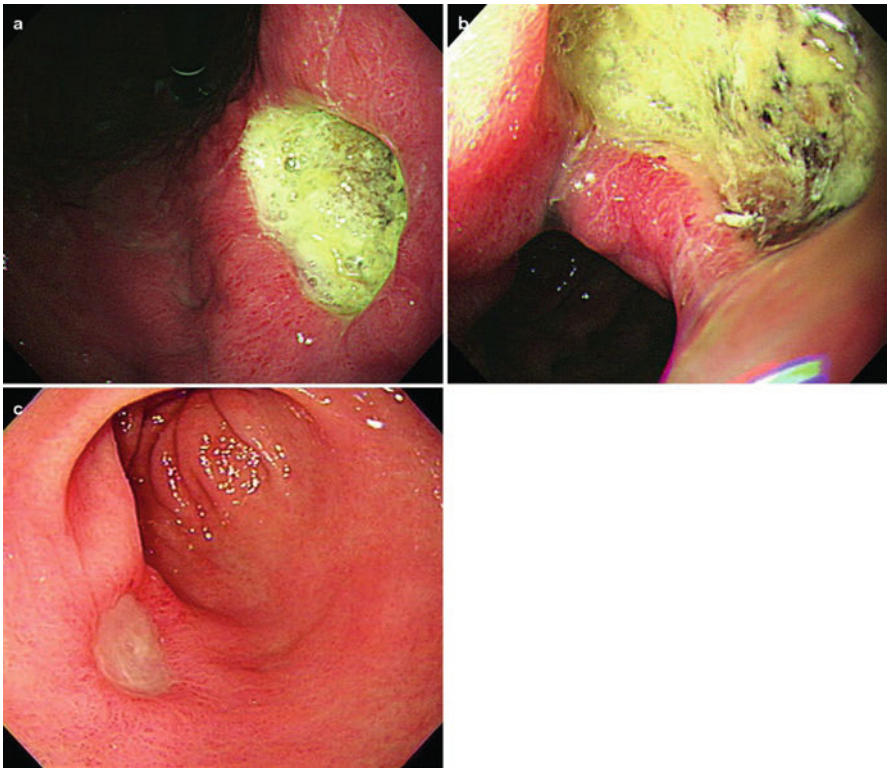
Stool antigen (Ag) tests to look for *H. pylori* have sensitivity and specificity above 90 %; these tests commonly are used to confirm cure 4 weeks after treatment completion.

- Invasive, endoscopically based tests include the rapid urease test, direct histologic examination, polymerase chain reaction tests, and culture. The only one of these tests routinely used in clinical practice is the rapid urease test. The others are expensive, as well as time and resource intensive; therefore they usually are used only used in research settings.
- If the clinical suspicion for infection is high, one positive test confirms infection. However, one negative test does not exclude infection, and a second test should be performed.
- In cases of acute bleeding, the biopsy rapid urease and stool Ag tests lack specificity; therefore, if testing must be done in this setting, the urea breath test should be used.

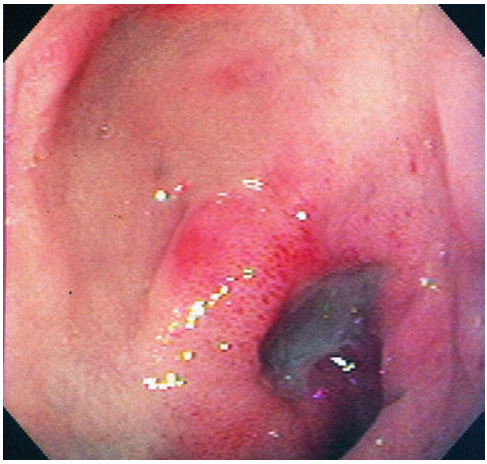
Imaging

- There are no diagnostic imaging findings of PUD
- Upper GI endoscopy is the diagnostic study of choice.

Gastric ulcer with greenish adherent exudate. [Graham D, Genta R. Helicobacter pylori. In: Lorber B, editor. Intra-abdominal infections, hepatitis and gastroenteritis. Philadelphia: Current Medicine; 1996. (Mandell GL, editor. Atlas of infectious diseases; vol. 7). ISBN 0-443-07730-4]



Endoscopic features of active gastric ulcers. (a) well-circumscribed and deeply penetrating active ulcer (b) Black pigmented area shown on close observation (c) clean ulcer base and a regular shape ulceration without exudate. [Lee SK. Gastritis and gastric ulcers. In: Chun HJ, Yang S-K, Choi M-G, editors. Clinical gastrointestinal endoscopy [Internet]. Berlin, Heidelberg: Springer; 2014 [cited 2015 Aug 28]. p. 99–122. Available from: http://link.springer.com/10.1007/978-3-642-35626-1_8] *Caption from original*



Duodenal ulcer. A deep duodenal ulcer is seen. There is surrounding inflammation with hyperemia of the mucosa. [Wilcox MC. Helicobacter pylori. In Feldman M, editor. Stomach and duodenum. Philadelphia: Current Medicine; 1996. Chapter 7. (Feldman M, editor. Gastroenterology and hepatology; vol. 3). ISBN: 0-443-07843-2]

Special Populations

Age

- The incidence of PUD increases with age.
- The incidence of upper GI bleeding from PUD increases with age.
- PUD rarely is encountered in the pediatric population.
- Younger children often present with emesis, hemorrhage, and perforation.
- *H. pylori* rarely is seen in pediatric patients; in this age range, most PUD is idiopathic.

Co-morbidities

- Patients who are acutely ill, such as those in intensive care units, have higher rates of PUD.
- Patients who smoke, abuse alcohol, use NSAIDs daily, or are maintained on glucocorticoids also are at higher risk for PUD.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- It is important not to ascribe symptoms to PUD prematurely, before evaluating for the more immediately life-threatening conditions that may present similarly.

Mimics

- The pain from PUD may mimic the pain of cardiac ischemia.
- Non-ulcer dyspepsia
- Gastritis
- Esophageal disorders

Time-Dependent Interventions

- If patients present with upper GI bleeding, they must be resuscitated and stabilized urgently.

Overall Principles of Treatment

- Most patients can be started empirically on a trial of acid suppression based on the history and normal physical examination findings. Most patients will be started on proton-pump inhibitors (PPIs), as these provide much greater acid suppression than H2-blockers.
- Patients with any of the red-flag symptoms discussed in the atypical presentation section, as well as those over 55 years old, should be referred to a gastroenterologist for endoscopy to confirm the diagnosis and rule out malignancy.
- Patients who test positive for *H. pylori* must be given appropriate antibiotic treatment to eradicate the infection. The recurrence rate of *H. pylori*–associated ulcers is 65–95 % if the infection is not eradicated and <10 % if it is. Generally, patients are started on a combination of antibiotics (most commonly, clarithromycin and amoxicillin) with a PPI. The antibiotics are given for 2 weeks; there is controversy over whether to discontinue the PPI at 2 weeks as well.
- All patients should be counseled on lifestyle modifications as appropriate. Patients who smoke cigarettes should try to quit, alcohol intake should be limited, and NSAIDs, including aspirin, should be avoided.

Disease Course

- Ulcers that are not treated, those that are poorly treated, and, rarely, even those that are adequately treated may develop many complications. Some may be life threatening.
- In order of prevalence, the most common complications of PUD are:
  - Bleeding, typically from inflamed mucosa, but sometimes from ulcer erosion into a submucosal vessel.
    - Hemorrhage is more common in older patients.
  - Perforation of the ulcer through the gastric or duodenal wall, most often posteriorly and causing severe back pain from leakage of gastric contents.
  - Gastric outlet obstruction from chronic inflammation and swelling around an ulcer in or near the gastroduodenal junction.

Chapter 54
Pericardial Effusion

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Jaime Friel

Name and Synonyms

Pericardial effusion; tamponade

Incidence/Epidemiology

- 60 % of cases are related to a known or suspected underlying process.
- Malignancies with the highest prevalence of pericardial effusion include lung, breast, and leukemia/lymphoma.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_54

Differential Diagnosis

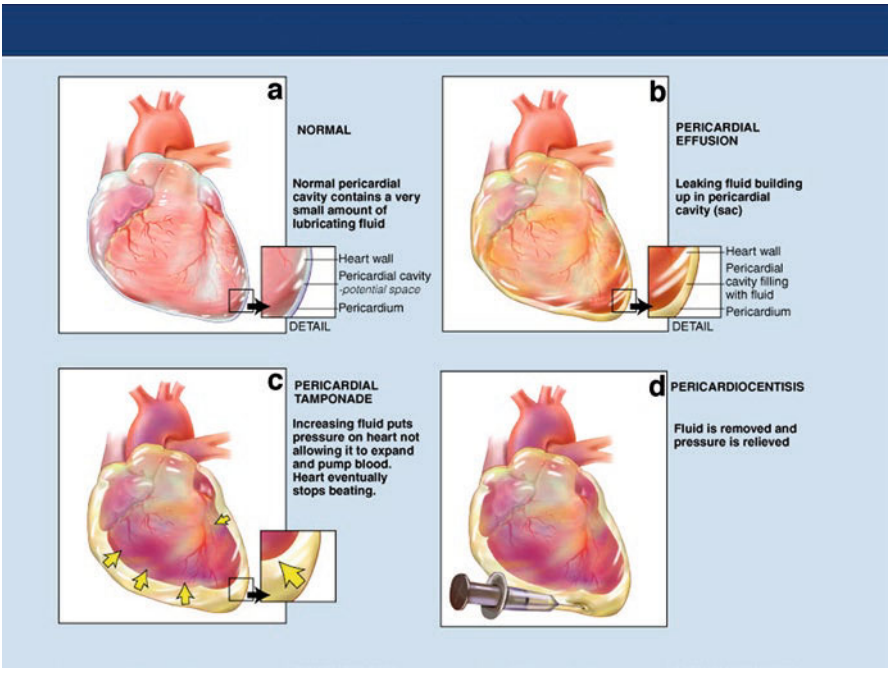
- Acute pericarditis
- Autoimmune disease
- Postmyocardial infarction or cardiac surgery
- Sharp or blunt chest trauma
- Malignancy
- Mediastinal radiation
- Renal failure with uremia
- Myxedema
- Aortic dissection extending into pericardium
- Dilated cardiomyopathy
- Pulmonary edema
- Pulmonary embolism
- Myocarditis

Pathophysiology and Etiology

- Accumulated fluid within the pericardial sac exceeds the small amount that is normally present.
  - 25–50 ml may be physiologic
- May develop rapidly or slowly.
- Accumulation of pericardial fluid into a closed space increases intrapericardial pressure.
- Cardiac tamponade is present when intrapericardial pressure becomes high enough to impede cardiac filling and function.
  - May occur with small amounts of fluid (~80 cc) when the pericardial cavity fills quickly; effusions may accumulate slowly to much higher volumes (up to 2 L) without symptoms.
  - Occurs when diastolic filling pressures equalize and prohibit effective pump function

Malignancy
Postoperative (postpericardiotomy)
Cardiac puncture from invasive procedures (electrophysiology studies, cardiac catheterization, pacemaker/ICD implantation)
Ischemic heart disease related (postinfarct as in Dressler's Syndrome; myocardial rupture)
Infectious
Immune/connective tissue diseases (lupus; rheumatoid arthritis; vasculitides)
Idiopathic
Renal failure
Drug-related and anticoagulants
Postradiation
Chest trauma
Hypothyroidism
Amyloidosis

Etiologies of pericardial effusion [Tsang TSM, Sinak LJ, Oh JK. Pericardial Effusion, Tamponade, and Constriction. In: Nihoyannopoulos P, Kisslo J, editors. Echocardiography [Internet]. London: Springer London; 2009 [cited 2015 Sep 2]. p. 297–310. Available from: http://link.springer.com/10.1007/978-1-84882-293-1_14] *Caption from original*



Illustrations demonstrate the progressive effects of a large pericardial effusion on the heart (a–c). If the effusion is large enough to compress the cardiac chambers it

will ultimately limit cardiac output. In this setting, an emergency pericardiocentesis is necessary (d) [Towbin R. The bowed catheter sign: a risk for pericardial tamponade. Pediatric Radiology. 2008 Mar;38(3):331–5.] *Caption from original*

Presentation

Typical/"Classic"

- Many patients with pericardial effusion have no symptoms.
- Signs and symptoms may not occur until a large amount of fluid has collected over time.
- Beck triad of pericardial **tamponade**: Hypotension, muffled heart sounds, jugular venous distention.

Atypical

- Atypical presentations might include primary complaints of syncope, shortness of breath (especially on exertion), and chest pain.

Primary Differential Considerations

- Diagnostic approach consists of 3 steps:

  1. Confirm the presences of a pericardial effusion
  2. Assess its hemodynamic impact
  3. Establish the cause of the effusion

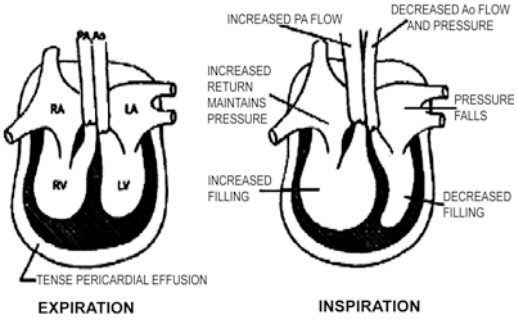
History and Physical Exam

Findings That Confirm Diagnosis

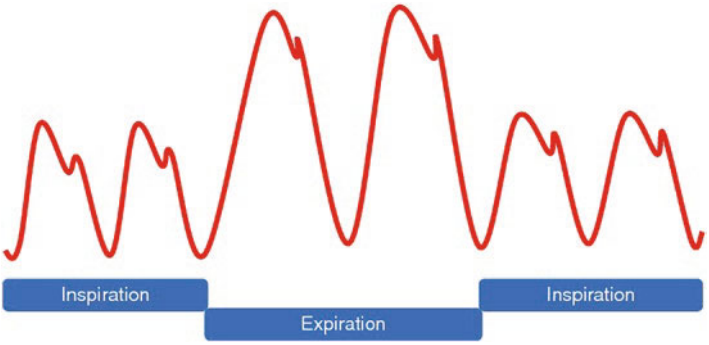
- The diagnosis is strongly suggested by the finding of concomitant hypotension, muffled heart sounds, and jugular venous distention. Confirmation requires imaging, typically with an echocardiogram.

Factors That Suggest Diagnosis

- Chest pain
- Syncope
- Cough
- Ewart's sign (triangular area of dullness at the tip of the left scapula along with tubular breath sounds and egophony at the same location)
- May have fever in the setting of pericarditis
- Elevated jugular venous pressure
- Edema
- Pulsus paradoxus
- Pericardial friction rub
- Tachycardia
- Hepatojugular reflux
- Tachypnea
- Hepatosplenomegaly



Pulsus paradoxus expiration and inspiration. [Reprinted from Curr Probl Cardiol., Vol. 29, Iss. 9, Goldstein JA. Cardiac tamponade, constrictive pericarditis, and restrictive cardiomyopathy. Pages 503-567, Copyright 2004, with permission from Elsevier].



Pulsus paradoxus demonstrating an exaggerated decline in systolic blood pressure during inspiration, resulting from an increase in negative intrathoracic pressure [Patel S, Kronzon I. History and Physical Examination of a Patient with Pericardial Disease. In: Herzog E, editor. Management of Pericardial Disease [Internet]. Cham: Springer International Publishing; 2014 [cited 2015 Sep 2]. p. 27–35. Available from: http://link.springer.com/10.1007/978-3-319-06124-5_3] *Caption from original*

Factors That Exclude Diagnosis

- The absence of a pericardial effusion on echocardiogram is the only way to exclude the diagnosis with certainty.

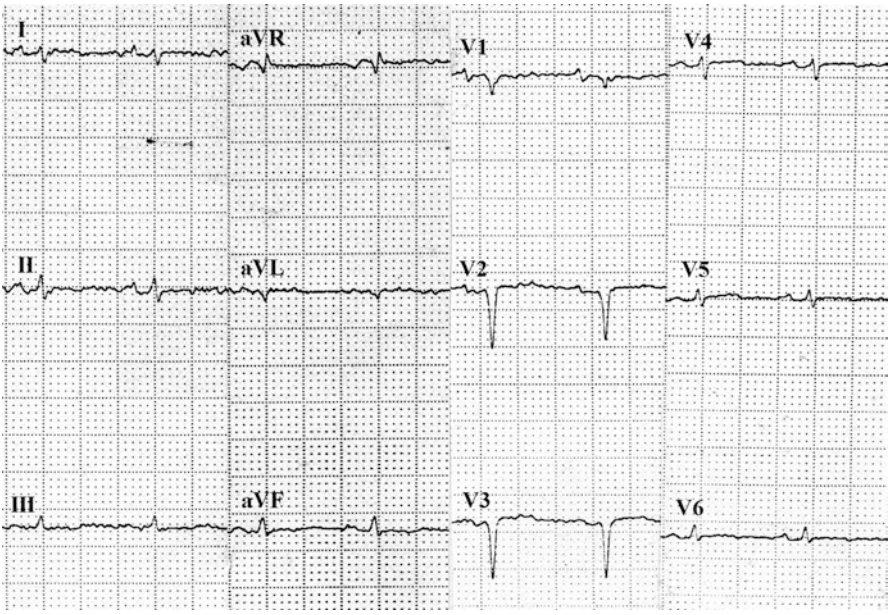
Ancillary Studies

Laboratory

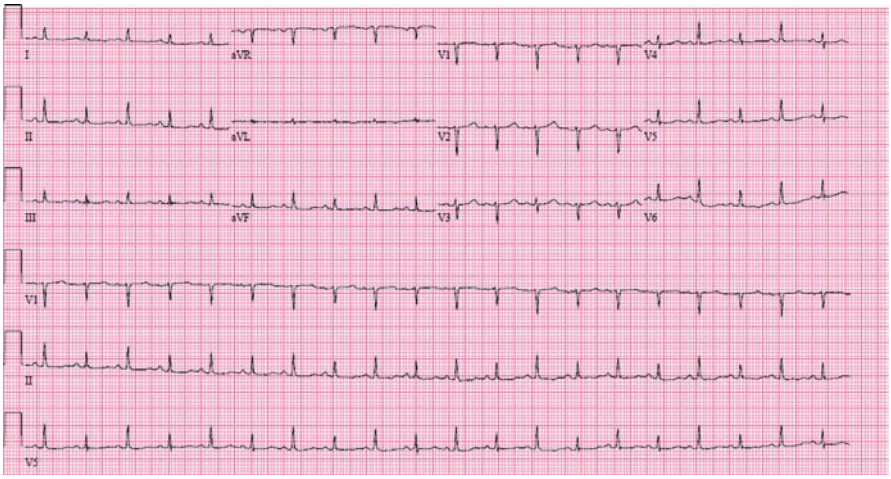
- Cardiac biomarkers may be elevated with acute myopericarditis or myocardial infarction.
- Moderate or large effusions etiology may be established with fluid and/or pericardial tissue analysis.
  - Fluid analysis may be obtained if clinical suspicion of purulent, tuberculous, or neoplastic pericarditis.
- CBC.
- Chemistry profile with renal function.
- Thyroid function.
- ANA testing.

ECG

- Sinus tachycardia.
- Low QRS voltage.
- Electrical Alternans.
- The combination of low voltage with sinus tachycardia should raise concern about pericardial effusion with tamponade.
- Electrical alternans with sinus tachycardia is highly specific of pericardial effusion.
    - Its absence does not exclude cardiac tamponade.



ECG in a patient with massive pericardial effusion causing pericardial tamponade. The key feature is a significant decrease in the QRS voltage in all leads [Romanò M. The Electrocardiogram in Diseases of the Pericardium and Myocardium. Text Atlas of Practical Electrocardiography [Internet]. Milano: Springer Milan; 2015 [cited 2015 Sep 2]. p. 209–12. Available from: http://link.springer.com/10.1007/978-88-470-5741-8_13] *Caption from original*



EKG demonstrating electrical alternans [Aksoy O, Rodriguez L. Tamponade. In: Anwaruddin S, Martin JM, Stephens JC, Askari AT, editors. Cardiovascular Hemodynamics [Internet]. Totowa, NJ: Humana Press; 2013 [cited 2015 Sep 2]. p. 181–96. Available from: http://link.springer.com/10.1007/978-1-60761-195-0_9] *Caption from original*

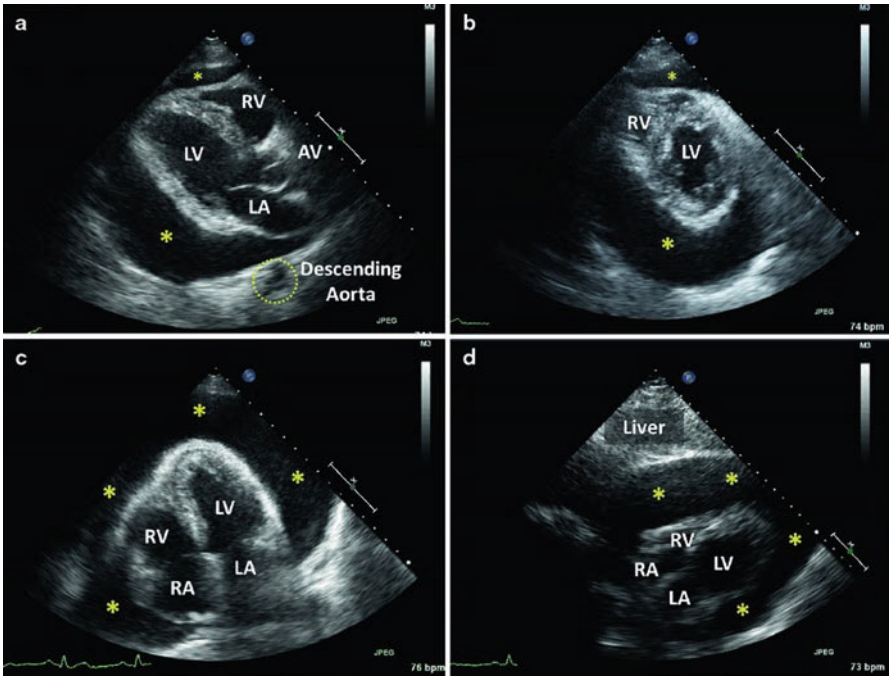
Imaging

- Chest x-ray
  - Variable.
  - Depends on etiology and size of effusion.
    - Small-to-moderate effusions (less than 200–300 ml) may not be apparent on CXR.
  - Enlarged cardiac silhouette "water bottle heart" is not specific and cannot be considered diagnostic.

Chest radiograph of a large pericardial effusion. The cardiac diameter is markedly enlarged and the cardiac silhouette has a characteristic globular shape. This picture is seen in slowly developing chronic effusions when there is time for the pericardium to stretch. In an acute cardiac tamponade caused by bleeding into the pericardium the chest radiograph may show little or no cardiac enlargement. [Woodcock B. Hemodynamic Emergencies. In: Miller RD, Tremper KK, editors. Atlas of Anesthesia: Principles of Anesthetic Techniques and Anesthetic Emergencies, Volume 4, 1e. Vol. IV. Philadelphia: Current Medicine; 1998. 195 p.] *Caption from original*

Echocardiography

- Sensitive and specific for pericardial effusion.
- Can provide information regarding the hemodynamic significance of the effusion.
- Small effusions (50–100 mL) can be seen posterior to the left ventricle.
- Most sensitive and specific view is the accumulation of pericardial fluid above the right atrium in the apical four chamber view with the patient in the left lateral decubitus.
- Plays important role in diagnosis of cardiac tamponade.
    - Collapse of the right atrium at end diastole and the right ventricle in early diastole.
    - Reciprocal changes in left and right ventricular volumes with respiration.
    - Dilation of IVC and less than a 50 % reduction in its diameter during inspiration.

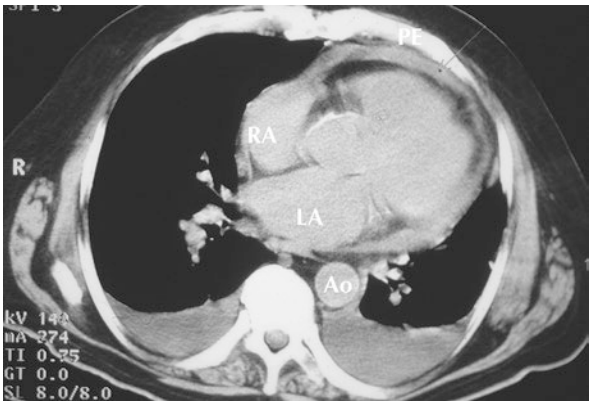


Pericardial effusion. Transthoracic echocardiogram demonstrates a large pericardial effusion (asterisks) in a 47-year-old woman with breast cancer. Panel a: Parasternal long axis view demonstrates typical interposition of the pericardial effusion (asterisks) between the heart and the descending thoracic aorta. This finding differentiates a pericardial effusion from a left pleural effusion in which there is no such interposition between the heart and the descending thoracic aorta. Panel b: Parasternal short axis at the level of the papillary muscles demonstrates that the pericardial effusion (asterisks) is larger posterior to the left ventricle that anterior to the right ventricle. This is due to gravity in this supine patient. Panel c: In the apical 4-chamber view, note that the pericardial effusion (asterisks) surrounds the cardiac apex. This feature helps distinguish a pericardial effusion from a pleural effusion. Panel d: Subcostal view demonstrates a large pericardial effusion (asterisks). Abbreviations: AV aortic valve, LA left atrium, LV left ventricle, RA right atrium, RV right ventricle [Saric M. Echocardiography in Pericardial Disease. In: Herzog E, editor. Management of Pericardial Disease [Internet]. Cham: Springer International Publishing; 2014 [cited 2015 Sep 2]. p. 49–70. Available from: http://link.springer.com/10.1007/978-3-319-06124-5_5] *Caption from original*

CT and MRI

- May be used after non-diagnostic echocardiography.

- May be useful when quantification and localization of pericardial fluid is important, when complex effusions are present, or when epicardial fat and pleural effusions need to be excluded.



Pericardial effusion (PE). PEs are usually well shown by echocardiography. However, they are often a finding on conventional computed tomography (CT) scan or ultrafast CT (UFCT; Imatron, South San Francisco, CA). CT may show loculated pericardial fluid that cannot be shown by echocardiography. A, On unenhanced scans, a PE often has attenuation similar to soft tissue and therefore has the same density as do myocardium and blood pool. PE is usually visible as a layer of abnormal thickening separated from the heart by a line of low-attenuation epicardial fat, as shown in this example. Sometimes the epicardial fat is very thin; however, it still should be visible. Ao—aorta; LA—left atrium; RA—right atrium. [Hartnell G. Chapter 7. In: Lee RT, Braunwald E, editors. Atlas of Cardiac Imaging. Atlas of Heart Diseases, Volume 01, Philadelphia: Current Medicine; 1998. ISBN: 0-443-07567-0] *Caption adapted from original*

B, If there is doubt whether there is a PE or if there is no epicardial fat, intravenous contrast medium will enhance the myocardium but not the pericardial fluid. The attenuation of the myocardium will increase, as shown in this patient with

lymphoma invading the pericardium, whereas the attenuation of the pericardial fluid (here mostly loculated posteriorly) is unchanged, enhancing the difference between the two. Although CT is not recommended as the first line method for detecting PEs, it frequently shows underlying conditions such as tumor, which may lead to pericardial effusion. In addition, in patients who are poor subjects for echocardiography, CT will show PEs, including effusions loculated in areas difficult to examine by echocardiography. [Hartnell G. Chapter 7. In: Lee RT, Braunwald E, editors. Atlas of Cardiac Imaging. Atlas of Heart Diseases, Volume 01, Philadelphia: Current Medicine; 1998. ISBN: 0-443-07567-0] *Caption adapted from original*

Special Populations

- Populations at particular risk for development of a pericardial effusion include patients with
  - Malignancy
  - Renal failure
  - Autoimmune diseases, such as lupus
  - Certain unusual systemic infections, such as tuberculosis
  - Some viral infections, incluing HIV
  - Very recent myocardial infarction
  - Very recent heart surgery

Age

- Most common in the fourth and fifth decades of life.
- Within the pediatric population, reported cases of pericardial effusion are most likely due to enteroviral infections, specifically Coxsackie viral infections. Other pediatric specific etiologies include malignancies, specifically the leukemias.
- In addition, cases of pediatric myocarditis may involve the pericardium as well.

Co-morbidities

- Patients with heart disease, renal failure, or malignancy are at risk of developing pericardial effusion.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Rapid diagnosis of cardiac tamponade is needed for urgent treatment.
- No positive-pressure ventilation because of its adverse effects on venous return and cardiac output.

Mimics

- Cardiomyopathy, which also causes diminished cardiac output and an enlarged cardiac silhouette on chest radograph.

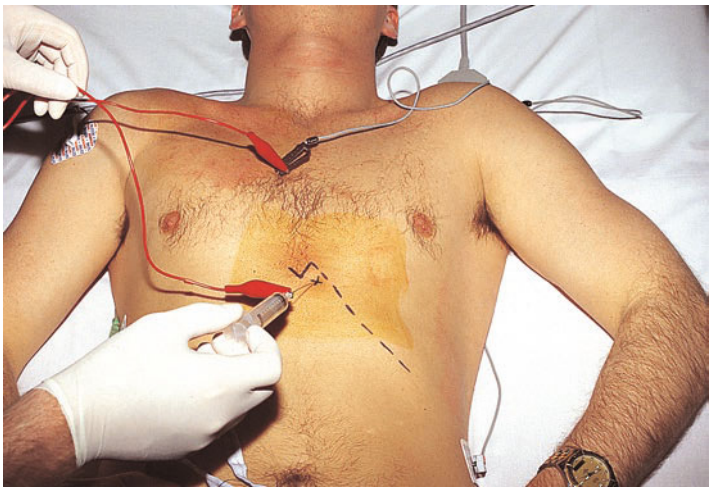
Time-Dependent Interventions

- Drainage of a pericardial effusion is often performed for therapeutic benefit, as in cardiac tamponade.
- Patients with a pericardial effusion and evidence of hemodynamic compromise should undergo urgent drainage.
- Cardiac tamponade is initially treated with expansion of intravascular volume and urgent pericardial drainage.

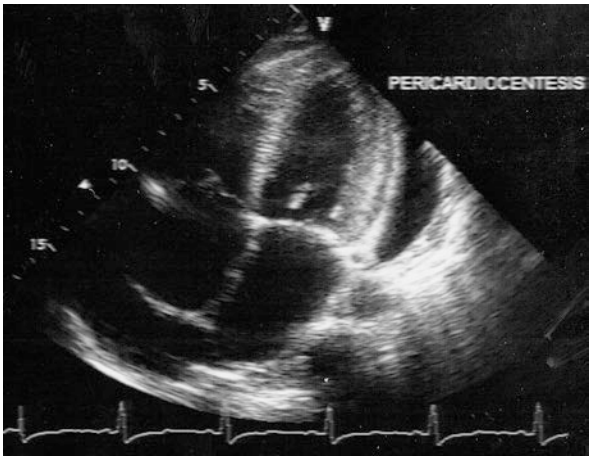
Overall Principles of Treatment

- Development of pericardial effusion may have implications for prognosis and diagnosis.
- Patient with effusion who are hemodynamically stable do not require immediate drainage.
- Manage underlying cause:
    - NSAIDs or prednisone for inflammatory effusions
    - Diuretics for heart failure-associated effusions
    - Antibiotic if infection is suspected
    - Malignant effusions may respond as the underlying cancer is treated with chemotherapy or radiation
- The choice between pericardiocentesis and open surgical drainage is multifactorial and institution specific:
    - Both techniques allow for rapid relief of cardiac tamponade
    - Both allow for fluid analysis if needed

- A percutaneous continuous catheter drain may be placed for intermittent or continuous removal until the rate of fluid return is negligible.

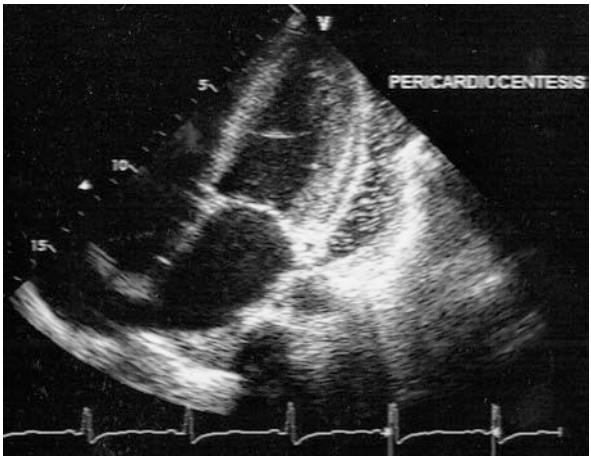


Pericardiocentesis [Woodcock B. Hemodynamic Emergencies. In: Miller RD, Tremper KK, editors. Atlas of Anesthesia: Principles of Anesthetic Techniques and Anesthetic Emergencies, Volume 4, 1e. Vol. IV. Philadelphia: Current Medicine; 1998. 195 p.]



Echocardiographically guided pericardiocentesis. In addition to confirming the presence, location, and distribution of pericardial effusion, two-dimensional echocardiography can enhance the safety of percutaneous pericardiocentesis by identifying the optimal entry site (the point at which the distance from skin to prominent

fluid accumulation is minimized, with no intervening vital organ). Once the needle has entered the pericardial space and a sheath or catheter is inserted, confirmation and documentation of intrapericardial location can be achieved by injecting a small amount of agitated saline. A moderate-to-large size pericardial effusion is present as shown in the modified apical four-chamber view (A). [Goldstein S, Pita F. Chapter 9. In: Vannan MA, Lang RM, Rakowski H, Tajik AJ, Braunwald E, editors. Atlas of Echocardiography. 1e. Philadelphia, PA: Current Medicine Group; 2005. 312 p. ISBN: 1-57340-217-6] *Caption adapted from original*



Proper catheter location is confirmed by the echogenic microbubbles observed within the pericardial space (B). This technique should be used routinely to minimize complications. [Goldstein S, Pita F. Chapter 9. In: Vannan MA, Lang RM, Rakowski H, Tajik AJ, Braunwald E, editors. Atlas of Echocardiography. 1e. Philadelphia, PA: Current Medicine Group; 2005. 312 p. ISBN: 1-57340-217-6] *Caption adapted from original*

Disease Course

- Often self-limited or responsive to NSAIDs or corticosteroids.
- Many secondary cases are responsive to better management of underlying disease.
- Perform follow-up echocardiography to rule out accumulation and constrictive physiology.

Chapter 55
Pleural Effusion

Charles V. Pollack, Jr., Melissa Platt, Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Pleural Effusion

- Hydrothorax, chylothorax, malignant effusion, parapneumonic effusion

Incidence/Epidemiology

- Pleural effusions may develop as a result of more than 50 different disorders.
  - The most common causes are congestive heart failure, malignancy, severe pneumonia, and thromboembolism.
  - A particularly worrisome, potentially infectious cause is tuberculosis.
  - In pediatrics, the incidence of parapneumonic effusions is increasing.

C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_55

Differential Diagnosis

- The differential diagnosis of pleural effusion is quite broad and includes the following:
  - Congestive heart failure
  - Hepatic hydrothorax
  - Nephrotic syndrome
  - Hypoproteinemia
  - Glomerulonephritis
  - Superior vena cava obstruction
  - Malignancy
  - Pneumonia
  - Tuberculosis
  - Pulmonary embolism
  - Fungal infection
  - Pancreatic pseudocyst
  - Intra-abdominal abscess
  - Post coronary artery bypass graft surgery
  - Post–cardiac injury syndrome
  - Pericardial disease
  - Meigs syndrome
  - Ovarian hyperstimulation syndrome
  - Rheumatoid pleuritis
  - Lupus
  - Drug-induced pleural disease
  - Asbestos pleural effusion
  - Uremia
  - Chylothorax
  - Acute respiratory distress syndrome
  - Chronic pleural thickening
  - Malignant mesothelioma

Pathophysiology and Etiology

- The pleural space (which lies between the parietal pleura and visceral pleura) is a potential anatomic space which normally holds only a small amount of sterile fluid. Fluid is filtered by the parietal pleura and absorbed by the visceral pleura. Governed by Starling's equation, blood and pleural fluid are in hydrostatic and oncotic balance. When an imbalance exists between the blood and pleural hydrostatic and oncotic pressure, fluid accumulates in the pleural space. Pleural effusions develop whenever influx of fluid into the pleural space exceeds lymphatic efflux.

- There are two types of pleural effusions: transudative and exudative.
  - The fluid in a transudative effusion contains very little protein but is otherwise similar to plasma.
    - Most transudates result from heart failure, but sometimes they are seen in advanced liver disease, nephrotic syndrome, and hypoalbuminemia.
  - The fluid in an exudative effusion is protein rich and is generally associated with pneumonia ("parapneumonic effusion") or cancer ("malignant effusion").

Presentation

Typical/"Classic"

- Small pleural effusions may be entirely asymptomatic.
- Large pleural effusions may present with significant respiratory distress that usually is insidious in onset.
- In pediatrics, the most common presenting symptoms are fever, cough, malaise, anorexia, chest pain, and dyspnea.

Atypical

- Chest pain in isolation is unusual; a viral-type prodrome with low-grade fever preceding chest pain is more common.

Primary Differential Considerations

- The underlying disease process may dominate or obscure the signs and symptoms of the pleural effusion.

History and Physical Exam

Findings That Confirm Diagnosis

- The diagnosis cannot be confirmed without imaging.

Factors That Suggest Diagnosis

- Localized reduced breath sounds on auscultation and dullness to percussion in the same area suggest pleural fluid collection.
- A history of typical predisposing diagnoses, such as heart failure, pneumonia, nephrotic syndrome, liver disease, or malignancy, in a patient with the aforementioned physical findings should prompt imaging. Pleural friction rub is sometimes appreciated and may suggest the diagnosis.

http://www.easyauscultation.com/cases?coursecaseorder=7&courseid=201

Pleural friction rub. [Pleural Rubs; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

Factors That Exclude Diagnosis

- The absence of effusion on radiographic study is the only way to exclude the diagnosis with certainty.
- Symmetric breath sounds on auscultation and the absence of dullness to percussion in the lower lung fields make the diagnosis of pleural effusion unlikely. Small loculated effusions may still be present, however, and must be excluded by imaging.

Ancillary Studies

Laboratory

- Usual laboratory studies for evaluating co-morbidities should be obtained.
- If pleural tap is performed, fluid should be sent for Gram stain, cytology, cell count, cultures, protein, lactate dehydrogenase (LDH), and glucose.
    - As menti.oned earlier, transudative fluid has little protein (pleural protein to serum protein < 0.5).

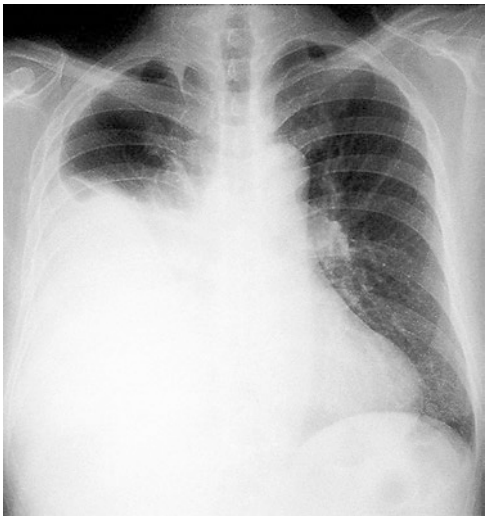
Infection
Bacterial
Mycobacterial
Fungal
Parasitic
Mixed
Gastrointestinal disease
Esophageal perforation
Mediastinitis
Subdiaphragmatic infection
Other
Collagen-vascular disease
Malignancy
Uremia
Drug-induced disease
Pulmonary embolism
Abestosis
Sarcoidosis
Radiation injury
Trauma
Hemothorax
Chylothorax

Differential diagnosis of exudative pleural effusion. Once an effusion is classified as exudative, diagnostic considerations include many infectious and noninfectious diseases. [Salmon C, Bryant R. Pleural effusion and empyema. In: Simberkoff MS, editor. Pleuropulmonary and bronchial infections. Philadelphia: Current Medicine; 1996. Chapter 10. (Mandell GL, editor. Atlas of infectious diseases; vol. 6). ISBN: 0-443-07740-1] *Caption from original*

- The measurement of pleural cholesterol, triglycerides, and amylase also may provide useful information in selected patients.
    - Blood cultures should be performed in all children with parapneumonic effusions. Blood cultures are positive in 10–22 % of children with complicated parapneumonic effusions.
    - In certain instances, tuberculosis testing may be warranted.

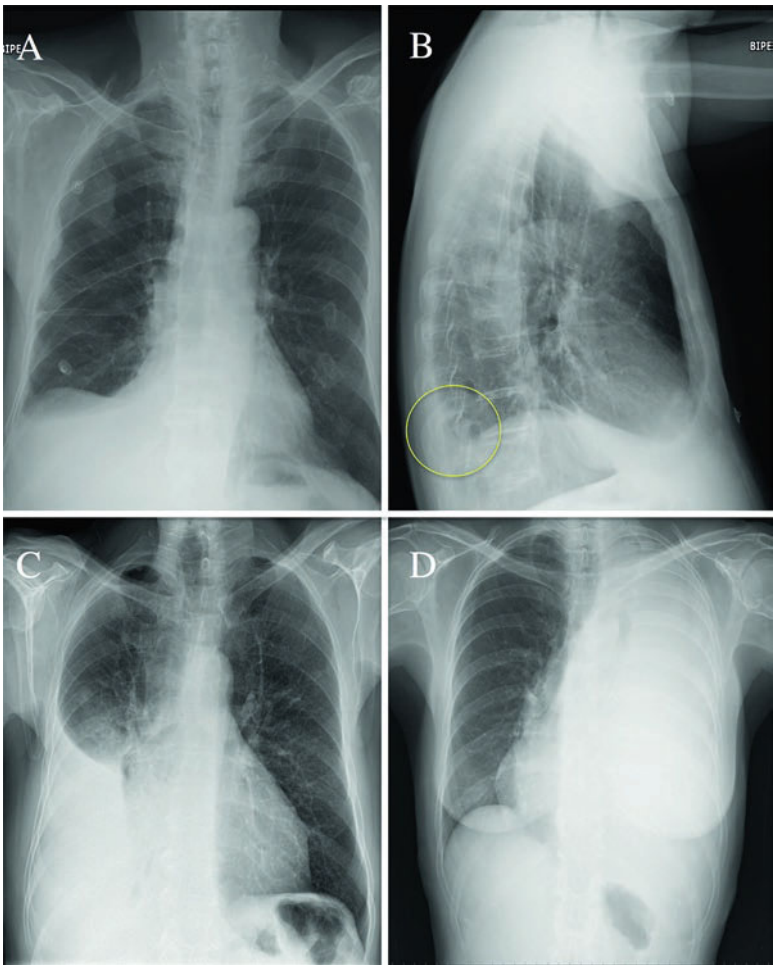
Imaging

- Chest radiography (posteroanterior [PA] or anteroposterior upright and lateral decubitus radiographs) confirms the following:
  - Blunting or obliteration of the costophrenic angle on an upright chest radiograph
  - A "meniscus sign" (rim of fluid ascending the lateral chest wall) may be seen.
  - On a PA view, opacification of more than half the thorax suggests a large effusion.
  - On a PA view, opacification of more than one quarter but less than half of the thorax suggests a moderate-sized effusion.
  - A decubitus permits free fluid to layer out on the dependent chest wall and may help distinguish the meniscus from pleural thickening.



Pleural effusion. Pleural effusion is present in about 6% of patients with ascites, and more often it is on the right side. This is the result of a defect in the diaphragm that allows the ascitic fluid to pass up into the pleural cavity. In contrast, a left-sided pleural effusion in an ascitic patient may indicate pulmonary pathology. Occasionally, a pleural effusion can be seen in the absence of ascites caused by the negative intrathoracic pressure drawing up the ascitic fluid through the diaphragmatic defect into the pleural cavity. Thoracocentesis is followed by rapid refilling of the pleural cavity because of the negative intrathoracic pressure. Control of the pleural effusion can only be achieved with the control of ascites. Insertion of a permanent chest tube can lead to the development of a fistula and is not recommended. [Wong F. Cirrhosis: ascites and spontaneous bacterial peritonitis. In: Maddrey WC, series editor. Atlas

of the liver, 4e. Philadelphia: Current Medicine; 2007 (Feldman M, editor. Atlas of gastroenterology and hepatology) ISBN: 1-57340-241-9] *Caption from original*



Different chest x-ray images in patients with pleural effusion. (a) Postero-anterior (PA) chest x-ray of a patient with minimal pleural effusion impossible to be detected in this projection. (b) Lateral chest x-ray of the same patient. The circle shows a detectable posterior costo-phrenic angle blunting confirming the presence of minimal pleural effusion. (c) PA chest x-ray of a patient with a moderate right pleural effusion. (d) PA chest x-ray of a patient with a massive left pleural effusion with contralateral mediastinal shift *[*Call S, Sánchez D, Rami-Porta R. Diagnosis and treatment of malignant pleural effusion. In: Kiselevsky MV, editor. Malignant effusions [Internet]. Dordrecht, Netherlands: Springer; 2012 [cited 2015 Aug 28]. p. 23–55. - Ultrasound is particularly helpful in guiding thoracentesis.
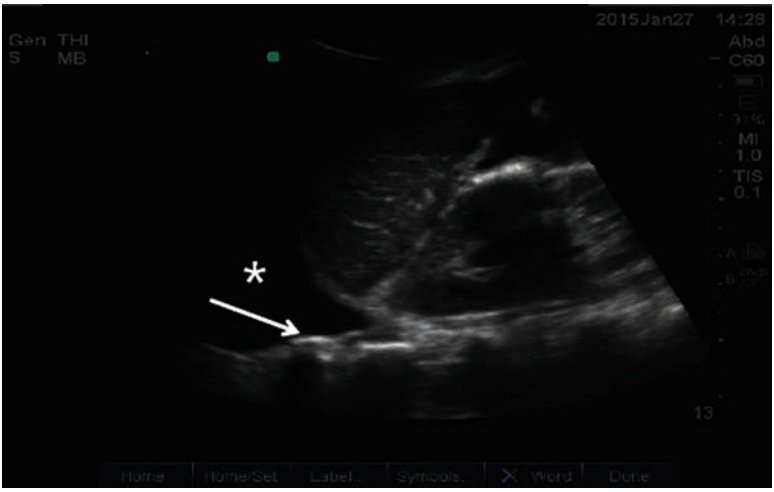
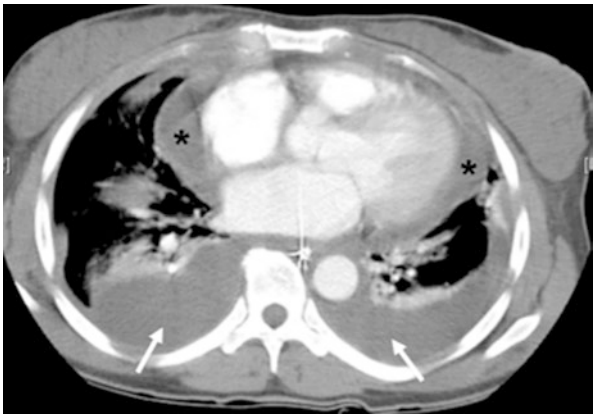
  - Preferred modality in pediatrics
  - Superior to CT because of better accuracy in detecting early loculations and septations



Pleural effusion. Pleural effusion (*asterisk*) permits the ultrasound beam to penetrate deeply to reveal the vertebral stripe (*arrow*). The vertebral stripe will not be visible above the diaphragm if the lung is aerated [From article: Clinically integrated multi-organ point-of-care ultrasound for undifferentiated respiratory difficulty, chest pain, or shock: a critical analytic review. J Intensive Care. 2016 Aug 15;4(1):54. https://doi.org/10.1186/s40560-016-0172-1, at http://link.springer.com/article/10.1186%2Fs40560-016-0172-1/fulltext.html; by Young-Rock Ha, Hong-Chuen Toh, © The Author(s). 2016; licensed under Creative Commons Attribution 4.0 International License http://creativecommons.org/licenses/by/4.0/] *Caption from original*

- Chest CT
  - Can identify small effusions and determine whether larger effusions are loculated, and may identify underlying disease



Pleural effusion in systemic lupus erythematosus. Enhanced CT scan at systemic lupus erythematosus (SLE) presentation. Bilateral pleural (arrows) and pericardial (asterisk) effusions resolved promptly with therapy. [Berney S, Heldmann M. Chapter 14. In: Crapo J, editor. Bone's atlas of pulmonary and critical care medicine. 3rd ed. Philadelphia: Current Medicine; 2005. ISBN: 1-57340-211-7] *Caption adapted from original*

Special Populations

Age

- Pleural effusion may occur at any age, although owing to the greater number of underlying disease processes (heart failure, cirrhosis, uremia, malignancy), the incidence increases with age.
- The most common cause of pleural effusion in the pediatric population is lung infection (parapneumonic effusion).
    - Within the pediatric population, reported cases of pleural effusion are on the rise, usually as a result of resistant organisms causing the primary infectious process.
    - Many emergency departments are using ultrasound to accurately diagnose pleural effusions in infants and children.

Co-morbidities

- Because pleural effusion likely is the result of an underlying disease process, those with a history of congestive heart failure, cirrhosis, nephrotic syndrome, mesothelioma, esophageal rupture, certain rheumatologic diseases, or drug-induced lupus, to name a few, also are at risk for pleural effusions.

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Any child who remains febrile or unwell 48 hours after initiation of antibiotic therapy for pneumonia should be reevaluated for possible pleural effusion.
- Always consider pulmonary embolism as a potential underlying cause of effusion.

Time-Dependent Interventions

- Emergency thoracentesis may be warranted for severe respiratory distress.

Overall Principles of Treatment

- Empyema mandates chest tube insertion.
- If effusion does not have a clear etiology, pleural fluid analysis is required.
- Heart failure–associated effusions usually improve with diuresis for the underlying disease.
- Many small effusions are not clinically important and resolve spontaneously.

Disease Course

- Malignant pleural effusions seldom resolve spontaneously.
- Effusions that do not clear with management of underlying disease are more worrisome.
- Effusions may recur, especially in patients with chronic underlying disease, such as heart failure, cirrhosis, or nephrotic syndrome.
- Effusions associated with acute disease, such as pneumonia, usually do not recur.

Chapter 56
Pleurisy

Charles V. Pollack, Jr., Richard M. Cantor, and Victoria G. Riese

Name and Synonyms

Pleurisy

- Pleuritic, pleuritic pain

Incidence/Epidemiology

- Pleurisy or pleuritic pain is common and nonspecific.
- There are no clear incidence data, as many patients with pleurisy do not seek medical attention. Others may have significant chest pain as a result of pleurisy.

Differential Diagnosis

- The differential considerations for chest pain due to pleurisy include immediate life threats such as pulmonary embolism, acute coronary syndrome, and aortic dissection.

C. V. Pollack, Jr. (✉)

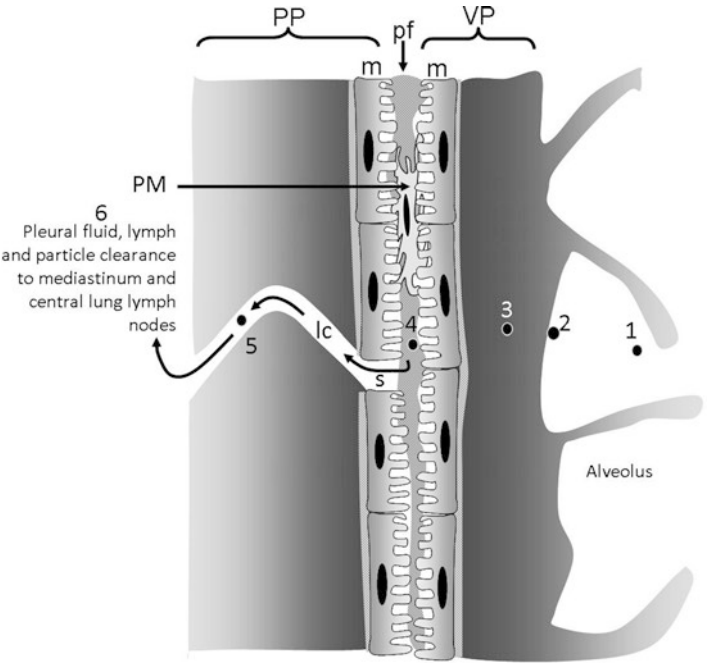
C. V. Pollack, Jr. (ed.), *Differential Diagnosis of Cardiopulmonary Disease*,
https://doi.org/10.1007/978-3-319-63895-9_56

- Less severe differential considerations include pneumonia and pneumothorax, which may cause pleuritic pain, as well as chest wall pain and anxiety.
- Pericarditis may present similarly.
- Acute chest syndrome in sickle cell disease is a differential consideration in at-risk patients.

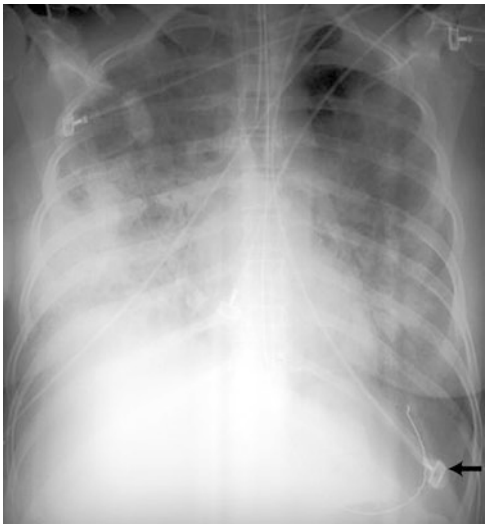
Pathophysiology and Etiology

- The pleura is a two-layer membrane in the thorax. The outer, or parietal, layer lines the chest cavity, whereas the inner, or visceral, layer adheres tightly to the lungs. Between these layers is a tiny space that normally contains a small amount of lubricating fluid. In pneumothorax, this space contains air, and in pleural effusion, this space contains larger amounts of fluid.

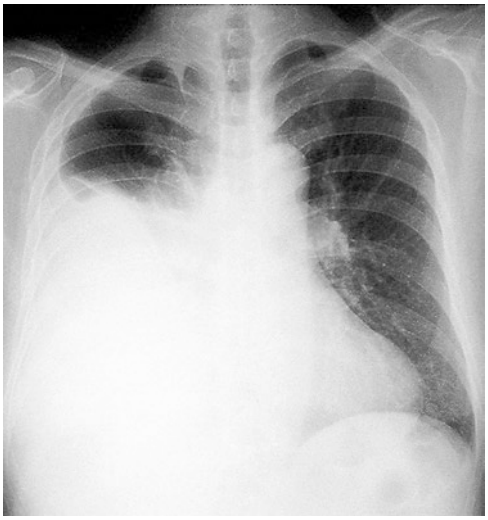


Diagrammatic representation of the relationship between the visceral and parietal pleurae. The visceral pleura (VP) and the parietal pleura (PP) are seen in close apposition separated by a pleural space that contains a small volume of pleural fluid (pf). Contact between the 2 pleurae is made via the mesothelial cell layers (m) on the surface of the parietal and visceral pleurae. Pleural macrophages (PM) are present

in the pleural space. The rigid chest wall is tightly locked to the lungs by the adherence of the visceral pleura to the parietal pleura allowing movements of the chest wall caused by the action of the diaphragmatic muscle and intercostal muscle (IM) to expand and relax the lungs, allowing pulmonary inspiration and expiration. The pathway for particles to reach the pleural space is unknown but the path for an airborne particle (1) that deposits in the distal alveoli (2) is shown as it passes into the interstitium (3) enters the pleural space (4) and exits through a stoma in the parietal pleura (s) into a lymphatic capillary (lc, 5) to enter the lymph flow to the lymph nodes in the mediastinum and central lung. [From article: Asbestos, carbon nanotubes and the pleural mesothelium: a review of the hypothesis regarding the role of long fibre retention in the parietal pleura, inflammation and mesothelioma. Part Fibre Toxicol. 2010 Mar;7:5. https://doi.org/10.1186/1743-8977-7-5, at http://link.springer.com/article/10.1186/1743-8977-7-5; by Ken Donaldson, Fiona A Murphy, Rodger Duffin, Craig A Poland, © Donaldson et al; licensee BioMed Central Ltd. 2010; licensed under Creative Commons Attribution License BY 2.0 http://creativecommons.org/licenses/by/2.0] *Caption from original*



Pneumothorax . A, Chest radiograph of a critically ill patient with a deep sulcus sign on the left (arrow), consistent with the diagnosis of a pneumothorax. B. Note the increase in volume of the right hemithorax, depression of the right hemidiaphragm, and contralateral mediastinal shift. [Huggins J, Sahn S. Pleural disease. In: Crapo J, editor. Bone's atlas of pulmonary and critical care medicine. Philadelphia: Current Medicine; 2005. Chapter 25. ISBN: 1-57340-211-7; 2005-01-14] *Caption from original*



Pleural effusion in ascites. Pleural effusion. [Wong W. Cirrhosis: ascitis and spontaneous bacterial peritonitis. In: Maddrey W, editor. Atlas of the liver. 4th ed. Philadelphia: Current Medicine; 2006. Chapter 10 (Feldman M, editor. Gastroenterology and hepatology; vol. 1; ISBN: 1-57340-241-9; 2006-06-27] *Caption adapted from original*

- Inflammation of the pleura causes the two layers to rub together and results in pain and dyspnea. Although the underlying problem may be the actual cause of dyspnea (pneumonia, pneumothorax), pleurisy itself does not actually *cause* shortness of breath or ventilatory compromise. Instead, the patient perceives dyspnea because of pain on inspiration, which may involuntarily limit inspiratory effort.

Presentation

Typical/"Classic"

- The classic presentation of pleuritic pain is:
  - Acute or relatively acute onset
  - One-sided
  - Exacerbated by inspiration, cough, sneeze, or sudden movement
  - Worse when lying down than when sitting up
  - May extend to shoulder (raising concern of acute coronary syndrome) or abdomen

- A pleural friction rub may be heard.

https://www.youtube.com/watch?v=t2QE0O_exAQ
Audio of pleural friction rub.

http://www.easyauscultation.com/cases?coursecaseorder=7&courseid=201
Pleural Friction Rub [Pleural Rubs; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

Atypical

- Because of underlying pathology, pleurisy may present with dyspnea that is more concerning to the patient than the chest pain.
- With pneumonia, fever may be a dominant symptom.

Primary Differential Considerations

- Keeping in mind that pleurisy may be either an independent diagnosis or a symptom of many other thoracic illnesses, the differential diagnosis is broad.
- The most worrisome primary differential considerations are pulmonary embolism and pneumonia.
- Myocardial ischemia and pleural effusion with pleuritis also should be considered early on.

History and Physical Exam

Findings That Confirm Diagnosis

- History and physical examination are not diagnostic for pleurisy.

Factors That Suggest Diagnosis

- Typical pain description (see earlier) with exacerbations from deep breathing or coughing. A change in position is suggestive.
- A pleural friction rub in patients with chest pain indicates pleural involvement.

https://www.youtube.com/watch?v=t2QE0O_exAQ
Audio of pleural friction rub.

Factors That Exclude Diagnosis

- There are no history or physical findings that conclusively exclude pleurisy.

Ancillary Studies

Laboratory

- There are no diagnostic laboratory studies for pleurisy.
- Laboratory tests target suspected underlying disease.
- If measured, erythrocyte sedimentation rate and C-reactive protein may be elevated in patients with pleurisy, but these tests are not essential for the diagnosis or treatment.

Imaging

- Chest radiography does not reveal pleurisy itself, but may reveal the underlying cause.
- Chest radiography or CT scanning may exclude pneumothorax and pulmonary embolism as causes of pleurisy.

Special Populations

Age and Gender

- The epidemiology of pleurisy follows that of the underlying cause. Therefore, it may occur at any age from childhood to old age. Some diseases (e.g., lung cancer) have a gender predilection, and secondary pleurisy therefore will follow that.
- Pleurisy in children is synonymous with any atraumatic cause of chest pain.
- Texidor's twinge, or precordial catch, is a benign cause of musculoskeletal chest pain in children. It is associated with brief, sharp, painful episodes near the left sternal border.
- Pleurodynia, or Bornholm disease, is an infrequent complication of Coxsackie B infections
    - It is characterized by sudden, severe episodes of unilateral chest pain, restricting air entry (hence the name "devil's grip").
    - It resolves spontaneously.

Co-morbidities

- Typical co-morbidities (and underlying causes) of pleurisy include:
  - Viral and bacterial lower respiratory tract infections
  - Chest wall trauma
  - Recent thoracic surgery
  - Sickle cell disease
  - Pulmonary embolism
  - Autoimmune disease (lupus, rheumatoid arthritis)
  - Pneumothorax
  - Pericarditis
  - Tuberculosis

Pitfalls in Diagnosis

Critical Steps Not to Miss

- Pleurisy is a symptom, not a disease. Therefore, there are no critical steps in the evaluation of pleurisy.
- Because there are underlying causes of pleurisy that are immediate life threats, evaluation for acute coronary syndrome, pulmonary embolism, and pneumonia should be considered early.

Mimics

- The entire constellation of diagnoses underlying chest pain syndrome, especially those often accompanied by dyspnea, can mimic the pain and overall presentation of pleurisy.
- Pericarditis may mimic pleurisy in presentation. Listen for a pericardial friction rub.

Acute Pericarditis Audio Recordings. [Acute Pericarditis; Easy Auscultation; www.easyauscultation.com; copyright 2015, MedEdu LLC]

Time-Dependent Interventions

- Underlying disease may be rapidly fatal, but therapy is targeted at the cause of the pleurisy not the pleurisy itself.

Overall Principles of Treatment

- Treatment of the symptoms of pleurisy usually is successful with nonsteroidal anti-inflammatory drugs.
- Treatment of the underlying disease usually will diminish pleurisy symptoms.

Disease Course

- Pleurisy will resolve as the underlying condition clears. There typically is no anatomic damage to the pleura, with the possible exception of tube thoracostomy for pneumothorax. Rarely, patients develop chronic pleuritic pain after chest tube placement.

Chapter 57
Pneumoconiosis

Christopher J. Rees, Charles V. Pollack, Jr., and Victoria G. Riese

Name and Synonyms

Pneumoconiosis
Black Lung Disease (Coal Worker's Pneumoconiosis)
Asbestosis
Silicosis

Incidence/Epidemiology

- The incidence of pneumoconiosis in Western nations has been declining for the past 20 years. However, in developing nations, where regulatory oversight is not as consistent, the incidence of these disorders continues to increase.
- From 1968 through 1992 in the United States, there were 100,800 death certificates listing pneumoconiosis as a contributing or primary cause of death.
- In 2013, there reportedly were about 250,000 deaths worldwide from pneumoconiosis.
- The most common pneumoconioses are the result of exposure to coal dust, silica, and asbestos.

https://doi.org/10.1007/978-3-319-63895-9_57

Differential Diagnosis

- The differential diagnosis of pneumoconiosis is broad and includes the entire spectrum of diseases that may present with cough and dyspnea, such as asthma, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), pneumonia, lung cancer, and all the other interstitial lung diseases (ILDs).

Pathophysiology and Etiology

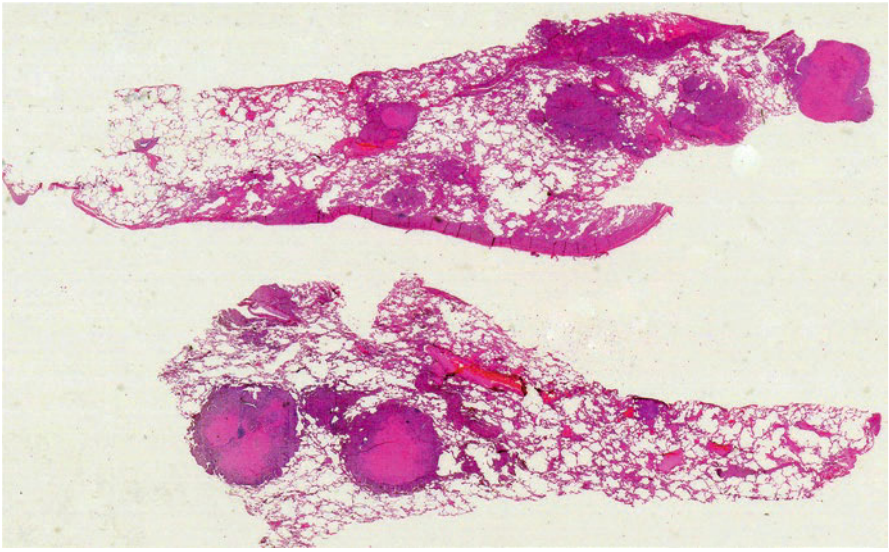
- Pneumoconioses are a group of ILDs caused by the chronic inhalation of inorganic dusts.
- *Pneumoconiosis* classically refers only to dusts that cause a fibrotic, restrictive pattern of lung disease.
- Exposure to organic dusts tends to cause reactive airway disease that may mimic asthma or, more chronically, obstructive diseases such as COPD.

Table Some types of pneumoconiosis according to dust and lung reaction

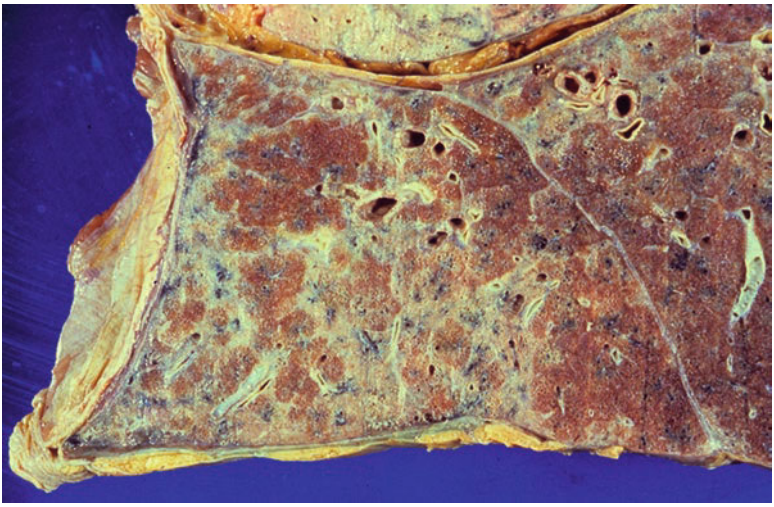
Inorganic Dust	**Type of Disease**	**Lung Reaction**
Asbestos	Asbestosis	Fibrosis
Silica (Quartz)	Silicosis	Fibrosis
Coal	Coal Pneumoconiosis	Fibrosis
Beryllium	Beryllium Disease	Fibrosis
Tungsten Carbide	Hard Metal Disease	Fibrosis
Iron	Siderosis	No Fibrosis
Tin	Stannosis	No Fibrosis
Barium	Baritosis	No Fibrosis
Organic Dust		
Mouldy hay, straw and grain	Farmer's lung	Fibrosis
Droppings and feathers	Bird fancier's lung	Fibrosis
Mouldy sugar cane	Bagassosis	Fibrosis
Compost dust	Mushroom worker's lung	No Fibrosis
Dust or mist	Humidifier fever	No Fibrosis
Dust of heat-treated sludge	Sewage sludge disease	No Fibrosis
Mould dust	Cheese washers' lung	No Fibrosis
Dust of dander, hair particles, and dried urine of rats	Animal handlers' lung	No Fibrosis

Some types of pneumoconiosis according to dust and lung reaction [*What are the Effects of Dust on the Lungs?, http://www.ccohs.ca/oshanswers/chemicals/lungs_dust.html, OSH Answers Fact Sheets,* Canadian Centre for Occupational Health and Safety (CCOHS)*, October 1, 2012.* Reproduced with the permission of CCOHS*, 2016.*]

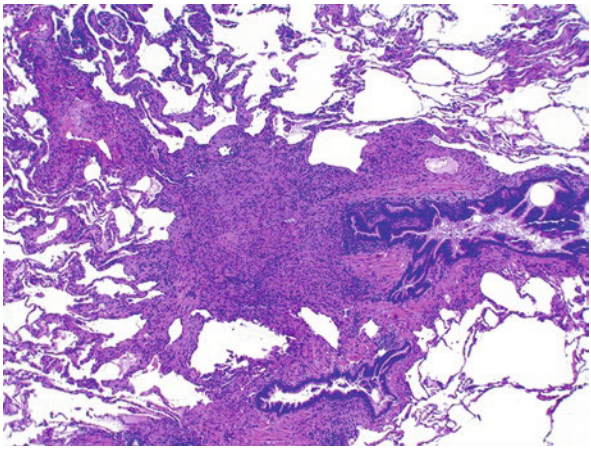
- Exposure to organic dusts also may cause a distinct syndrome: hypersensitivity pneumonitis.
- This discussion is limited to the classic pneumoconioses.
- The etiology of these diseases usually is multifactorial, with occupational and environmental factors (such as exposure to cigarette smoke) interacting with genetic risk to produce a spectrum of disease activity in affected individuals.
- Many different industries and metals may be associated with the development of pneumoconiosis. This discussion centers on the three most common: coal dust, silica, and asbestos.
- The exact pathophysiologic mechanisms by which these substances produce fibrosis are not well elucidated. In general, it involves chronic immune activation due to direct exposure, phagocytosis of the inorganic particles by macrophages, and the generation of reactive oxygen species with subsequent oxidative injury to the lung tissue.



Silicosis. “Dirty” macrophages in a subpleural perilymphatic and peribronchovascular distribution associated with bronchiolocentric fibrotic nodules (haematoxylin–eosin, ×20. Courtesy Dr Alberto Cavazza Reggio Emilia, Italy). [Spagnolo P, Sverzellati N, Wells AU, Hansell DM. Imaging aspects of the diagnosis of sarcoidosis. Eur Radiol. 2014 Apr;24(4):807-16.] *Caption from original*

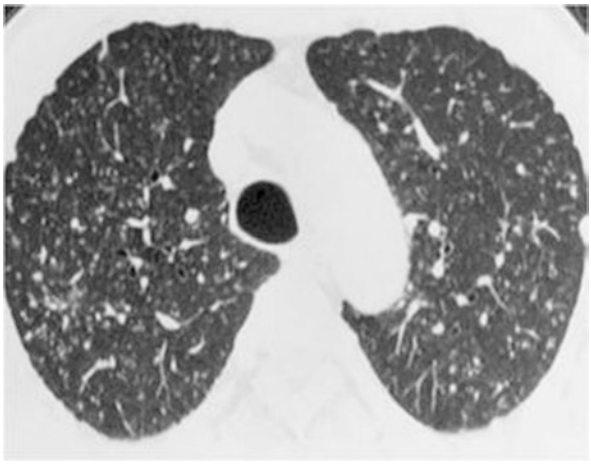


Coronal section of the lower lobe in an insulator with asbestosis. There is coarse linear interstitial fibrosis, but changes of advanced fibrosis or honeycombing are not present. Note accompanying visceral pleural fibrosis [Sporn TA, Roggli VL. Asbestosis. In: Oury TD, Sporn TA, Roggli VL, editors. Pathology of asbestos-associated diseases [Internet]. Berlin, Heidelberg: Springer; 2014 [cited 2015 Dec 22]. p. 53-80. Available from: http://link.springer.com/10.1007/978-3-642-41193-9_4] *Caption from original*



Silicosis. There is a cuff of dust-filled histiocytes around a small bronchiole [Colby TV, Leslie KO. Pathology of diffuse lung disease. In: Baughman RP, du Bois RM, editors. Diffuse lung disease [Internet]. New York: Springer; 2012 [cited 2016 Jan 14]. p. 49-70. Available from: http://link.springer.com/10.1007/978-1-4419-9771-5_4] *Caption from original*

- Coal dust: Coal is a combustible rock formed over eons by the biologic and geologic processing of dead plant matter. Coal is considered a fossil fuel, and the burning of coal is the largest source of energy for electricity generation worldwide. Long-term exposure (>10–20 years) to coal dust in coal mines may cause coal worker's pneumoconiosis (CWP). Inhaled coal dust appears to become phagocytized by macrophages, which tend to group together and develop into "coal macules" within the lung tissue. CWP may be classified radiographically and clinically into simple or complicated CWP. Cigarette smoking does not appear to increase the incidence of CWP.
  - Simple CWP is diagnosed when coal macules grow to about 2–5 mm and become visible on plain chest x-ray (CXR; within upper lung zones). These patients usually are asymptomatic. Simple CWP may be seen in about 10–15 % of coal miners who have worked in the mines for 20 years or more.

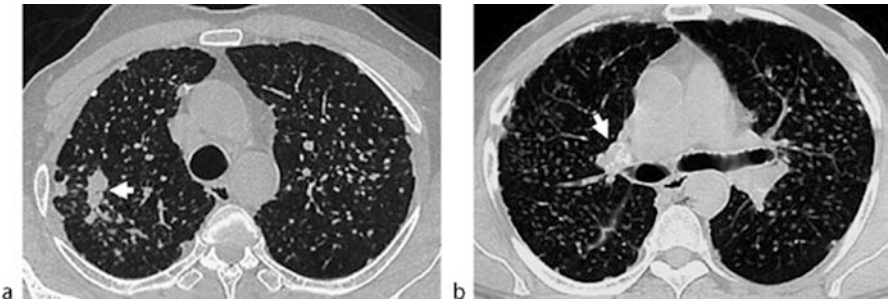


Coal workers pneumoconiosis. HRCT at the level of the upper lobes exhibits a "nodular without tree-in-bud pattern" characterized by ill-defined centrilobular nodules of slightly variable size that have an upper lobe and posterior predominance. A distinctive characteristic occasionally observed is that the micronodules of CWP tend to be less sharply defined and of more granular density than those of silicosis. [From article: Mimics in chest disease: interstitial opacities. Insights Imaging. 2013 Feb;4(1):9-27. https://doi.org/10.1007/s13244-012-0207-7, at http://link.springer.com/article/10.1007%2Fs13244-012-0207-7; by Anastasia Oikonomou, Panos Prassopoulos, © The Author(s) 2012; licensed under Creative Commons Attribution License http://creativecommons.org/licenses/by/2.0] *Caption and text from original*

- Complicated CWP is diagnosed when these macules coalesce into nodules 1 cm or larger. These nodules may take up an entire lobe. These patients usually have symptoms of dyspnea and chronic cough with a restrictive physiology. When the macules become very large and associated with fibrosis, the term *progressive massive fibrosis* (PMF) may be applied. This also is often referred to as "black lung". These patients have severe symptoms associated with hypoxia and a high mortality rate.

Coal worker's pneumoconiosis. PA chest film: This study demonstrates progressive massive fibrosis, which is usually seen in the upper lobes and posterior to midline on lateral view. Peripheral to the masses is lucency, also very characteristic as the masses "migrate" toward the hila [Goodman PC. Radiography and CT of occupational and environmental lung diseases. In: Huang Y-CT, Ghio AJ, Maier LA, editors. A clinical guide to occupational and environmental lung diseases [Internet]. Totowa, NJ: Humana Press; 2012 [cited 2015 Dec 22]. p. 59-92. Available from: http://link.springer.com/10.1007/978-1-62703-149-3_4] *Caption from original*

- Silica: Free silica (silicon dioxide, SiO2, crystalline quartz) is commonly encountered by employees in the mining, stonecutting, cement manufacturing, and other stone-related industries. In general, many years of exposure are required to develop pulmonary fibrosis. Silicosis also may be classified as simple or complicated. There also is a much less common syndrome from acute, high-intensity exposure: acute silicosis. Silica is taken up by alveolar macrophages, to which it is toxic. Patients with silicosis therefore have an increased risk for atypical lung infections associated with decreased macrophage function, such as tuberculosis, atypical mycobacteria, and fungi.
    - Simple silicosis, like simple CWP, is marked by the appearance on CXR of small (0.3–5-mm) round opacities in the upper lobes. These patients are mostly asymptomatic. About 20 % of patients will have associated calcification of their hilar lymph nodes, which gives a characteristic "eggshell" appearance on CXR and high-resolution CT (HRCT).



Silicotic nodules. (a) Centrilobular and randomly distributed pleural nodules and large opacity (arrow) due to complicated silicosis (progressive massive fibrosis). (b) Egg-shell calcification (arrow) in lymph nodes. [Hering KG. Pneumoconioses. In: Baert AL, editor. Encyclopedia of diagnostic imaging [Internet]. Berlin, Heidelberg: Springer; 2008 [cited 2015 Dec 22]. p. 1509-12. Available from: http://www.springerlink.com/index/10.1007/978-3-540-35280-8_1976] *Caption from original*
